Microtubule growth *in vitro* depends on the concentration of tubulin dimers. The tubulin heterodimer concentration at which MT assembly is exactly balanced with disassembly is called the overall **critical concentration**. MTs tend to grow when the tubulin concentration exceeds the critical concentration and depolymerize when the tubulin concentration falls below the critical concentration.

Addition of Tubulin Dimers Occurs More Quickly at the Plus Ends of Microtubules

The inherent structural polarity of microtubules means that the two ends differ chemically. Another important difference between the two ends of the MT is that one end can inherently grow or shrink much faster than the other. This difference in assembly rate can readily be visualized by mixing the MT-associated structures found at the base of cilia, known as *basal bodies*, with tubulin heterodimers. Assembly of the tubulin heterodimers occurs at both ends, but the MTs grow much faster from one end than the other. (The position of the basal body in the growing MT can be assessed because of its different appearance under the electron microscope; Figure 15-4.) The rapidly growing end of the microtubule is called the **plus end**, and the other end is the **minus end**. As we will see below, minus ends of MTs are often anchored at the centrosome; in this case MT dynamics are confined to plus ends.

The different growth rates of the plus and minus ends of microtubules reflect the different critical concentrations required for assembly at the two ends of the MT; the critical concentration for the plus end is lower than that

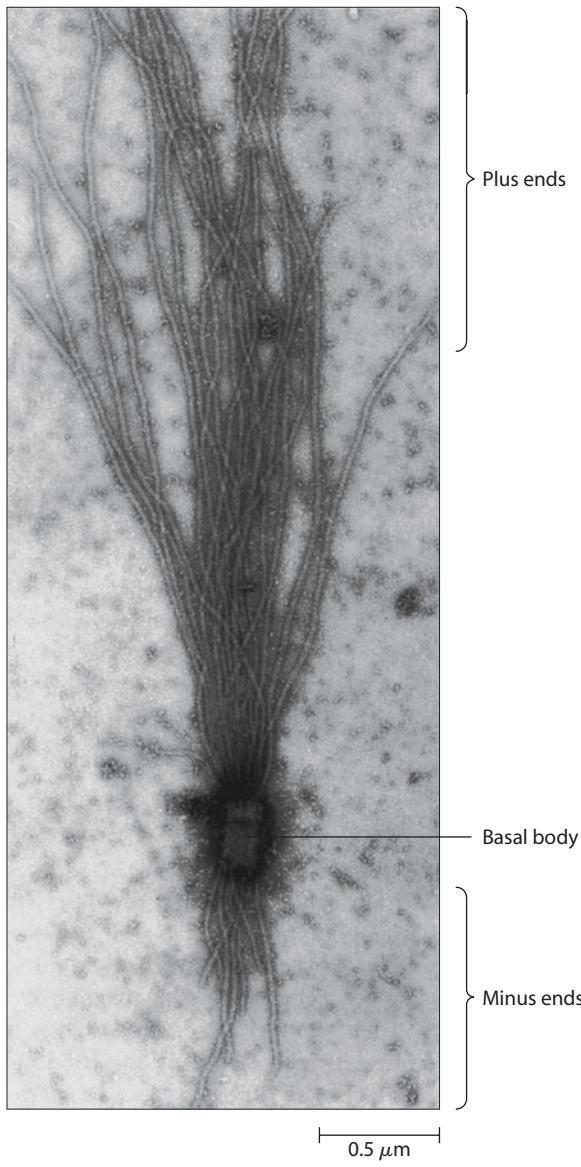

FIGURE 15-4 Polar Assembly of Microtubules in Vitro. The polarity of MT assembly can be demonstrated by adding basal bodies to a solution of tubulin dimers. The tubulin dimers add to the plus and minus ends of the microtubules in the basal body. However, MTs that grow from the plus end are much longer than those growing from the minus end.

for the minus end. If the free tubulin concentration is higher than the critical concentration for the plus end but lower than the critical concentration for the minus end, assembly will occur at the plus end while disassembly takes place at the minus end. This simultaneous assembly and disassembly produces the phenomenon known as *treadmilling* (Figure 15-5). Treadmilling arises when a given tubulin molecule incorporated at the plus end is displaced progressively along the MT and eventually lost by depolymerization at the opposite end. By examining fluorescent MTs, treadmilling has been observed in living cells, although it is uncertain how important it is to overall MT dynamics.

Drugs Can Affect the Assembly of Microtubules

A number of drugs affect microtubule assembly (Table 15-3). One well-known drug of this sort is **colchicine**, an alkaloid from the autumn crocus, *Colchicum autumnale*, which binds to tubulin monomers, strongly inhibiting their assembly into microtubules and fostering the disassembly of existing ones. The resulting tubulin-colchicine complex can still add to the growing end of an MT, but it then prevents any further addition of tubulin molecules and destabilizes the structure, thereby promoting MT disassembly. **Vinblastine** and **vincristine** are related compounds from the periwinkle plant (*Vinca rosea*) that cause tubulin to aggregate inside the cell. **Nocodazole** (a synthetic benzimidazole) is another compound that inhibits MT assembly and is frequently used in experiments instead of colchicine, because its effects are more readily reversible when the drug is removed.

These compounds are called *antimitotic drugs* because they disrupt the mitotic spindle of dividing cells, blocking the further progress of mitosis. The sensitivity of the mitotic spindle to these drugs is understandable because the spindle fibers are composed of many microtubules. Indeed, vinblastine and vincristine find application in medical practice as anticancer drugs. They are useful for this purpose because cancer cells divide rapidly and are therefore preferentially susceptible to drugs that interfere with the mitotic spindle.

In contrast, **taxol** (from the Pacific yew tree, *Taxus brevifolia*) binds tightly to microtubules and stabilizes them, causing much of the free tubulin in the cell to assemble into microtubules. Within cells, taxol causes free tubulin to assemble into MTs and arrests dividing cells in mitosis. Thus, both taxol and colchicine block cells in mitosis, but

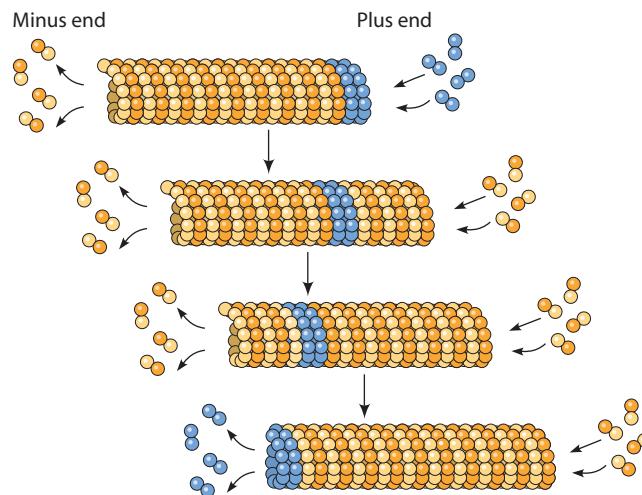

FIGURE 15-5 Treadmilling of Microtubules. Microtubule assembly occurs more readily at the plus end of an MT than at the minus end. When the tubulin concentration is higher than the critical concentration for the plus end but lower than the critical concentration for the minus end, the microtubule can add tubulin heterodimers to its plus end while losing them from its minus end.

they do so by opposing effects on MTs and hence on the fibers of the mitotic spindle. Taxol is also used in the treatment of some cancers, especially breast cancer.

GTP Hydrolysis Contributes to the Dynamic Instability of Microtubules

In the previous section, we saw that tubulin can assemble in vitro in the presence of Mg^{2+} and GTP. In fact, GTP is required for MT assembly. Each tubulin heterodimer binds two GTP molecules. The α -tubulin binds one GTP; the other GTP is bound by β -tubulin and can be hydrolyzed to GDP sometime after the heterodimer is added to an MT. GTP is apparently needed for MT assembly because the association of GDP-bound tubulin heterodimers with each other is too weak to support polymerization. However, hydrolysis of GTP is not necessary for assembly, since MTs polymerize from tubulin heterodimers bound to a nonhydrolyzable analogue of GTP.

Studies of MT assembly in vitro using isolated centrosomes (a structure we will discuss in detail below) as nucleation sites show that some microtubules can grow by polymerization at the same time that others shrink by depolymerization. As a result, some MTs effectively enlarge at the expense of others.

To explain how both polymerization and depolymerization might occur simultaneously, Tim Mitchison and Marc Kirschner proposed the **dynamic instability model**. This model presumes two populations of microtubules, one growing in length by continued polymerization at their plus ends and the other shrinking in length by depolymerization. The distinction between the two populations is that growing MTs have GTP bound to the tubulin at their plus ends, while shrinking MTs have GDP instead. GTP-tubulin molecules are thought to protect MTs by preventing the peeling away of subunits from their plus ends; this *GTP cap* provides a stable MT tip to which further dimers can be added (Figure 15-6a). Hydrolysis of GTP by β -tubulin eventually results in an unstable tip, at which point depolymerization may occur rapidly.

The concentration of tubulin bound to GTP is crucial to the dynamic instability model. When GTP-tubulin is readily available, it is added to the microtubule quickly, creating a large GTP-tubulin cap. If the concentration of GTP-tubulin falls, however, the rate of tubulin addition decreases. At a sufficiently low concentration of GTP-tubulin, the rate of hydrolysis of GTP on the β -tubulin subunits near the tip of the MT exceeds the rate of addition of new, GTP-bound tubulin. This results in shrinkage of the GTP cap. When the GTP cap disappears, the MT becomes unstable, and loss of GDP-bound subunits from its tip is favored.

Direct evidence for dynamic instability comes from observation of individual microtubules in vitro via light microscopy. An individual MT can undergo alternating periods of growth and shrinkage (Figure 15-6b). When an MT switches from growth to shrinkage, an event called

microtubule catastrophe, the MT can disappear completely, or it can abruptly switch back to a growth phase, a phenomenon known as *microtubule rescue*. The frequency of catastrophe is inversely related to the free tubulin concentration. High tubulin concentrations make catastrophe less likely, but it can still occur. When catastrophe does

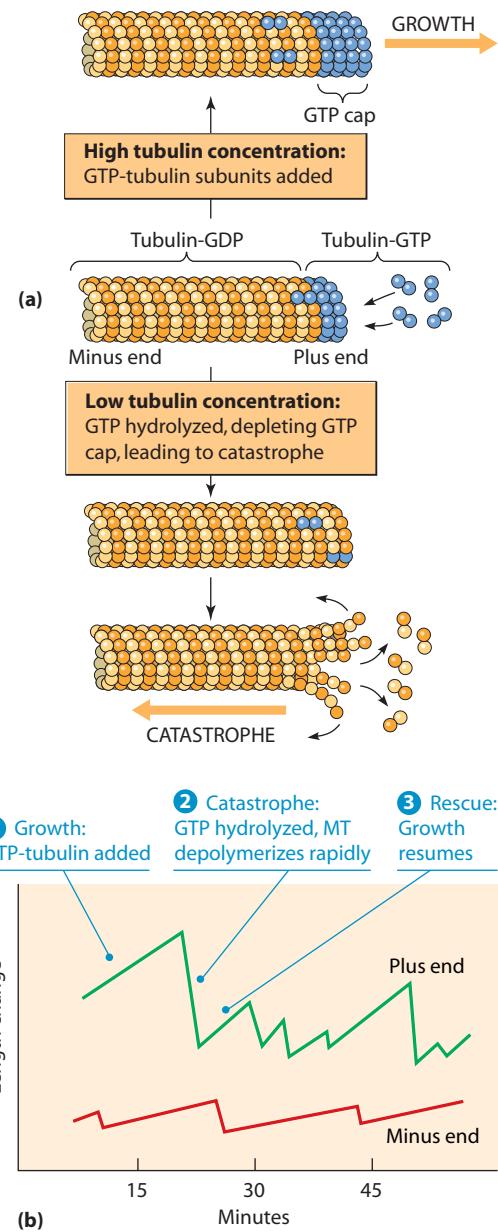

FIGURE 15-6 The GTP Cap and Its Role in the Dynamic Instability of Microtubules. (a) A model illustrating the role of the GTP cap. When the tubulin concentration is high, tubulin-GTP is added to the microtubule tip faster than the incorporated GTP can be hydrolyzed. The resulting GTP cap stabilizes the MT tip and promotes further growth. At lower tubulin concentrations the rate of growth decreases, thereby allowing GTP hydrolysis to catch up. This creates an unstable tip (no GTP cap) that favors MT depolymerization. (b) In an individual MT observed by light microscopy, ① growth and ② catastrophic shrinkage can occur. The plus and minus ends grow and shrink independently; changes in length are much more dynamic at the plus end. ③ Rescue involves the switch from shrinkage to growth.

occur, higher tubulin concentrations make the rescue of a shrinking MT more likely. At any tubulin concentration, catastrophe is more likely at the plus end of an MT—that is, dynamic instability is more pronounced at the plus end of the MT. Dynamic instability has been demonstrated in living cells using video-enhanced differential interference contrast microscopy and live-cell fluorescence microscopy to follow the life cycles of individual MTs (Figure 15-7). These studies have shown that dynamic instability is a key feature of MTs in living cells.

Microtubules Originate from Microtubule-Organizing Centers Within the Cell

In the previous sections, we primarily discussed the properties that tubulin and microtubules exhibit *in vitro*, providing a foundation for understanding how MTs function in the cell. However, MT formation *in vivo* is a more ordered and regulated process, one that produces sets of MTs in specific locations for specific cell functions.

Microtubules commonly originate from a structure in the cell called a **microtubule-organizing center** (MTOC).

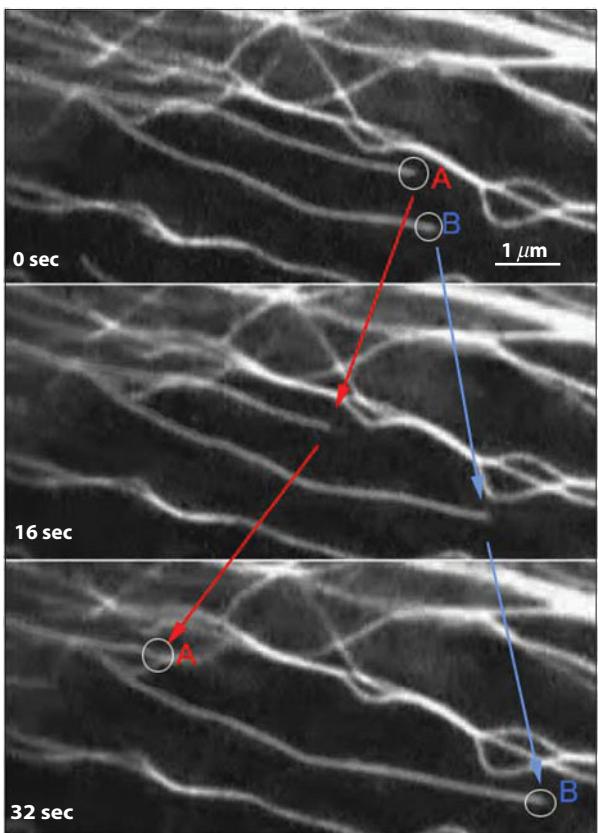

FIGURE 15-7 The Dynamic Instability of Microtubules *In Vivo*. Microtubules visualized in a living cell by live-cell fluorescence microscopy exhibit dynamic instability *in vivo*. Here, two individual MTs have been labeled to allow them to be followed over time. MT B grows over a 32-sec time span, whereas A shrinks.

 [VIDEOS](http://www.thecellplace.com) www.thecellplace.com Interphase microtubule dynamics

An MTOC serves as a site at which MT assembly is initiated and acts as an anchor for one end of these MTs. Many cells during interphase have an MTOC called the **centrosome** that is positioned near the nucleus. The centrosome in an animal cell is normally associated with two **centrioles** surrounded by a diffuse granular material known as **pericentriolar material** (Figure 15-8a). In electron micrographs of the centrosome, MTs originate from the pericentriolar material (Figure 15-8b).

The symmetrical structure of centrioles is remarkable: The walls of centrioles are formed by nine pairs of triplet microtubules (Figure 15-8a). In most cases, centrioles are oriented at right angles to one another; the significance of this arrangement is still unknown. Centrioles are known to be involved in the formation of basal bodies, which are important for the formation of cilia and flagella (see Chapter 16). The role of centrioles in non-ciliated cells is less clear. In animal cells, centrioles may serve to recruit pericentriolar material to the centrosome, which then nucleates growth of microtubules. When centrioles are missing from many animal cells, microtubule-nucleating material disperses, and the MTOC disappears. Cells lacking centrioles can still divide, probably because chromosomes can organize microtubules to some extent on their own. However, the resulting spindles are poorly organized. In contrast to animal cells, the cells of higher plants lack centrioles; their absence indicates that centrioles are not essential for the formation of MTOCs.

Large, ring-shaped protein complexes in the centrosome contain another type of tubulin, **γ-tubulin**. In conjunction with a number of other proteins called *GRIPs* (gamma tubulin ring proteins), rings of γ-tubulin can be seen at the base of MTs that emerge from the centrosome (Figure 15-9). These **γ-tubulin ring complexes** (**γ-TuRCs**) serve to nucleate the assembly of new MTs away from the centrosome. The importance of γ-TuRCs has been demonstrated by depleting cells of γ-tubulin or other components of the γ-TuRC; in the absence of these proteins, centrosomes can no longer nucleate MTs. In addition to the centrosome, some types of cells have other MTOCs. For example, the basal body at the base of each cilium in ciliated cells also serves as an MTOC. During cell division, centrosomes are duplicated, creating new MTOCs for each of the daughter cells. We will discuss mitosis in detail in Chapter 19.

MTOCs Organize and Polarize the Microtubules Within Cells

MTOCs play important roles in controlling the organization of microtubules in cells. The most important aspect of this role is probably the MTOC's ability to nucleate and anchor MTs. Because of this ability, MTs extend out from an MTOC toward the periphery of the cell. Furthermore, they grow out from an MTOC with a fixed polarity—their minus ends are anchored in the MTOC, and their plus ends extend out toward the cell membrane. The

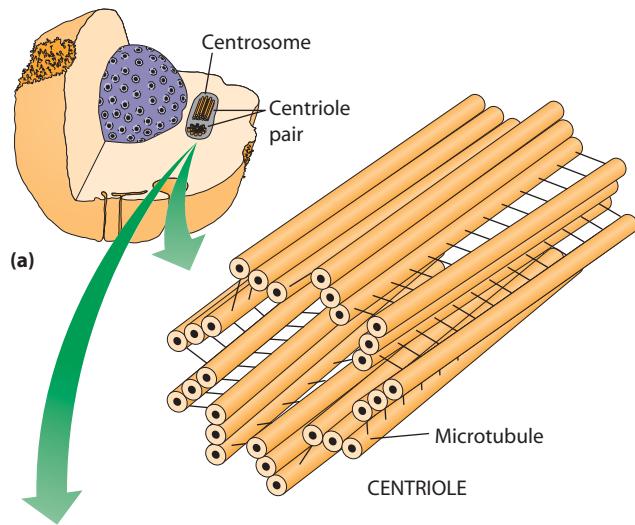

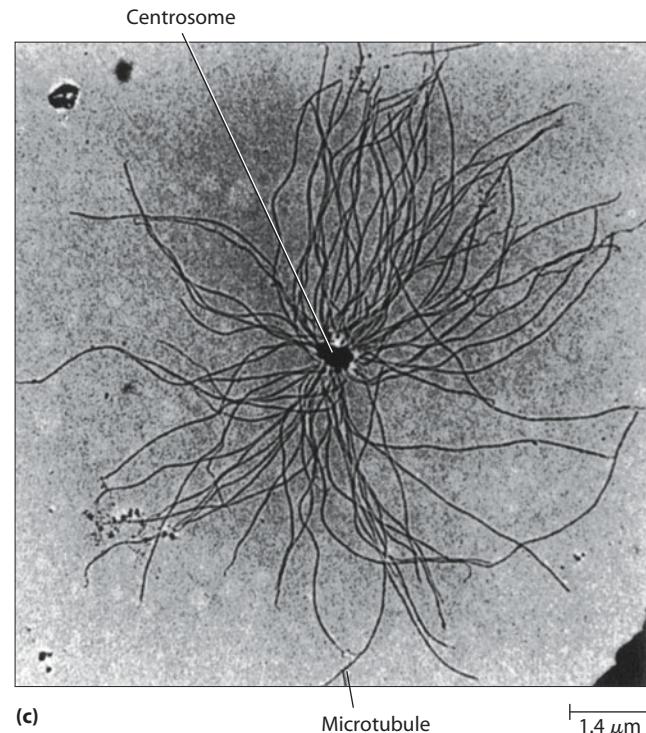

FIGURE 15-8 The Centrosome. (a) In animal cells, the centrosome contains two centrioles and associated pericentriolar material. The walls of centrioles are composed of nine sets of triplet microtubules. (b) An electron micrograph of a centrosome showing the centrioles and the pericentriolar material. Notice that microtubules originate from the pericentriolar material. (c) Nucleation and assembly of MTs at a centrosome in vitro.

relationship between the MTOC and the distribution and polarity of MTs are shown in **Figure 15-10**. The nucleating ability of MTOCs such as the centrosome has an important consequence for microtubule dynamics within cells. Since the minus ends of many MTs are anchored at the centrosome, dynamic growth and shrinkage of these MTs at the plus ends tends to occur at the periphery of cells.

The MTOC also influences the number of microtubules in a cell. Each MTOC has a limited number of nucleation and anchorage sites that seem to control how many MTs can form. However, the MT-nucleating capacity of the MTOC can be modified during certain processes such as mitosis. For example, centrosomes associated with spindle poles in mitotic cells have the highest MT-nucleating activity during prophase and metaphase (see Chapter 19).

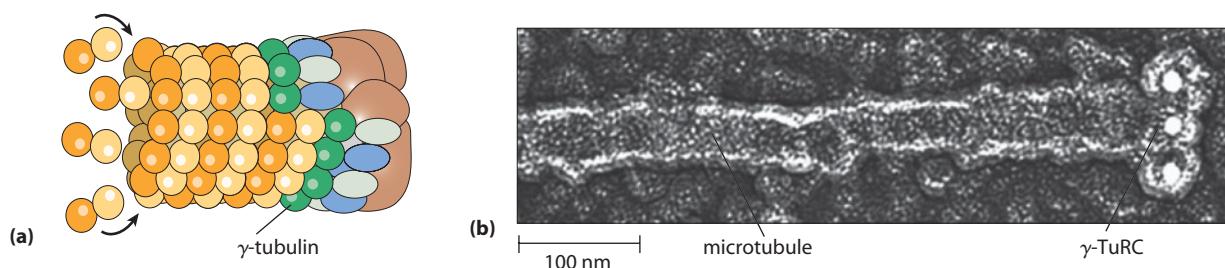

FIGURE 15-9 γ -Tubulin Ring Complexes (γ -TuRCs) Nucleate Microtubules. (a) γ -TuRCs, found at centrosomes, nucleate microtubule growth. The plus ends of MTs are oriented away from the γ -TuRC. (b) A platinum replica of an MT in vitro. Here, a component of the γ -TuRC (Xgrip109) was labeled with antibodies to which small particles of metal are attached. In the electron micrograph, these antibodies appear as bright spheres (TEM).

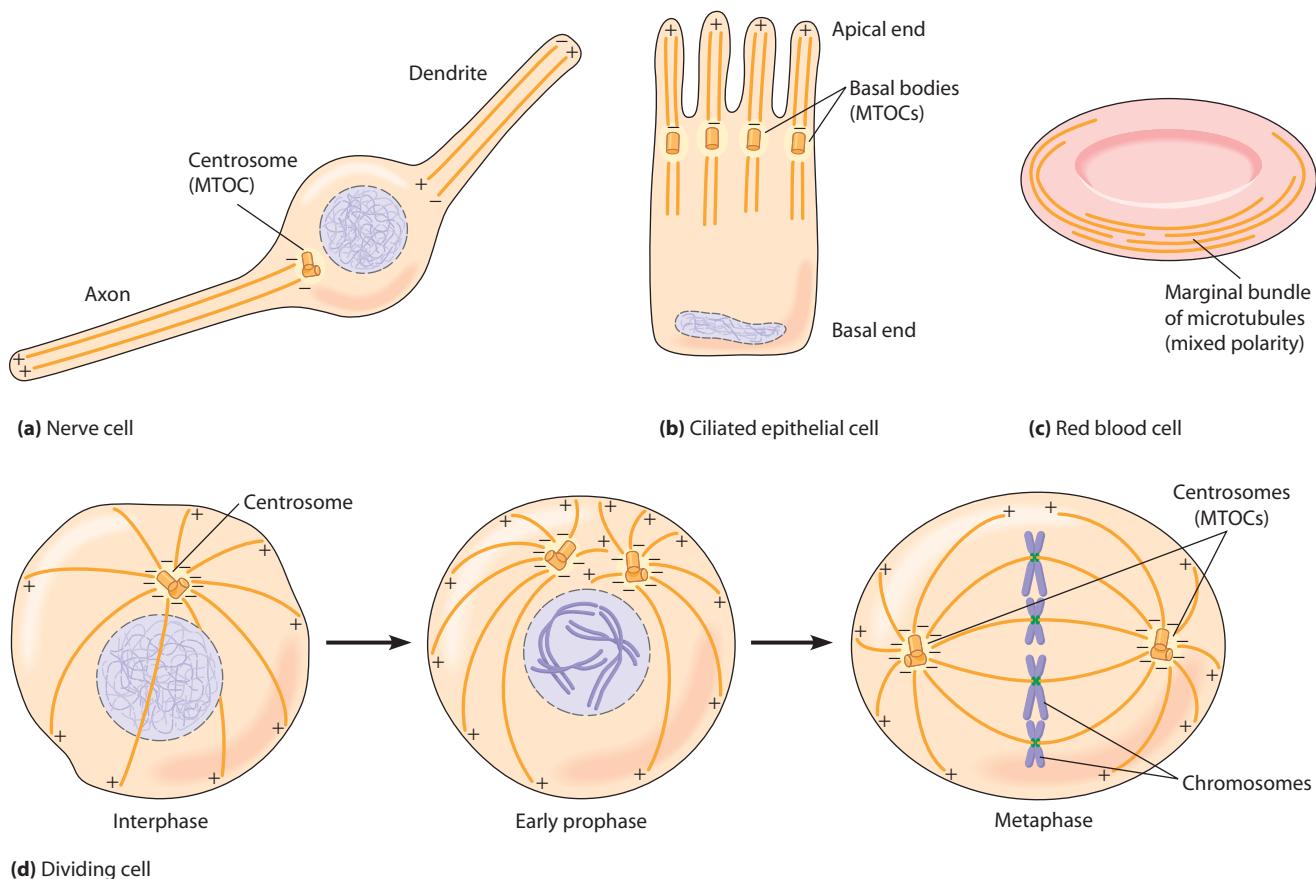

FIGURE 15-10 The Effects of Microtubule Polarity on MT Orientation in Animal Cells. In the cell, the distribution of most microtubules is determined by the microtubule-organizing center (MTOC), which is sometimes a centrosome. MT orientation in a cell may vary with that cell's function. Microtubules are shown in orange. (a) Nerve cells contain two distinct sets of MTs, those of the axon and those of the dendrite. Axonal MTs are attached at their minus ends to the centrosome, with their plus ends at the tip of the axon. However, dendritic MTs are not associated with the centrosome and are of mixed polarities. (b) Ciliated epithelial cells have many MTOCs called basal bodies, one at the base of each cilium. Ciliary MTs originate with their minus ends in the basal bodies and elongate with their plus ends toward the tips of the cilia. (c) Mature human red blood cells have no nucleus or MTOC. However, MTs of mixed polarities persist as a circular band at the periphery of the cell. This band helps to maintain the cell's round, disk-like shape. (d) Throughout the process of mitosis, MTs in a dividing cell are oriented with their minus ends anchored in the centrosome and their plus ends pointing away from the centrosome. Cell division is preceded by the division of the centrosome. The two centrosomes then separate, each forming one pole of the mitotic spindle. At metaphase, the centrosomes are at opposite sides of the cell. Each centrosome, or spindle pole, forms half of the spindle MTs—some extending from pole to chromosomes, others extending from one pole to the other pole.

Microtubule Stability Is Tightly Regulated in Cells by a Variety of Microtubule-Binding Proteins

We have seen that cellular microtubules exhibit dynamic instability; they grow out from the centrosome and then disassemble. This process could account for randomly distributed and short-lived MTs, but not for organized and stable arrays of MTs within cells. Indeed, cells regulate MTs with great precision. To do so, they use a variety of proteins to regulate MT structure, assembly, and function. Some MT-binding proteins use ATP to drive the transport of vesicles and organelles or to generate sliding forces between MTs. These proteins will be discussed in detail in Chapter 16. Here we focus on proteins that regulate MT structure.

Microtubule-Stabilizing/Bundling Proteins. Microtubule-associated proteins (MAPs) account for 10–15% of the mass of MTs isolated from cells. MAPs bind at regular intervals along the wall of a microtubule, allowing interaction with other filaments and cellular structures. Most MAPs have been shown to increase MT stability, and they can affect the density of bundles of MTs.

MAP function has been studied extensively in brain cells, as they are the most abundant source of these proteins. Recall from Chapter 13 that neurons have axons, which carry electrical signals away from the cell body of the neuron, and dendrites, which receive signals from neighboring cells and carry them to the cell body. The MT bundles are characteristically denser in axons than they are in dendrites. A MAP called *Tau* causes microtubules to form tight bundles in axons. Another MAP, MAP2, is present

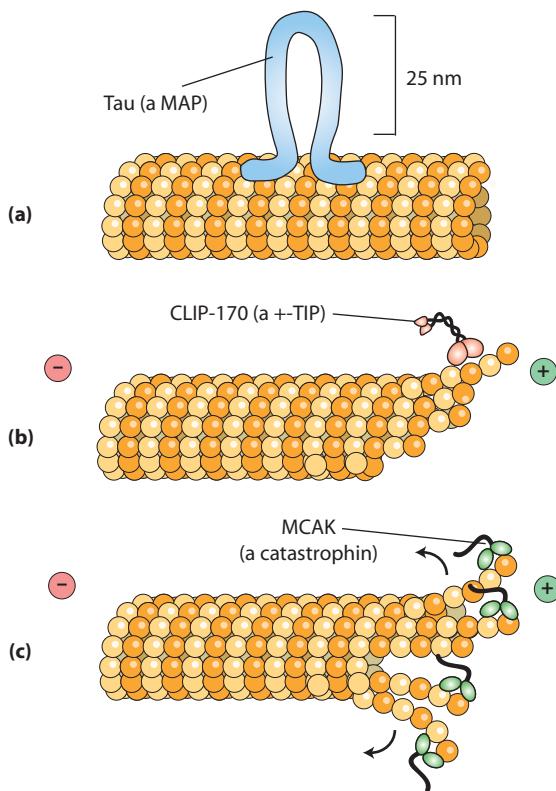

FIGURE 15-11 Microtubule-Interacting Proteins Regulate Microtubule Function in Vivo.

Microtubule Function in Vivo. Three different MT-interacting proteins are shown. (a) Tau is a MAP. Part of Tau binds along the length of an MT; another portion of Tau extends away from the MT, regulating MT spacing. (b) +TIP proteins, such as CLIP-170, bind at or near the plus ends of MTs, stabilizing them. (c) Catastrophins, such as MCAK, are kinesin family proteins that destabilize MTs.

in dendrites and causes the formation of looser bundles of MTs. One portion of MAPs such as Tau and MAP2 binds along the length of an MT; another portion extends at right angles to the microtubule, where it can interact with other proteins (Figure 15-11a). The length of these “arms” controls the spacing of MTs in bundles; MAP2 has a longer arm than Tau does, and so MAP2 causes MT bundles to form that are less densely packed than with Tau.

The importance of MAPs can be demonstrated by forcing nonneuronal cells to make Tau protein. These cells are normally rounded, but when they express large amounts of Tau, these cells extend single long processes that look remarkably similar to axons. Tau is also important in human disease. Dense tangles of neurites, known as *neurofibrillary tangles*, are a hallmark of several diseases that result in dementia, such as Alzheimer’s disease, Pick’s disease, and several types of palsy. In the case of Alzheimer’s disease, these tangles contain large amounts of hyperphosphorylated Tau protein, which forms paired helical filaments. Human mutations that result in defective Tau protein lead to hereditary predisposition to form such neurofibrillary tangles. Such diseases are therefore sometimes called *tauopathies*.

+TIP Proteins. MTs are generally too unstable to remain intact for long periods of time and will depolymerize

unless they are stabilized in some way. One way to stabilize MTs is to “capture” and protect their growing plus ends. To do so, **+TIP proteins** (*+end tubulin interacting proteins*) associate with MT plus ends. Some of these proteins, either directly or indirectly, appear to stabilize plus ends, decreasing the likelihood that they will undergo catastrophic subunit loss (Figure 15-12). One important example of MT capture involves kinetochores during mitosis, as we will discuss in Chapter 19. Other +TIPs associate with the cell *cortex*, an actin-based network underneath the plasma membrane, and can stabilize MTs that extend there.

Microtubule-Destabilizing/Severing Proteins. As we have seen, some proteins stabilize microtubules, making them less likely to depolymerize. Other proteins *promote* depolymerization of MTs. For example, the protein *stathmin/Op18* binds to tubulin heterodimers, preventing them from polymerizing. Other proteins act at the ends of MTs once they have polymerized, promoting the peeling of subunits from their ends. Several proteins of the *kinesin* family, called *catastrophins*, act in this way (Figure 15-12c; we will learn more about other kinesins in Chapter 16). By tightly regulating where catastrophins act, a cell can precisely control where and when MTs form and depolymerize. A prime example of such regulation is the mitotic spindle, which we will examine in Chapter 19. Still other proteins sever MTs; one example of such proteins are *katanins*.

Microfilaments

With a diameter of about 7 nm, **microfilaments (MFs)** are the smallest of the cytoskeletal filaments (see Table 15-1). Microfilaments are best known for their role in the contractile fibrils of muscle cells, where they interact with thicker filaments of myosin to cause the contractions characteristic of muscle (see Chapter 16). MFs are not confined to muscle cells, however. They occur in almost all eukaryotic cells and are involved in numerous other phenomena, including a variety of locomotory and structural functions.

Examples of cell movements in which microfilaments play a role include *cell migration* via lamellipodia and filopodia, *amoeboid movement*, and *cytoplasmic streaming*, a regular pattern of cytoplasmic flow in some plant and animal cells. We will discuss all of these phenomena in detail in Chapter 16. MFs also produce the cleavage furrows that divide the cytoplasm of animal cells during cytokinesis (see Chapter 19), and MFs are found at sites of attachment of cells to one another and to the extracellular matrix (see Chapter 17).

In addition to mediating a variety of cell movements, MFs are important in developing and maintaining cell shape. Most animal cells, for example, have a dense network of microfilaments called the *cell cortex* just beneath the plasma membrane. The cortex confers structural rigidity on the cell surface and facilitates shape changes and cell movement. Parallel bundles of MFs also make up the structural core of *microvilli*, the fingerlike extensions found on the surface of many animal cells (see Figure 4-2).

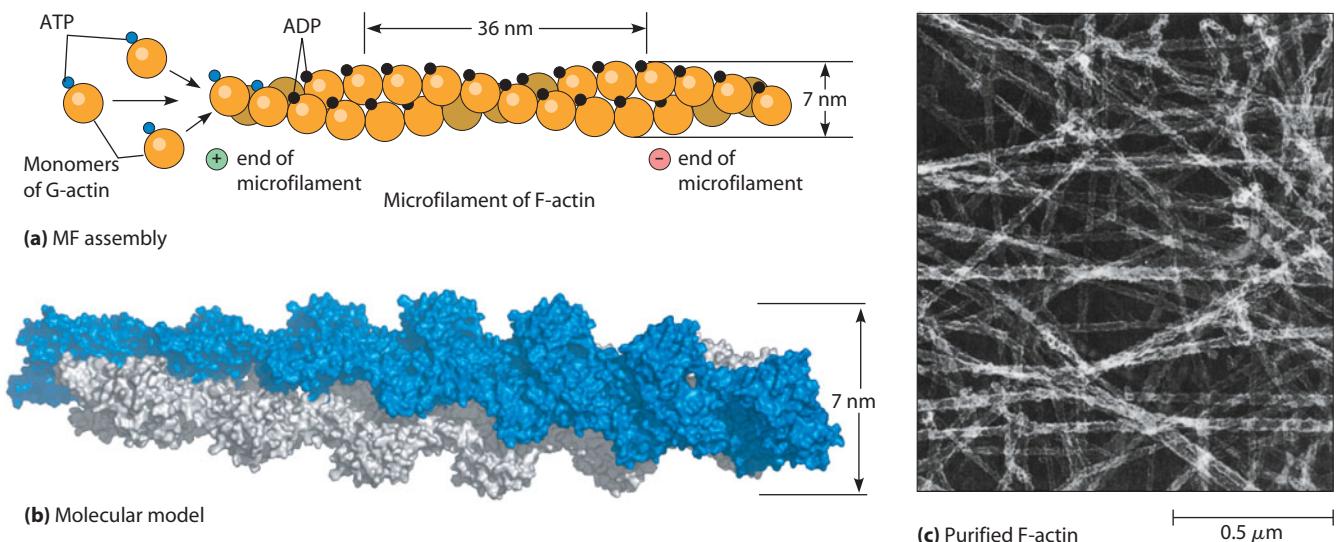

FIGURE 15-12 A Model for Microfilament Assembly in Vitro. (a) Monomers of G-actin polymerize into long filaments of F-actin with a diameter of about 7 nm. A full turn of the helix occurs every 36–37 nm, with about 13.5 monomers required for a full turn. Addition of each G-actin monomer is usually accompanied or followed by hydrolysis of the ATP molecule, although the energy of ATP hydrolysis is not required to drive the polymerization reaction. (b) A molecular model of F-actin, based on X-ray crystal structures of G-actin. Two strands of 13 G-actin monomers each are shown. One strand is colored blue, the other gray. (c) An electron micrograph of purified F-actin (TEM).

Actin Is the Protein Building Block of Microfilaments

Actin is an extremely abundant protein in virtually all eukaryotic cells, including those of plants, algae, and fungi. Actin is synthesized as a single polypeptide consisting of 375 amino acids, with a molecular weight of about 42 kDa. Once synthesized, it folds into a roughly U-shaped molecule, with a central cavity that binds ATP or ADP. Individual actin molecules are referred to as **G-actin** (globular actin). Under the right conditions, G-actin molecules polymerize to form microfilaments; in this form, actin is referred to as **F-actin** (filamentous actin; see Figure 15-12). Actin in the G or F form also binds to a wide variety of other proteins, collectively known as *actin-binding proteins*.

Different Types of Actin Are Found in Cells

Of the three types of cytoskeletal proteins, actin is the most highly conserved. In functional assays, all actins appear to be identical, and actins from diverse organisms will copolymerize into filaments. Despite this high degree of sequence similarity, actins do differ among different organisms and among tissues of the same organism. Based on sequence similarity, actins can be broadly divided into two major groups: the *muscle-specific actins* (α -actins) and the *nonmuscle actins* (β - and γ -actins). β - and γ -actin localize to different regions of the cell and appear to have different interactions with actin-binding proteins. For example, in epithelial cells, one end of the cell, the apical end, contains microvilli, whereas the opposite side of the cell, known as the basal

end, is attached to the extracellular matrix (see Figure 17-18). β -actin is predominantly found at the apical end of epithelial cells, whereas γ -actin is concentrated at the basal end and sides of the cell.

G-Actin Monomers Polymerize into F-Actin Microfilaments

Like tubulin dimers, G-actin monomers can polymerize reversibly into filaments with a lag phase corresponding to filament nucleation, followed by a more rapid polymer elongation phase. The kinetics of actin polymerization can be studied in solution using fluorescent G-actin. The fluorescence of the labeled F-actin can be measured to yield data similar to that for tubulin. The F-actin filaments that form are composed of two linear strands of polymerized G-actin wound around each other in a helix, with roughly 13.5 actin monomers per turn (Figure 15-12).

Within a microfilament, all the actin monomers are oriented in the same direction, so that an MF, like a microtubule, has an inherent polarity, with one end differing chemically and structurally from the other end. This polarity can be readily demonstrated by incubating MFs with **myosin subfragment 1 (S1)**, a proteolytic fragment of myosin (Figure 15-13). S1 fragments bind to, or “decorate,” the actin MFs to give a distinctive arrowhead pattern, with all the S1 molecules pointing in the same direction (Figure 15-13c). Based on this arrowhead pattern, the terms *pointed end* and *barbed end* are commonly used to identify the minus and plus ends of an MF, respectively. The polarity of the MF is important, because it

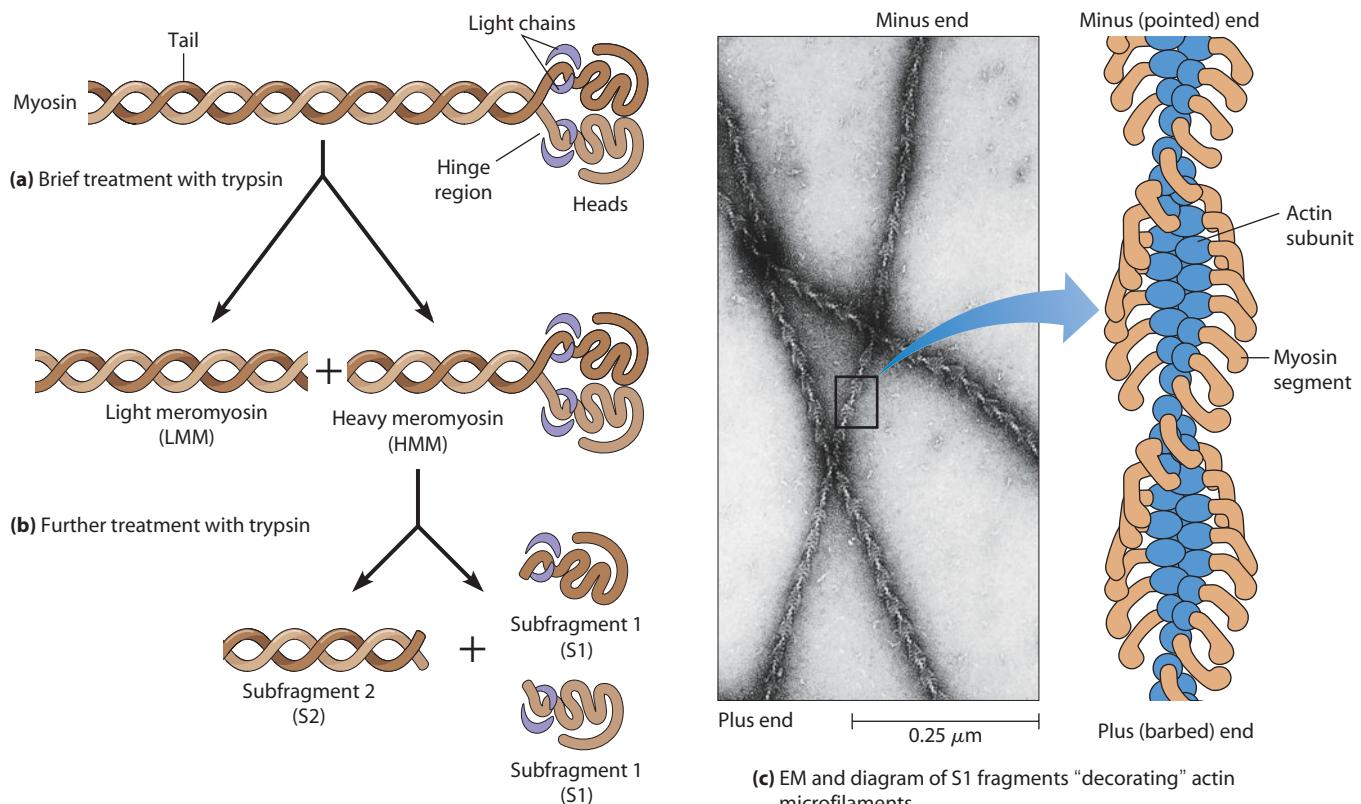

FIGURE 15-13 Using Myosin S1 Subfragments to Determine Actin Polarity. Myosin II is part of the contractile machinery found in muscle cells. The globular head of the myosin molecule binds to actin, while the myosin tails can associate with filaments of myosin (the thick myofilaments of muscle cells). (a) Myosin II can be cleaved by proteases such as trypsin into two pieces, heavy meromyosin (HMM) and light meromyosin (LMM). (b) HMM can be further digested, leaving only the globular head. This fragment, called myosin subfragment 1 (S1), retains its actin-binding properties. (c) When actin microfilaments are incubated with myosin S1 and then examined with an electron microscope, the S1 fragments appear to “decorate” the microfilaments like arrowheads. All the S1 arrowheads point toward the minus end, indicating the polarity of the MF.

allows for independent regulation of actin assembly or disassembly at each end of the filament.

The polarity of microfilaments is reflected in more rapid addition or loss of G-actin at the plus end, and slower addition or loss of G-actin at the minus end (see Figure 15-12a). If G-actin is polymerized onto short fragments of S1-decorated F-actin, polymerization proceeds much faster at the barbed end, indicating that the barbed end of the filament is also the plus end. Thus, even when conditions are favorable for adding monomers to both ends of the filament, the plus end will grow faster than the minus end.

As G-actin monomers assemble onto a microfilament, the ATP bound to them is slowly hydrolyzed to ADP, much the same as the GTP bound to tubulin is hydrolyzed to GDP. Thus, the ends of a growing MF tend to have ATP-F-actin, whereas the bulk of the MF is composed of ADP-F-actin. However, ATP hydrolysis is not a strict requirement for MF elongation, since MFs can also assemble from ADP-G-actin or from nonhydrolyzable analogues of ATP-G-actin.

Specific Drugs Affect Polymerization of Microfilaments

As we saw with microtubules, several drugs have been used to perturb the assembly of actin into microfilaments (Table 15-3). Processes that are disrupted in cells treated with these drugs are likely to depend in some way on microfilaments. Several drugs result in depolymerization of microfilaments. The **cytochalasins**, such as *cytochalasin D*, are fungal metabolites that prevent the addition of new monomers to existing polymerized MFs. As subunits are gradually lost from the minus ends of MFs in cytochalasin-treated cells, they eventually depolymerize. In contrast, **latrunculin A**, a marine toxin isolated from the Red Sea sponge *Latrunculia magnifica*, acts by sequestering actin monomers, preventing their addition to the plus ends of growing MFs. In either case, the net result is the loss of MFs within the treated cells. Conversely, the drug **phalloidin**, a cyclic peptide from the death cap fungus (*Amanita phalloides*), stabilizes microfilaments, preventing their depolymerization. Fluorescently labeled phalloidin

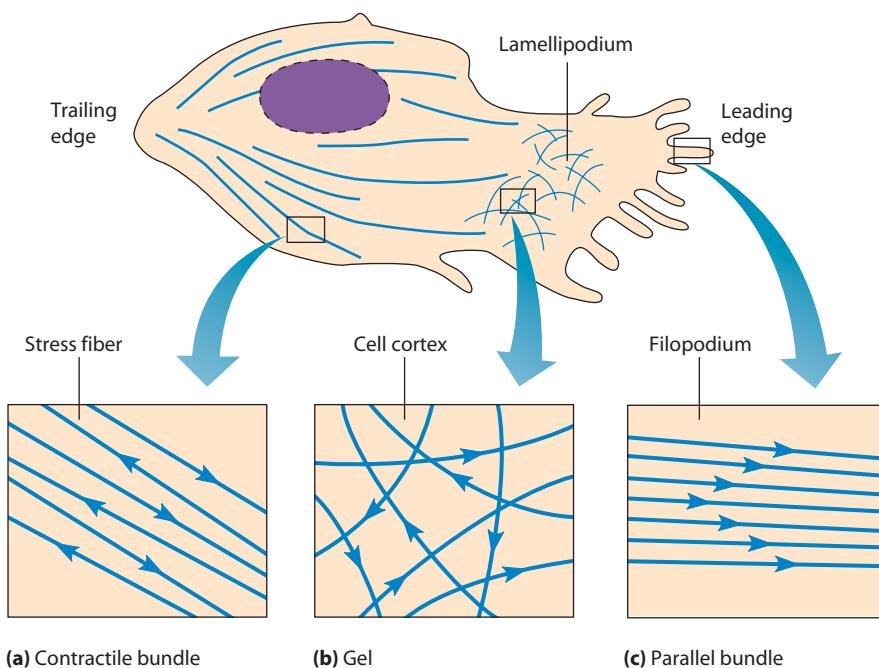

FIGURE 15-14 The Architecture of Actin in Crawling Cells. Actin is found in a variety of structures in crawling cells such as this macrophage. (a) Running from the trailing edge of the cell to the leading edge are contractile bundles of actin, the stress fibers. (b) At the periphery of the cell is the cortex, which contains a three-dimensional meshwork of actin filaments crosslinked into a gel. (c) The broad leading edge of lamellipodia can produce thin, fingerlike projections called filopodia. Whereas the bulk of lamellipodia contain an actin meshwork, filopodia contain parallel bundles of actin filaments.

is also useful for visualizing F-actin via fluorescence microscopy.

Cells Can Dynamically Assemble Actin into a Variety of Structures

As with microtubules, cells can dynamically regulate where and how G-actin is assembled into microfilaments. For example, cells that crawl have specialized structures called *lamellipodia* and *filopodia* at their leading edge that allow them to move along a surface (we will consider these specialized structures in more detail in Chapter 16). The form of the protrusion appears to depend on the nature of the cell's movement and on the organization of the actin filaments within the cell. In cells that adhere tightly to the underlying substratum and do not move well, organized bundles of actin, called *stress fibers*, stretch from the tail, or trailing edge, of the cell to the front (Figure 15-14a). Rapidly moving cells typically do not have such striking actin bundles. In such cells, the cell *cortex*, which lies immediately beneath the plasma membrane and is enriched in actin, is crosslinked into a gel or very loosely organized lattice of microfilaments (Figure 15-14b). At the leading edge, and especially in filopodia, microfilaments form highly oriented, polarized cables, with their barbed (plus) ends oriented toward the tip of the protrusion (Figure 15-14c). The actin in lamellipodia is typically less well organized than in filopodia (Figure 15-15). Understanding how cells regulate such a wide variety of actin-based structures requires understanding both how cells can regulate the polymerization of MFs and how MFs, once polymerized, assemble into networks.

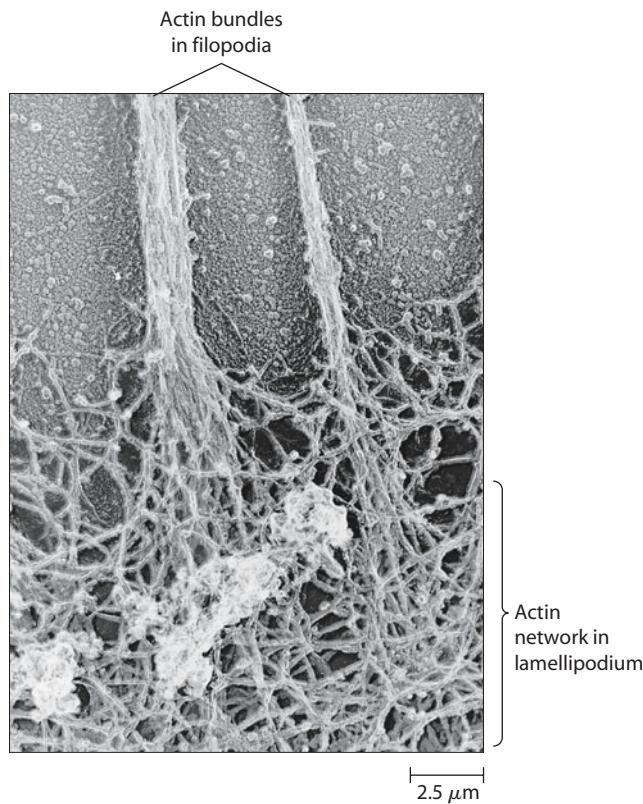

FIGURE 15-15 Deep-Etch Electron Micrograph Showing Actin Bundles in Filopodia. This view of the periphery of a macrophage shows two prominent actin bundles contained within filopodia that extend from the cell surface. The actin filaments in the filopodia merge with a network of actin filaments lying just beneath the plasma membrane of the lamellipodium.

Actin-Binding Proteins Regulate the Polymerization, Length, and Organization of Microfilaments

As we saw with microtubules, cells can precisely control where actin assembles and the structure of the resulting actin networks. To do so, cells use a variety of **actin-binding proteins** (Figure 15-16). Control of the process of MF polymerization occurs at several steps, including the nucleation of new MFs, the elongation and severing of preexisting MFs, and the association of MFs into networks. We consider each of these briefly here.

Proteins That Regulate Polymerization. In the absence of other factors, the growth of microfilaments depends on the concentration of ATP-bound G-actin. If the concentration of ATP-bound G-actin is high, microfilaments will assemble until the G-actin is limiting. In the cell, however, a large amount of free G-actin is not available for assembly into filaments because it is bound by the protein *thymosin β4*. A second protein called *profilin* appears to compete with thymosin $\beta 4$ for binding to G-actin monomers. When the profilin concentration is high, polymerization is favored—but only if there are free filament ends available. Yet another protein, known as *ADF/cofilin*, is known to bind to ADP-G-actin and F-actin. ADF/cofilin is thought

to increase the rate of turnover of ADP-actin at the minus ends of MFs. The ADP on these G-actin monomers can then be exchanged for a new ATP, and the ATP-G-actin can then be recycled for addition to the growing plus ends of MFs. ADF/cofilin also severs filaments, creating new plus ends as it does so.

Proteins That Cap Actin Filaments. Whether microfilament ends are available for further growth depends on whether the filament end is *capped*. Capping occurs when a **capping protein** binds the end of a filament and prevents further addition or loss of subunits, thereby stabilizing it. One such protein that functions as a cap for the plus ends of microfilaments is appropriately named *CapZ*. When CapZ is bound to the end of a filament, further addition of subunits at the plus end is prevented; when CapZ is removed, addition of subunits can resume. Another class of proteins called *tropomodulins* bind to the minus ends of actin filaments, preventing loss of subunits from the pointed ends of F-actin. Tropomodulins are found in muscle sarcomeres, as we will see in Chapter 16.

Proteins That Crosslink Actin Filaments. In many cases, actin networks form as loose meshworks of crisscrossing, crosslinked MFs. One of the crosslinking proteins that is important for such networks is *filamin*, a long molecule consisting of two identical polypeptides joined head to head, with an actin-binding site at each tail. Molecules of filamin act as “splices,” joining two MFs together where they intersect. In this way, actin MFs are linked to form large three-dimensional networks.

Proteins That Sever Actin Filaments. Other proteins play the opposite role, breaking up the microfilament network and causing the cortical actin gel to soften and liquefy. They do this by severing and/or capping MFs. In some cases, such proteins can serve both functions. One of these severing and capping proteins is *gelsolin*, which functions by breaking actin MFs and capping their newly exposed plus ends, thereby preventing further polymerization.

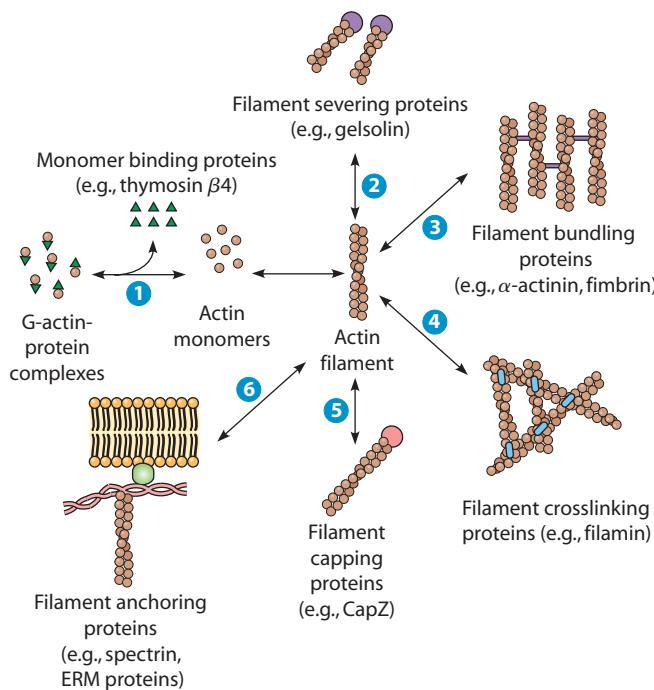

FIGURE 15-16 Actin-Binding Proteins Regulate the Organization of Actin. Actin-binding proteins are responsible for converting actin filaments from one form to another. These include ① monomer-binding proteins, such as thymosin $\beta 4$ and profilin; ② filament severing proteins, such as gelsolin; ③ filament bundling proteins, such as α -actinin, fimbrin, and fascin; ④ filament crosslinking proteins, such as filamin; ⑤ filament capping proteins such as CapZ and tropomodulin; and ⑥ filament anchoring proteins, such as spectrin and ERM proteins.

Proteins That Bundle Actin Filaments. In contrast to the loose organization of the actin at the cell cortex, other actin-containing structures in migrating and nonmigrating cells can be highly ordered. In such cases, actin may be bundled into tightly organized arrays, and a number of actin-binding proteins mediate such bundling. One such protein is *α-actinin*, a protein that is prominent within structures known as *focal contacts* and *focal adhesions*, which are required for cells to make adhesive connections to the extracellular matrix as they migrate. We will consider these structures in more detail in Chapter 17. Another bundling protein, *fascin*, is found in filopodia; fascin keeps the actin within the core of a filopodium tightly bundled, contributing to the spike-like appearance of such protrusions.

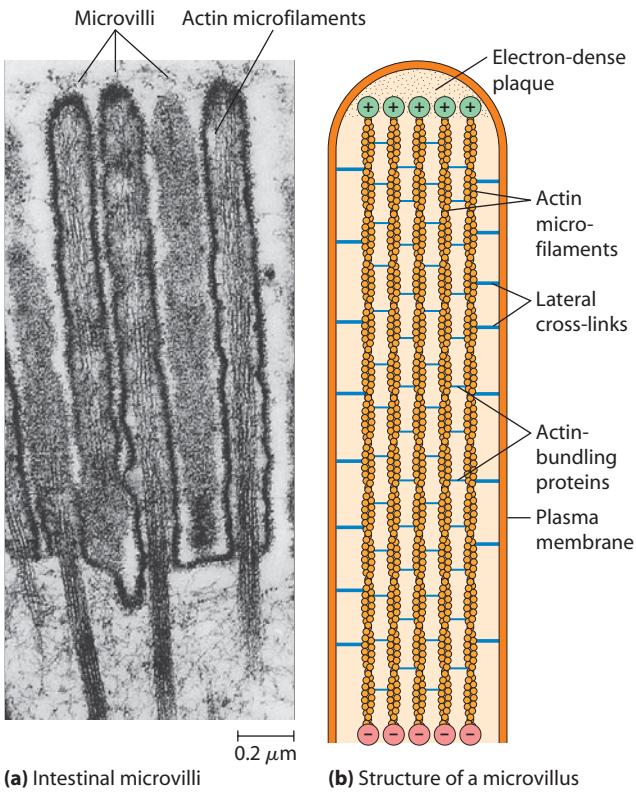

FIGURE 15-17 Microvillus Structure. (a) An electron micrograph of microvilli from intestinal mucosal cells (TEM). (b) A schematic diagram of a single microvillus, showing the core of microfilaments that gives the microvillus its characteristic stiffness. The core consists of several dozen microfilaments oriented with their plus ends facing outward toward the tip and their minus ends facing toward the cell. The plus ends are embedded in an amorphous, electron-dense plaque. The MFs are tightly linked together by actin-bundling (crosslinking) proteins and are connected to the inner surface of the plasma membrane by lateral crosslinks.

Perhaps the best-studied example of ordered actin arrays is the actin bundles found in microvilli. **Microvilli** (singular: **microvillus**) are especially prominent features of intestinal mucosal cells (**Figure 15-17a**). A single mucosal cell in your small intestine, for example, has several thousand microvilli, each about 1–2 μm long and about 0.1 μm in diameter, which increase the surface area of the cell about twentyfold. This large surface area is essential to intestinal function because the uptake of digested food depends on an extensive absorptive surface.

As illustrated in Figure 15-17b, the core of the intestinal microvillus consists of a tight bundle of microfilaments. The plus ends point toward the tip, where they are attached to the membrane through an amorphous, electron-dense plaque. The MFs in the bundle are also connected to the plasma membrane by lateral crosslinks consisting of the proteins *myosin I* and *calmodulin*. These crosslinks extend outward about 20–30 nm from the bundle to contact electron-dense patches on the inner membrane surface. Adjacent MFs in the bundle are bound tightly together at regular intervals by the crosslinking proteins (also called actin-bundling proteins) *fimbrin* and *villin*.

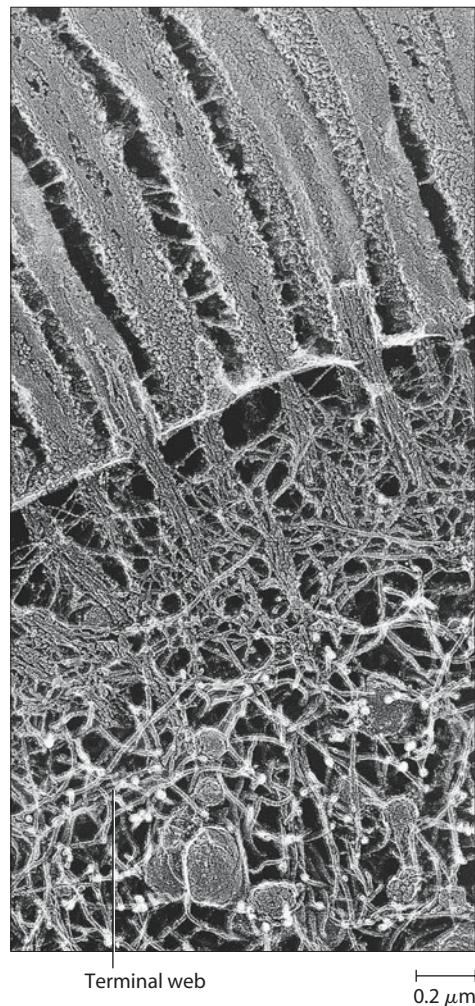

FIGURE 15-18 The Terminal Web of an Intestinal Epithelial Cell. The terminal web beneath the plasma membrane is seen in this freeze-etch electron micrograph of an intestinal epithelial cell. Bundles of microfilaments that form the cores of microvilli extend into the terminal web.

At the base of the microvillus, the MF bundle extends into a network of filaments called the **terminal web** (**Figure 15-18**). The filaments of the terminal web are composed mainly of myosin and spectrin, which connect the microfilaments to each other, to proteins within the plasma membrane, and perhaps also to the network of intermediate filaments beneath the terminal web. The terminal web apparently gives rigidity to the microvilli by anchoring their MF bundles securely so that they project straight out from the cell surface.

Proteins That Link Actin to Membranes. For MFs to exert force on the plasma membrane during events such as cell movement and cytokinesis, they must be connected to the plasma membrane. The connection of MFs to the plasma membrane is indirect and requires one or more linker proteins that anchor MFs to transmembrane proteins embedded within the plasma membrane.

One group of proteins that appears to function widely in linking microfilaments to membranes is the *band 4.1*,

ezrin, *radixin*, and *moesin* family of actin-binding proteins. When these proteins are mutated, a wide variety of cellular processes are affected, including cytokinesis, secretion, and the formation of microvilli. Another example of how actin can be linked to membranes involves the proteins *spectrin* and *ankyrin* (Figure 15-19). As we saw in Chapter 7, the plasma membrane of the erythrocyte is supported by a network of spectrin filaments that are

crosslinked by very short actin chains. This network is connected to the plasma membrane by molecules of the proteins ankyrin and band 4.1 that link the spectrin filaments to specific transmembrane proteins. Based on mutations in the genes encoding spectrins and ankyrins in *Drosophila* and in the nematode *Caenorhabditis elegans*, these proteins are important in a wide variety of cells for maintenance of cell shape.

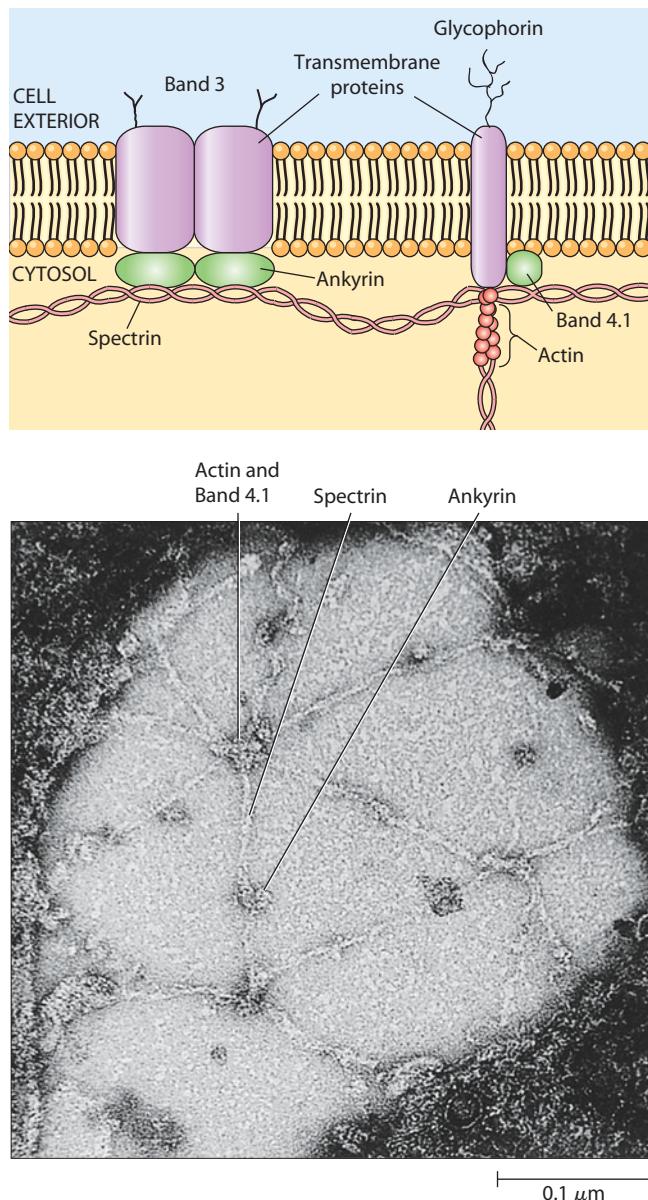

FIGURE 15-19 Support of the Erythrocyte Plasma Membrane by a Spectrin-Ankyrin-Actin Network. The plasma membrane of a red blood cell is supported on its inner surface by a filamentous network that gives the cell both strength and flexibility. (a) A diagram showing the major components of the spectrin-ankyrin-actin network. Long filaments of spectrin are crosslinked by short actin filaments. The network is anchored to the band 3 transmembrane protein by molecules of the protein ankyrin. (b) An electron micrograph of an erythrocyte membrane, showing actual spectrin network components (TEM).

Proteins That Promote Actin Branching and Growth.

In addition to loose networks and bundles, cells can assemble actin into branched networks that form a treelike, or *dendritic*, network (Figure 15-20a). Such dendritic networks are a prominent feature of lamellipodia in migrating cells. A complex of actin-related proteins, the **Arp2/3 complex**, helps branches to form by nucleating new branches on the sides of existing filaments (Figure 15-20b). Proteins we have already discussed, such as profilin, cofilin, and capping proteins, regulate the length of filaments that polymerize from branch points, thereby regulating the length of such structures.

Arp2/3 branching is activated by a family of proteins that includes the *Wiskott-Aldrich syndrome protein*, or WASP, and *WAVE/Scar*. Human patients who cannot produce functional WASP have defects in the ability of their platelets to undergo changes in shape and so have difficulties in forming blood clots. A very different kind of disease also involves the Arp2/3 complex: Pathogenic bacteria can “hijack” the actin polymerization machinery of the cell to spread (Box 15A).

Branched actin networks are only one type of actin-based structure that cells can produce. For some cellular events, long actin filaments are more useful. Actin polymerization in this case can be regulated independently of the Arp2/3 complex, through proteins known as *formins*. Formins are required to assemble certain unbranched F-actin structures, including actin cables and the contractile ring during cell division (see Chapter 19). Formins appear to be able to act “processively” moving along the end of a growing filament as they stimulate filament growth (Figure 15-20c). Formins can form dimers, binding to the barbed (plus) ends of actin filaments. Some formins have extensions that can bind profilin and are therefore thought to act as “staging areas” for the addition of actin monomers to growing filaments. Plants have a large number of formin-like proteins, which are thought to play similar roles in regulating the actin cytoskeleton.

Cell Signaling Regulates Where and When Actin-Based Structures Assemble

We have seen that actin-binding proteins regulate the types of actin-based structures that cells assemble. Cell signaling, in turn, regulates the activity of these proteins. Both plasma membrane lipids and several small G proteins related to Ras (see Chapter 14) regulate the formation, stability, and breakdown of MFs.

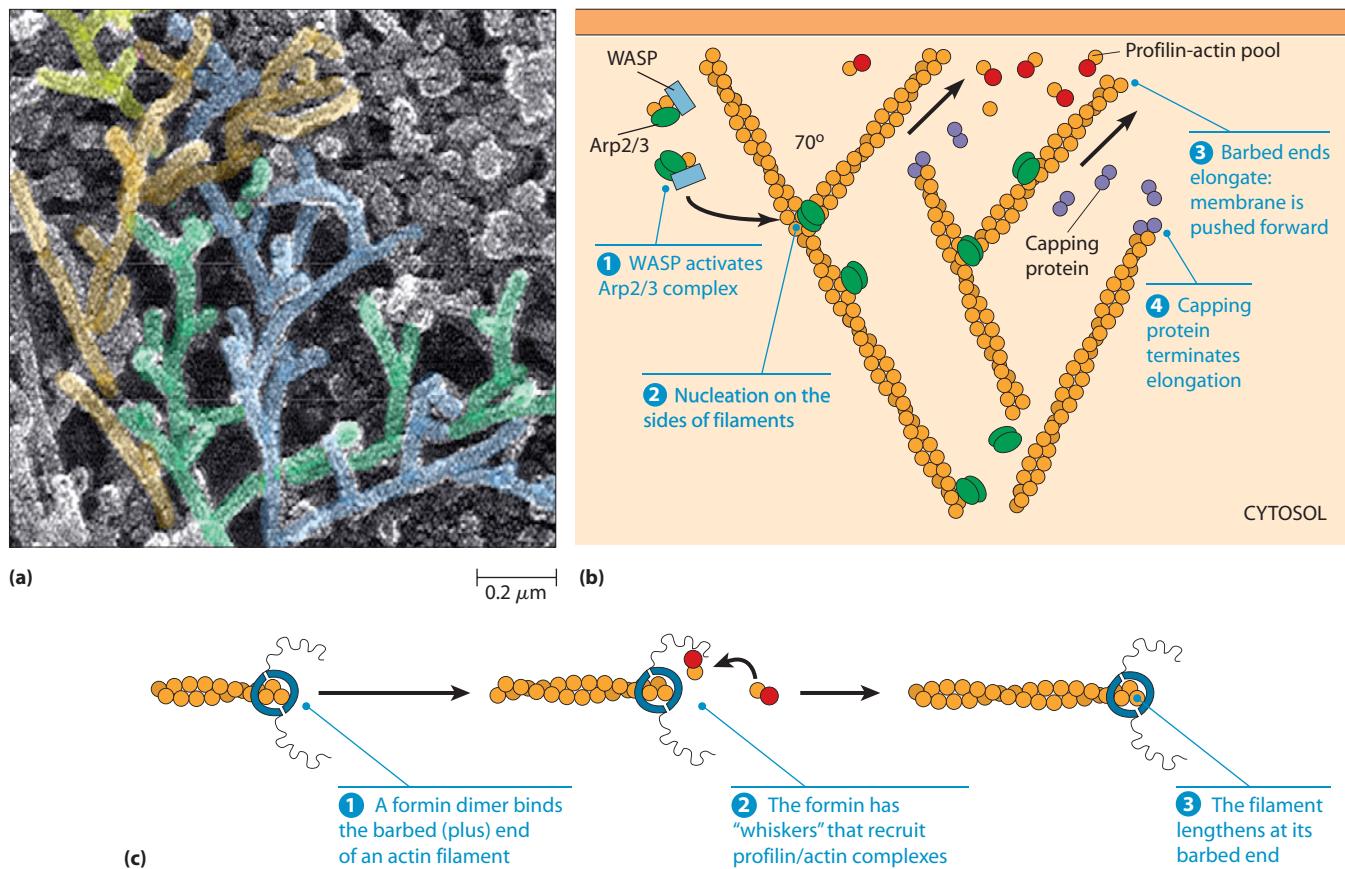

FIGURE 15-20 Formation of Actin Networks by Actin Polymerization. Actin networks, like those found in migrating cells, have a characteristic pattern of branching. (a) Branched actin filaments in a frog keratocyte. Individual branched actin filaments are colored to make them easier to distinguish (deep-etch TEM). (b) Model for Arp2/3-dependent branching. Branching is stimulated by WASP family proteins; capping protein helps regulate the length of new branches. (c) Model for formin-induced elongation of an actin filament. Formin dimers bind profilin-actin, serving as a “staging area” for actin polymerization.

 [VIDEOS www.thecellplace.com](http://www.thecellplace.com) Formation of branched actin

Inositol Phospholipids. Inositol phospholipids are one type of membrane phospholipid that regulates actin assembly. Recall that *phosphatidylinositol-4,5-bisphosphate* (PIP₂) is important during some signaling events, such as insulin signaling (see Chapter 14). PIP₂ can bind to proflin, CapZ, and proteins such as ezrin, thereby recruiting them to the plasma membrane, as well as regulating the ability of these proteins to interact with actin. For example, CapZ binds tightly to PIP₂, resulting in its removal from the end of a microfilament, thereby permitting the filament to be disassembled and making its monomers available for assembly into new filaments. Gelsolin is another actin-binding protein that can be regulated by binding to polyphosphoinositides. When gelsolin binds to a specific polyphosphoinositide, it can no longer cap the plus end of an MF, allowing the uncapped end to undergo changes in length.

Rho Family GTPases. One striking case of regulation of the actin cytoskeleton is the dramatic change in the cytoskeleton of cells exposed to certain growth factors. For example, in response to stimulation by platelet-derived

growth factor (PDGF), fibroblasts will begin to grow, divide, and form actin-rich membrane extensions that resemble lamellipodia. Other factors, such as lysophosphatidic acid (LPA), induce cells to form stress fibers.

How do such signals result in such dramatic reorganization of the actin cytoskeleton? Many of these signals result in changes in the actin cytoskeleton through their action on a family of monomeric G proteins known as **Rho GTPases**. Three key members of this family are **Rho**, **Rac**, and **Cdc42**. Originally identified in yeast, these proteins are important regulators of the actin cytoskeleton in all eukaryotes. Each Rho GTPase has profound and different effects on the actin cytoskeleton (**Figure 15-21**). For example, activation of the Rho pathway results in the formation of stress fibers, and Rho inactivation prevents the appearance of stress fibers following exposure of fibroblasts to LPA. Similarly, Rac activation often results in extension of lamellipodia by cultured cells, and inhibition of Rac prevents this normal response to PDGF. Finally, activation of Cdc42 results in the formation of filopodia. Rho GTPases perform a vast array of function within cells, from formation of protrusions to assembly

Infectious Microorganisms Can Move Within Cells Using Actin “Tails”

One of the most remarkable findings of modern cell motility research is the discovery that disease-causing microorganisms can co-opt the cell's normal cell adhesion and cell motility systems to penetrate a cell's defenses and enter the cell. The best-studied example of such motility is the gram-positive bacterium *Listeria monocytogenes*. One way that *Listeria* attaches to the host's cells involves the binding of a *Listeria* protein known as *internalin A* to *E-cadherin* on the cell surface (see Chapter 17 for more on cadherins). Once bound, *Listeria* enter a cell, move through it at a rate of 11 $\mu\text{m}/\text{min}$, and progress to nearby uninfected cells, where they continue the cycle of infection (Figure 15A-1). Short actin filaments radiate away from the bacteria, forming “comet tails” of branched F-actin (Figure 15A-1b). By using fluorescently labeled actin, investigators have determined that the tails form by Arp2/3-dependent polymerization of actin, which is nucleated near the surface of the internalized bacterium.

The protein on the surface of *Listeria* that promotes actin polymerization is known as *ActA*. The microfilaments nucleated by *ActA* are strikingly similar to those found at the leading edge of migrating cells and are formed using much of the same cellular machinery.

Other bacteria induce different sorts of actin “tails.” Bacteria of the genus *Rickettsia* that cause spotted fevers induce long, unbranched actin filaments reminiscent of filopodia. Thus, different pathogens have devised various ways of recruiting the host cytoskeleton for propulsion.

Some pathogens bind to the cell surface but are not internalized. For example, the enteropathogenic form of *E. coli*, which causes diarrhea in infants by forming colonies on the surface of intestinal epithelial cells, attaches to the surface of intestinal cells, where it organizes actin-rich “pedestals” that may function like the actin tails induced by *Listeria*.

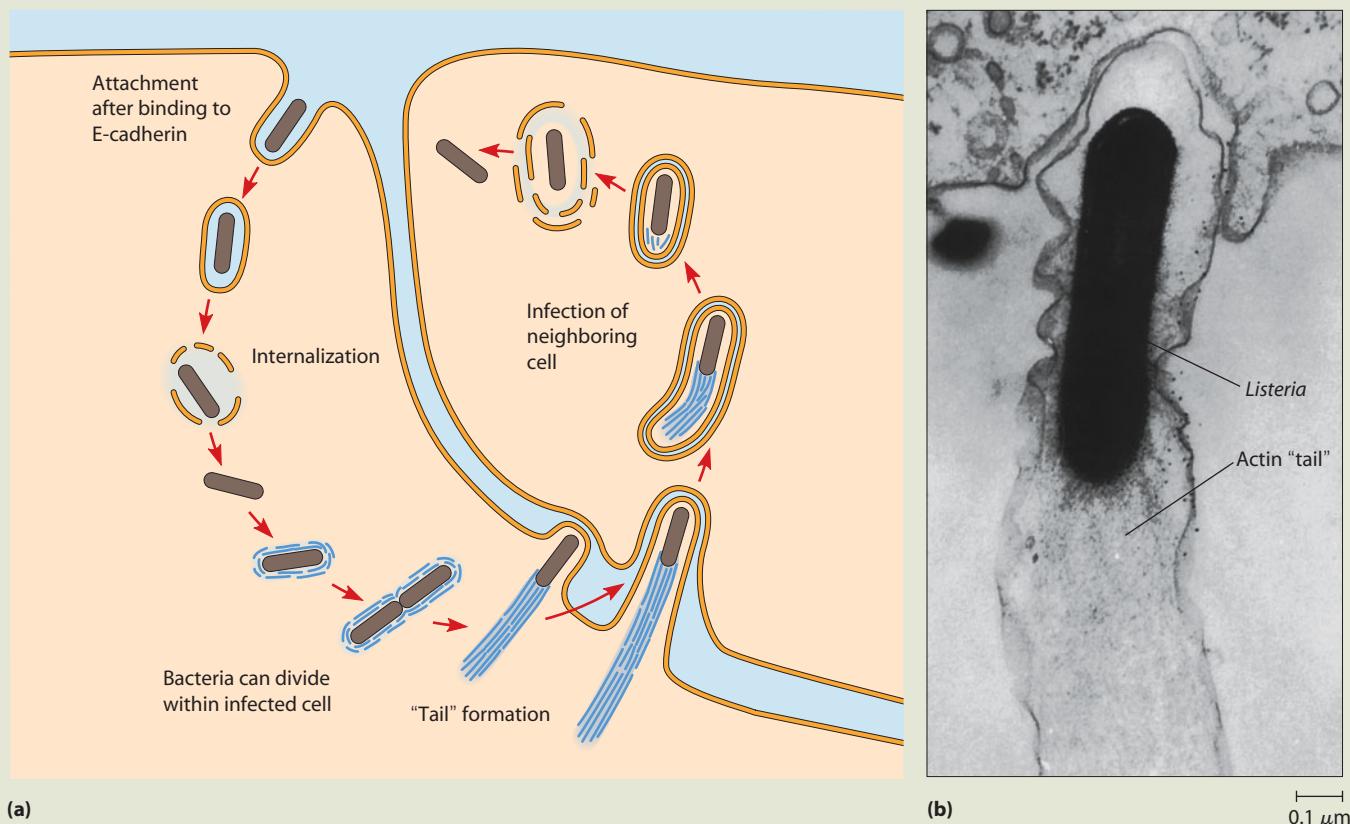

FIGURE 15A-1 Infection of a Macrophage by *Listeria monocytogenes*. (a) Life cycle of *Listeria*. A bacterium attaches to the surface of an uninfected cell. The bacterium then moves inside the cell, where it can divide to produce more bacteria in the infected cell. It then spreads to a nearby cell by producing a “comet tail” of polymerized actin, which propels the bacterium forward. (b) A transmission electron micrograph showing a *Listeria* within an infected macrophage and the “comet tail” of actin filaments that forms behind the bacterium.

VIDEOS www.thecellplace.com *Listeria movement via actin polymerization*

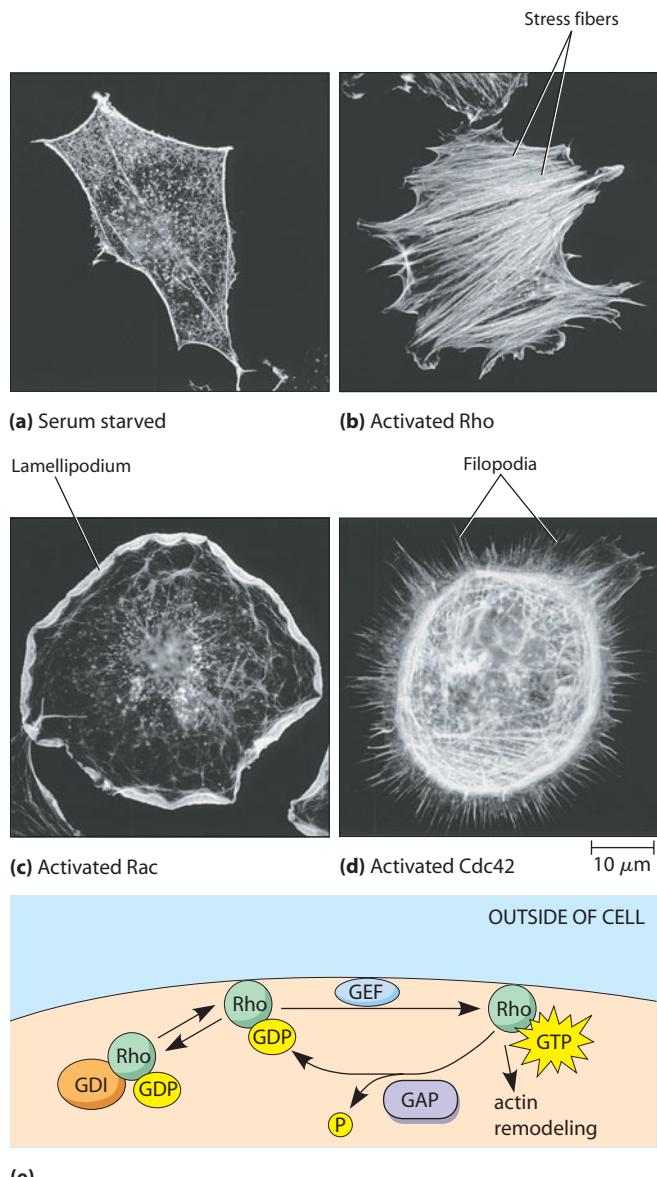

FIGURE 15-21 Regulation of Protrusions by Rho Family Proteins. (a) When a cultured fibroblast in the absence of growth factors (“serum starved”) is stained for actin, it has few actin bundles and shows little protrusive activity. (b) Under conditions that activate the Rho signaling pathway (such as addition of lysophosphatidic acid, LPA), stress fibers form. (c) When the Rac pathway is activated (in this case by injecting mutated Rac that is always active), lamellipodia form. (d) When Cdc42 is activated (e.g., by injecting a guanine nucleotide exchange factor that activates Cdc42), filopodia form. (e) Regulation of Rho family proteins. Guanine-nucleotide exchange factors (GEFs) stimulate exchange of a bound GDP for GTP, activating Rho family proteins, and allowing them to stimulate actin remodeling. GTPase activating proteins (GAPs) stimulate Rho GTPases to hydrolyze their bound GTP, thereby inactivating them. Guanine-nucleotide displacement inhibitors (GDIs) can sequester inactive Rho family G proteins, retaining them in the cytosol.

and disassembly of the cytokinetic furrow to regulating endo- and exocytosis. Many of these events are under the control of cell signaling; not surprisingly, then, these proteins are essential for growth factors such as PDGF and LPA to exert their effects.

Like Ras (see Chapter 14), Rho family GTPases are stimulated by *guanine-nucleotide exchange factors* (GEFs), which foster exchange of a bound GDP for GTP (Figure 15-21e). Corresponding *GTPase activating proteins* (GAPs) stimulate Rho GTPases to hydrolyze their bound GTP, thereby inactivating them. In addition, proteins known as *guanine-nucleotide dissociation inhibitors* (GDIs) can sequester inactive Rho GTPases in the cytosol. All of these events can be modulated by cell signals, allowing fine-tuning of where actin-based structures are assembled. Once active, different Rho GTPases can stimulate different types of actin polymerization. For example, activated Cdc42 can bind to and activate WASP, stimulating actin polymerization by the Arp2/3 complex. Rac can activate another WASP family protein, WAVE. Rho is known to bind to and activate formins, which explains why Rho activation can lead to formation of longer, less branched actin filaments.

Intermediate Filaments

Intermediate filaments (IFs) have a diameter of about 8–12 nm, which makes them intermediate in size between microtubules and microfilaments (see Table 15-1), or between the thin (actin) and thick (myosin) filaments in muscle cells, where IFs were first discovered. To date, most studies have focused on animal cells, where IFs occur singly or in bundles and appear to play a structural or tension-bearing role. One well-known and abundant intermediate filament protein is *keratin*. Keratin is an important component of structures that grow from skin in animals, including hair, claws and fingernails, horns and beaks, turtle shells, feathers, scales, and the outermost layer of the skin. **Figure 15-22** is an electron micrograph of IFs from a cultured human fibroblast cell.

Intermediate filaments are the most stable and the least soluble constituents of the cytoskeleton. Treatment of cells with detergents or with solutions of high or low ionic strength removes most of the microtubules,

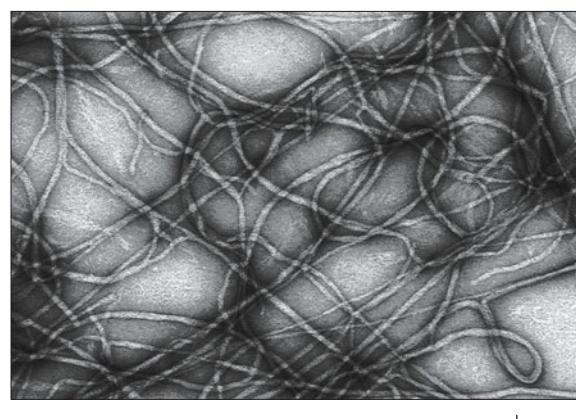

FIGURE 15-22 Intermediate Filaments. Electron micrograph of negatively stained keratin 5 and 14 intermediate filaments reconstituted in vitro (TEM).

microfilaments, and other proteins of the cytosol but leaves networks of IFs that retain their original shape. Due to the stability of the IFs, some scientists suggest that they serve as a scaffold to support the entire cytoskeletal framework. In contrast to MTs and MFs, IFs do not appear to be polarized.

Intermediate Filament Proteins Are Tissue Specific

In contrast to microtubules and microfilaments, intermediate filaments differ markedly in amino acid composition from tissue to tissue. Based on the cell type in which they are found, IFs and their proteins can be grouped into six classes (Table 15-4). Classes I and II comprise the *keratins*, proteins that make up the *tonofilaments* found in the epithelial cells covering the body surfaces and lining its cavities. (The IFs visible beneath the terminal web in the intestinal mucosa cell of Figure 15-18 consist of keratin.) Class I keratins are *acidic keratins*, whereas class II are *basic* or *neutral keratins*; each of these classes contains at least 15 different keratins.

Class III IFs include vimentin, desmin, and glial fibrillary acidic protein. *Vimentin* is present in connective tissue and other cells derived from nonepithelial cells. Vimentin-containing filaments are often prominent features in cultured fibroblast cells, in which they form a network that radiates from the center out to the periphery of the cell. *Desmin* is found in muscle cells, and *glial fibrillary acidic (GFA) protein* is characteristic of the glial cells that surround and insulate nerve cells. Class IV IFs are the *neurofilament (NF) proteins* found in the neurofilaments of nerve cells. Class V IFs are *nuclear lamins A, B, and C*,

which form a filamentous scaffold along the inner surface of the nuclear membrane of virtually all eukaryotic cells, including those in plants. Neurofilaments found in cells in the embryonic nervous system are made of *nestin*, which constitutes class VI.

As IF proteins and their genes have been sequenced, it has become clear that these proteins are encoded by a single (though large) family of related genes and can therefore be classified according to amino acid sequence relatedness as well. The six classes of IF proteins have been distinguished on this basis (see Table 15-4).

Due to the tissue specificity of intermediate filaments, animal cells from different tissues can be distinguished on the basis of the IF protein present, as determined by immunofluorescence microscopy. This *intermediate filament typing* serves as a diagnostic tool in medicine. IF typing is especially useful in the diagnosis of cancer because tumor cells are known to retain the IF proteins characteristic of the tissue of origin, regardless of where the tumor occurs in the body. Because the appropriate treatment often depends on the tissue of origin, IF typing is especially valuable in cases where diagnosis using conventional microscopic techniques is difficult.

Intermediate Filaments Assemble from Fibrous Subunits

As products of a family of related genes, all IF proteins have some common features, although they differ significantly in size and chemical properties. In contrast to actin and tubulin, all IF proteins are fibrous, rather than globular, proteins. All IF proteins have a homologous central

Table 15-4 Classes of Intermediate Filaments

Class	IF Protein	Molecular Mass (kDa)	Tissue	Function
I	Acidic cytokeratins	40–56.5	Epithelial cells	Mechanical strength
II	Basic cytokeratins	53–67	Epithelial cells	Mechanical strength
III	Vimentin	54	Fibroblasts; cells of mesenchymal origin; lens of eye	Maintenance of cell shape
III	Desmin	53–54	Muscle cells, especially smooth muscle	Structural support for contractile machinery
III	GFA protein	50	Glial cells and astrocytes	Maintenance of cell shape
IV	Neurofilament proteins		Central and peripheral nerves	Axon strength; determines axon size
	NF-L (major)	62		
	NF-M (minor)	102		
	NF-H (minor)	110		
V	Nuclear lamins		All cell types	Form a nuclear scaffold to give shape to nucleus
	Lamin A	70		
	Lamin B	67		
	Lamin C	60		
VI	Nestin	240	Neuronal stem cells	Unknown

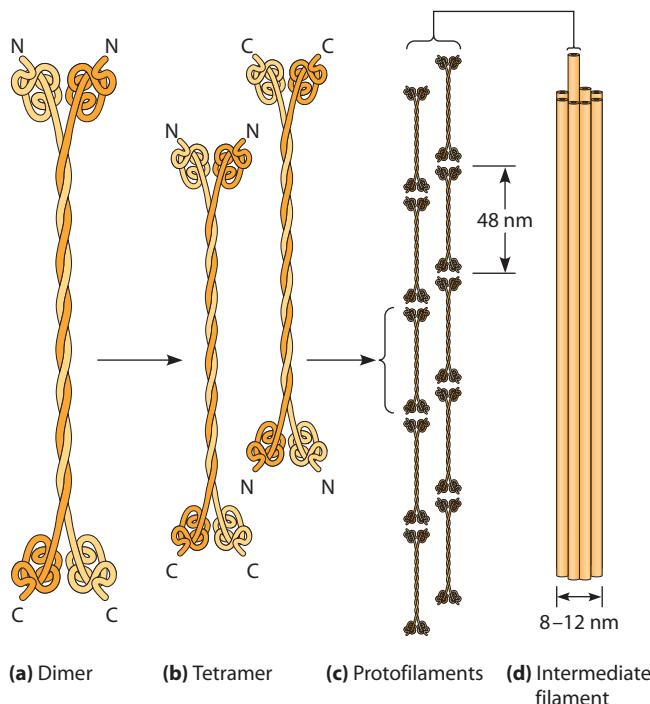

FIGURE 15-23 A Model for Intermediate Filament Assembly in Vitro. (a) The starting point for assembly is a pair of intermediate filament (IF) polypeptides. The two polypeptides are identical for all IFs except keratin filaments, which are obligate heterodimers with one each of the type I and type II polypeptides. The two polypeptides twist around each other to form a two-chain coiled coil, with their conserved center domain aligned in parallel. (b) Two dimers align laterally to form a tetrameric protofilament. (c) Protofilaments assemble into larger filaments by end-to-end and side-to-side alignment. (d) The fully assembled intermediate filament is thought to be eight protofilaments thick at any point.

rodlike domain of 310–318 amino acids that has been remarkably conserved in size, in secondary structure, and, to some extent, in sequence. This central domain consists of four segments of coiled helices interspersed with three short linker segments. Flanking the central helical domain are N- and C-terminal domains that differ greatly in size, sequence, and function among IF proteins, presumably accounting for the functional diversity of these proteins.

A possible model for IF assembly is shown in **Figure 15-23**. The basic structural unit of intermediate filaments consists of two IF polypeptides intertwined into a *coiled coil*. The central helical domains of the two polypeptides are aligned in parallel, with the N- and C-terminal regions protruding as globular domains at each end. Two such dimers then align laterally to form a tetrameric *protofilament*. Protofilaments interact with each other, associating in an overlapping manner to build up a filamentous structure both laterally and longitudinally. When fully assembled, an intermediate filament is thought to be eight protofilaments thick at any point,

with protofilaments probably joined end to end in staggered overlaps.

Intermediate Filaments Confer Mechanical Strength on Tissues

Intermediate filaments are considered to be important structural determinants in many cells and tissues. Because they often occur in areas of the cell that are subject to mechanical stress, they are thought to have a tension-bearing role. For example, when keratin filaments are genetically modified in the keratinocytes of transgenic mice, the epidermal cells are fragile and rupture easily. In humans, naturally occurring mutations of keratins give rise to a blistering skin disease called *epidermolysis bullosa simplex (EBS)*. IF defects are also suspected in other pathological conditions, including *amyotrophic lateral sclerosis (ALS)* and certain types of inherited *cardiomyopathies*, which result from defects in the organization of heart muscle.

Although our discussion of IFs may give the impression that they are static structures, this is not the case. In neurons, for example, IFs are dynamically transported and remodeled. Different IFs form a structural scaffold called the *nuclear lamina* on the inner surface of the nuclear membrane (discussed in detail in Chapters 18 and Chapter 19). The nuclear lamina is composed of three separate IF proteins called *nuclear lamins A, B, and C*. These lamins become phosphorylated and disassemble as a part of nuclear envelope breakdown at the onset of mitosis. After mitosis, lamin phosphatases remove the phosphate groups, allowing the nuclear envelope to form again.

The Cytoskeleton Is a Mechanically Integrated Structure

In the preceding sections, we have looked at the individual components of the cytoskeleton as separate entities. In fact, cellular architecture depends on the unique properties of the different cytoskeletal components working together. Microtubules are generally thought to resist bending when a cell is compressed, while microfilaments serve as contractile elements that generate tension. Intermediate filaments are elastic and can withstand tensile forces.

The mechanical integration of intermediate filaments, microfilaments, and microtubules is made possible by specific linker proteins that connect them, known as *plakins*. One plakin, called *plectin*, is a versatile linker protein that is found at sites where intermediate filaments are connected to microfilaments or microtubules (**Figure 15-24**). Plectin, as well as several other plakins, contains binding sites for intermediate filaments, microfilaments, and microtubules. By linking these major types of polymers, plakins help to integrate them into

a mechanically integrated cytoskeletal network. As a result, interconnected cytoskeletal structures can adapt to stretching forces in such a way that the tension-bearing elements become aligned with the direction of stress. These stress-bearing properties of the cytoskeleton are important in epithelial cells such as those that line the gut. These cells are subjected to stress as smooth muscle within the intestinal wall contracts and puts pressure on the contents of the gut.

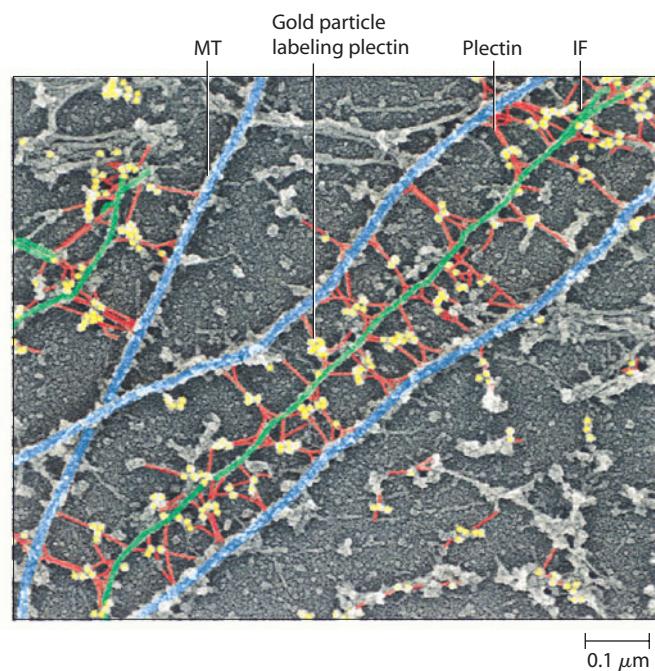

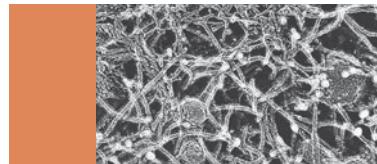

FIGURE 15-24 Connections Between Intermediate Filaments and Other Components of the Cytoskeleton.

Intermediate filaments are linked to both microtubules and actin filaments by a protein called plectin. Plectin (red) links IFs (green) to MTs (blue). Gold particles (yellow) label plectin (deep-etch TEM). Plectins can also bind actin MFs (not shown). Here, IFs serve as strong but elastic connectors between the different cytoskeletal filaments.

SUMMARY OF KEY POINTS

The Cytoskeleton

- Both prokaryotes and eukaryotes possess an interconnected network of proteins that polymerize from smaller subunits called the cytoskeleton. In eukaryotes, it consists of an extensive three-dimensional network of microtubules (MTs), microfilaments (MFs), and intermediate filaments (IFs) that determines cell shape and allows a variety of cell movements.
- The cytoskeleton is a structural feature of cells that is revealed especially well by digital video, fluorescence, and electron microscopy.
- A variety of drugs can be used to perturb the assembly and disassembly of microtubules and microfilaments in eukaryotes. Such drugs are useful for determining which cellular processes require different cytoskeletal filaments.

Microtubules

- Microtubules (MTs) are hollow tubes with walls consisting of heterodimers of α - and β -tubulin polymerized linearly into

protofilaments. Both α - and β -tubulin can bind GTP. First identified as components of the axonemal structures of cilia and flagella and the mitotic spindle of dividing cells, microtubules are now recognized as a general cytoplasmic constituent of most eukaryotic cells.

- MTs are polar structures that elongate preferentially from one end, known as the plus end. MT growth occurs when the concentration of tubulin rises above the critical concentration, the concentration of monomers at which subunit addition is exactly balanced by subunit loss from an MT.
- Drugs such as nocodazole, colchicine, and colcemid cause depolymerization of MTs; taxol stabilizes MTs.
- MTs can undergo cycles of catastrophic shortening and elongation—a phenomenon known as dynamic instability, which involves hydrolysis of GTP by β -tubulin near the plus end, followed by recovery of the GTP-cap at the plus end.
- Within cells, MT dynamics and growth are organized by microtubule-organizing centers (MTOCs). The centrosome is a major MTOC, which contains nucleation sites that are rich in γ -tubulin and are used to nucleate MT growth.

- Microtubule-associated proteins (MAPs) stabilize MTs along their length, +TIP proteins stabilize and anchor their plus ends, and catastrophins hasten their catastrophic depolymerization.

Microfilaments

- Microfilaments (MFs), or F-actin, are double-stranded polymers of G-actin monomers, which bind ATP. Originally discovered because of their role in muscle cells, MFs are components of virtually all eukaryotic cells.
- Like microtubules, MFs are polar structures; G-actin monomers preferentially add to the plus (barbed) ends of MFs; their minus (pointed) ends display far slower subunit addition and loss.
- Actin-binding proteins tightly regulate the polymerization and function of F-actin. These include monomer-binding proteins, which regulate polymerization, and proteins that cap, crosslink, sever, bundle, and anchor F-actin in various ways.

- Microfilament assembly within cells is regulated by cell signaling, which can be mediated by the activity of phosphoinositides and by the monomeric G proteins, Rho, Rac, and Cdc42.

Intermediate Filaments

- Intermediate filaments (IFs) are the most stable and least soluble constituents of the cytoskeleton. They appear to play a structural or tension-bearing role within cells.
- IFs are tissue specific and can be used to identify cell type. Such typing is useful in the diagnosis of cancer.
- All IF proteins have a highly conserved central domain flanked by terminal regions that differ in size and sequence, presumably accounting for the functional diversity of IF proteins.
- IFs, MTs, and MFs are interconnected within cells to form cytoskeletal networks that can withstand tension and compression, providing mechanical strength and rigidity to cells.

MAKING CONNECTIONS

In our overview of the cell in Chapter 4, we saw that the cytoskeleton is a key component of cellular structure and function. In this chapter, you learned that the cytoskeleton is a structural feature of bacterial and eukaryotic cells. The eukaryotic cytoskeleton consists of an extensive three-dimensional network of microtubules, microfilaments, and intermediate filaments that determines cell shape and allows a variety of cell movements. The cytoskeleton is required for a wide variety of cellular events—from the trafficking of vesicles within the cell (see Chapter 12) to the adhesion of cells in animal tissues to the construction of the cell wall in plants, as we will see in Chapter 17. Like other biological polymers, such as the individual proteins, nucleic acids, and carbohydrates we examined in Chapter 3, polymerization of cytoskeletal polymers involves assembly of macromolecules from repeating subunits. Where and when local polymerization of the cytoskeleton occurs is an important and tightly controlled event. One

way polymerization is controlled is through cell signaling; in some cases cell signals activate Rho family GTPases. These are similar to the monomeric G protein Ras, which you saw was a key component of receptor tyrosine kinase signaling in Chapter 14. A major event that requires the coordinated activity of the cytoskeleton—cell division—is a major topic in Chapter 19. There we will see that microtubules are crucial for mitosis, and actin is essential for cytokinesis. Because the cytoskeleton is required for cell proliferation, it is a target of chemotherapy for the treatment of cancer; you will explore this topic in more detail in Chapter 24.

To understand in more detail how the cytoskeleton is employed in dynamic events such as cell division and cell movement, we need to consider how assembled arrays of cytoskeletal proteins are used in cell movement and to move structures within cells. We will explore these topics in the next chapter.

PROBLEM SET

More challenging problems are marked with a •.

15-1 Filaments and Tubules. Indicate whether each of the following descriptions is true of microtubules (MT), microfilaments (MF), intermediate filaments (IF), or none of these (N). More than one response may be appropriate for some statements.

- Involved in muscle contraction.
- Involved in the movement of cilia and flagella.

- More important for chromosome movements than for cytokinesis.
- More important for cytokinesis than for chromosome movements in animal cells.
- Most likely to remain when cells are treated with solutions of nonionic detergents or solutions of high ionic strength.
- Structurally similar proteins are found in bacterial cells.
- Their subunits can bind and catalyze hydrolysis of phosphonucleotides.

(h) Can be detected by immunofluorescence microscopy.

(i) Play well-documented roles in cell movement.

(j) The fundamental repeating subunit is a dimer.

15-2 True or False. Identify each of the following statements as true (T) or false (F). Provide a brief justification for your answer.

- (a) The minus end of microtubules and microfilaments is so named because subunits are lost and never added there.
- (b) The energy required for tubulin and actin polymerization is provided by hydrolysis of a nucleoside triphosphate.
- (c) Microtubules, microfilaments, and intermediate filaments all exist in a typical eukaryotic cell in dynamic equilibrium with a pool of subunit proteins.
- (d) Latrunculin A treatment would block intracellular movements of *Listeria*.
- (e) An algal cell contains neither tubulin nor actin.
- (f) All of the protein subunits of intermediate filaments are encoded by genes in the same gene family.
- (g) All microtubules within animal cells have their minus ends anchored at the centrosome.
- (h) As long as actin monomers continue to be added to the plus end of a microfilament, the MF will continue to elongate.

15-3 Cytoskeletal Studies. Described here are the results of several recent studies on the proteins of the cytoskeleton. In each case, state the conclusion(s) that can be drawn from the findings.

- (a) Small vesicles containing pigment inside of pigmented fish epidermal cells aggregate or disperse in response to treatment with certain chemicals. When nocodazole is added to cells in which the pigment granules have been induced to aggregate, the granules cannot disperse again.
- (b) When an animal cell is treated with colchicine, its microtubules depolymerize and virtually disappear. If the colchicine is then washed away, the MTs appear again, beginning at the centrosome and elongating outward at about the rate ($1\mu\text{m}/\text{min}$) at which tubulin polymerizes in vitro.
- (c) Extracts from nondividing frog eggs in the G2 phase of the cell cycle were found to contain structures that could induce the polymerization of tubulin into microtubules in vitro. When examined by immunostaining, these structures were shown to contain γ -tubulin.

• 15-4 Stabilization and the Critical Concentration. Suppose you have determined the overall critical concentration for a sample of purified tubulin. Then you add a preparation of centrosomes (microtubule-organizing centers), which nucleate microtubules so that the minus end is bound to the centrosome and stabilized against disassembly. When you again determine the overall critical concentration, you find it is different. Explain why the overall critical concentration would change.

15-5 Actin' up. The polymerization of G-actin into microfilaments can be followed using pyrene-labeled actin and a device to measure the fluorescence of polymerized actin in a test tube. The increase in fluorescence can then be plotted over time, similar to light-scattering experiments to measure tubulin polymerization (Figure 15-25). Examine the graph, and

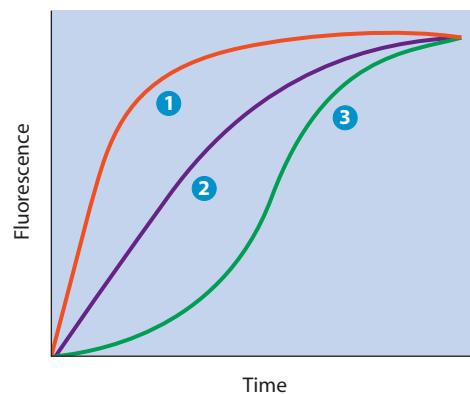

FIGURE 15-25 Actin Polymerization Kinetics Measured by Pyrene Actin Incorporation Under Various Experimental Conditions. See Problem 15-5.

identify which of the curves corresponds to each of the following situations. In each case, state your reasoning.

- (a) Pyrene actin is added alone in the presence of buffer.
- (b) Pyrene actin is added along with purified Arp2/3 complex proteins.
- (c) Pyrene actin is added along with purified Arp2/3 complex proteins and a purified protein fragment that corresponds to active N-WASP (a WASP family protein).

• 15-6 Spongy Actin. You are interested in the detailed effects of cytochalasin D on microfilaments over time. Based on what you know about the molecular mechanism of action of cytochalasins, draw diagrams of what happens to microfilaments within cells treated with the drug. In particular, explain why existing actin polymers eventually depolymerize.

• 15-7 A New Wrinkle. Fibroblasts can be placed on thin sheets of silicone rubber. Under normal circumstances, fibroblasts exert sufficient tension on the rubber so that it visibly wrinkles. Explain how the ability of fibroblasts to wrinkle rubber would compare with that of normal cells under the following conditions.

- (a) The cells are injected with large amounts of purified gelsolin.
- (b) The cells are treated with a permeable form of C3 transferase, a toxin from the bacterium, *Clostridium botulinum*, which covalently modifies an amino acid in Rho by ADP-ribosylation. This renders Rho unable to bind to proteins that it would normally bind to when active.
- (c) The cells are treated with taxol.
- (d) The cells are treated with latrunculin A, the drug is washed out, and the cells are observed periodically.
- (e) A constitutively activated Rho is introduced into the cell.

15-8 Stressed Out. It is now possible, using nanoengineering techniques, to attach magnetic beads to the surface of large cells to measure how mechanically stiff they are. It is also known that acrylamide, which is polymerized to make gels for protein electrophoresis, is very toxic. One effect of acrylamide is to depolymerize intermediate filaments, such as keratin. What effect would you predict acrylamide treatment would have on the mechanical rigidity of a keratinocyte (skin cell)? Explain your answer.

Cellular Movement: Motility and Contractility

In the previous chapter, we saw that the cytoskeleton of eukaryotic cells serves as an intracellular scaffold that organizes structures within the cell and shapes the cell itself. In this chapter, we will explore the role of these cytoskeletal elements in cellular **motility**. This may involve the movement of a cell (or a whole organism) through its environment, the movement of the environment past or through the cell, the movement of components within the cell, or the shortening of the cell itself. **Contractility**, a related term often used to describe the shortening of muscle cells, is a specialized form of motility.

Motile Systems

Motility occurs at the tissue, cellular, and subcellular levels. The most conspicuous examples of motility, particularly in the animal world, take place at the tissue level. The muscle tissues common to most animals consist of cells specifically adapted for contraction. The movements produced are often obvious, whether manifested as the bending of a limb, the beating of a heart, or a uterine contraction during childbirth.

At the cellular level, motility occurs in single cells or in organisms consisting of one or only a few cells. It occurs among cell types as diverse as ciliated protozoa and motile sperm, depending in each case on cilia or flagella, cellular appendages adapted for propulsion. Other examples include the actin-dependent migration of single cells, amoeboid movement, and the invasiveness of cancer cells in malignant tumors.

Equally important is the movement of *intracellular* components. For example, highly ordered microtubules of the mitotic spindle play a key role in the separation of chromosomes during cell division, as we will see in Chapter 19. Nondividing cells continuously shuttle components—such

as RNAs, multiprotein complexes, and the membrane-bounded vesicles we learned about in Chapter 12—from one location to another.

Motility is an especially intriguing use of energy by cells because it often involves the conversion of chemical energy directly to mechanical energy. In contrast, most mechanical devices that produce movement from chemicals (such as an automobile engine, which depends on the combustion of gasoline) require an intermediate form of energy, (e.g., heated gasses). As we will see, the cellular energy for motility typically comes from ATP, whose hydrolysis is coupled to changes in the shape of specific proteins that mediate movement. To generate movement, the microfilaments and microtubules of the cytoskeleton provide a basic scaffold for specialized **motor proteins**, or **mechanoenzymes**, which interact with the cytoskeleton to produce motion at the molecular level. The combined effects of these molecular motions produce movement at the cellular level. In cases such as muscle contraction, the combined effects of many cells moving simultaneously produce motion at the tissue level.

In eukaryotes, there are two major motility systems. The first involves interactions between specialized motor proteins and microtubules. Microtubules are abundant in cells and are used for a variety of intracellular movements. A specific example of such microtubule-based movement is *fast axonal transport*, one of the processes used by a nerve cell to transport materials between its cell body and outlying regions. Another process is the sliding of microtubules in *cilia* and *flagella*. The second type of eukaryotic motility requires interactions between actin microfilaments and members of the *myosin* family of motor molecules. A familiar example of microfilament-based movement is *muscle contraction*. We begin our detailed examination of the two motility systems with two proteins essential for microtubule-based movement.

Intracellular Microtubule-Based Movement: Kinesin and Dynein

Microtubules (MTs) provide a rigid set of tracks for the transport of a variety of membrane-enclosed organelles and vesicles. As we saw in Chapter 15, the centrosome organizes and orients MTs because the minus ends of most MTs are embedded in the centrosome. The centrosome is generally located near the center of the cell, so traffic toward the minus ends of MTs might be considered “inbound” traffic. Traffic directed toward the plus ends might likewise be considered “outbound,” meaning that it is directed toward the periphery of the cell.

While microtubules provide an organized set of tracks along which organelles can move, they do not directly generate the force necessary for movement. The mechanical work needed for movement depends on *microtubule-associated motor proteins*, which attach to vesicles or organelles and then “walk” along the MT, using ATP to provide the needed energy. Furthermore, MT motor proteins recognize the polarity of the MT, with each motor protein having a preferred direction of movement. At present, we are aware of two major families of MT motors: **kinesins** and **dyneins** (Table 16-1).

MT Motor Proteins Move Organelles Along Microtubules During Axonal Transport

A historically important cell type for studying microtubule-dependent intracellular movement is the squid giant axon (see Figure 13-2 for further details regarding the squid giant axon). Proteins or neurotransmitters synthesized in the cell body of the neuron must be transported over distances up to a meter between the cell body and the nerve ending. The need for such transport arises because ribosomes are present only in the cell body, so no protein synthesis occurs in the axons or synaptic knobs. Instead, proteins and membranous vesicles are synthesized in the cell body and transported along the axons to the synaptic knobs. Some form of energy-dependent transport is clearly required, and MT-based movement provides the mechanism. The process, called **fast axonal transport**, involves the movement of vesicles and other organelles along MTs. (We will not discuss slow axonal transport, which involves somewhat different processes.)

The role of microtubules in axonal transport was initially suggested because the process is inhibited by drugs that depolymerize MTs but is insensitive to drugs that affect microfilaments. Since then, MTs have been visualized along the axon and have been shown to be prominent features of the axonal cytoskeleton. Moreover, axonal MTs have small, membranous vesicles and mitochondria associated with them (Figure 16-1).

Evidence that a motor protein drives the movements of organelles was obtained when investigators found that organelles in the presence of ATP could move along fine filamentous structures present in exuded *axoplasm* (the

*Kinesins and myosins comprise large families of proteins. There are many families of kinesins and myosins.

cytosol of axons), which could be visualized by video-enhanced differential interference contrast microscopy (see the Appendix for details). The rate of organelle movement was shown to be about $2 \mu\text{m/sec}$, comparable to the axonal transport rate in intact neurons. A combination of immunofluorescence and electron microscopy demonstrated that the fine filaments the organelles move along are single microtubules.

Since that time, two MT motor proteins responsible for fast axonal transport, kinesin 1 and cytoplasmic dynein, have been purified and characterized. To determine the direction of transport by these motors, purified proteins were used experimentally to drive the transport of polystyrene beads along microtubules polymerized from purified centrosomes. When polystyrene beads, purified kinesin, and ATP were added to such MTs, the beads moved toward the plus ends (i.e., away from the centrosome). This finding means that in a nerve cell,

FIGURE 16-1 A Vesicle Attached to a Microtubule in a Crayfish Axon. Cross-bridges connect the membrane vesicle (round structure at center) to the microtubule (deep-etch TEM).

kinesin mediates transport from the cell body down the axon to the nerve ending (called *anterograde axonal transport*). When similar experiments were carried out with purified cytoplasmic dynein, particles were moved in the opposite direction, toward the minus ends of the MTs (called *retrograde axonal transport* when it occurs in neurons). Thus these two motors transport their *cargo*, those organelles or components that they shuttle along microtubules, in opposite directions within the cytosol (**Figure 16-2**), a finding that has been abundantly confirmed by more recent molecular and genetic analysis.

Figure 16-2 may suggest that cargo always moves in one direction or another along MTs. In some cases, such as fast axonal transport, such unidirectional transport is the rule. However, some vesicles are capable of changing direction as they move along an MT. In these cases cargo is attached to both kinesins and dyneins; the direction of motion seems to be determined by which type of motor predominates.

Motor Proteins Move Along Microtubules by Hydrolyzing ATP

The first kinesins, originally identified in the cytoplasm of squid giant axons, consist of three parts: a globular *head* region that attaches to microtubules and is involved in hydrolysis of ATP, a coiled helical region, and a *light-chain* region that is involved in attaching the kinesin to other proteins or organelles (**Figure 16-3a**). The movements of single kinesin molecules along MTs have

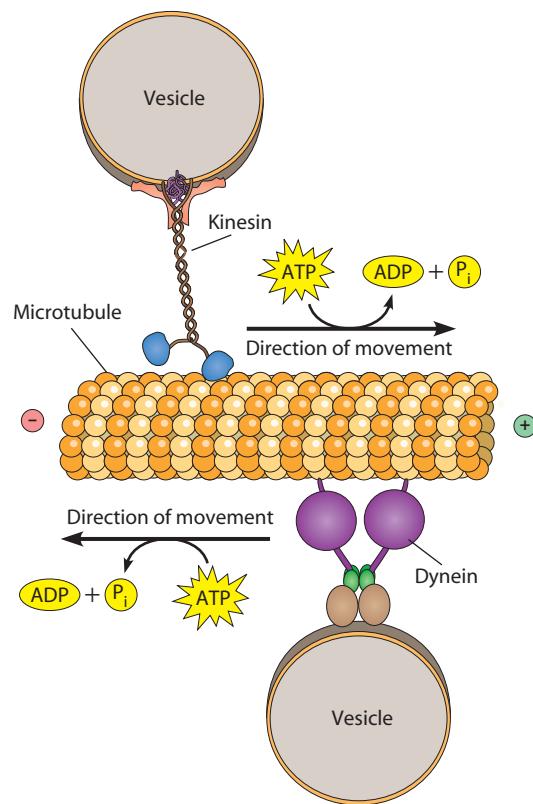

FIGURE 16-2 Microtubule-Based Motility. Kinesins and dyneins are motor proteins that couple ATP hydrolysis to conformational changes to “walk” along microtubules. Most kinesins move vesicles or organelles toward the plus ends of MTs. Dyneins move in the opposite direction, toward the minus ends of MTs.

VIDEOS www.thecellplace.com Movement of organelles *in vivo*

been studied by tracking the movement of beads attached to kinesin or by measuring the force exerted by single kinesin molecules using calibrated glass fibers or beads trapped in a special type of laser beam known as an “optical tweezer” (see the Appendix). Classic kinesins move along MTs in 8-nm steps: One of the two globular heads moves forward to make an attachment to a new β -tubulin subunit, followed by detachment of the trailing globular head, which can now make an attachment to a new region of the MT. It is easiest to visualize this movement as analogous to walking, with the two globular heads taking turns as the front “foot” (Figure 16-3b). This movement is coupled to the hydrolysis of ATP bound at specific sites within the heads. The result is that kinesin moves toward the plus end of an MT in an ATP-dependent fashion. A single kinesin-1 molecule exhibits *processivity*. It can cover long distances before detaching from an MT. To do so, it releases its bound ADP and acquires a new molecule of ATP, allowing the cycle to repeat. A single kinesin molecule can move as far as 1 μm , which is a great distance relative to its size. As a molecular motor, kinesin appears to be quite efficient; estimates of its efficiency in converting the energy of ATP hydrolysis to useful work are on the order of 60–70%.

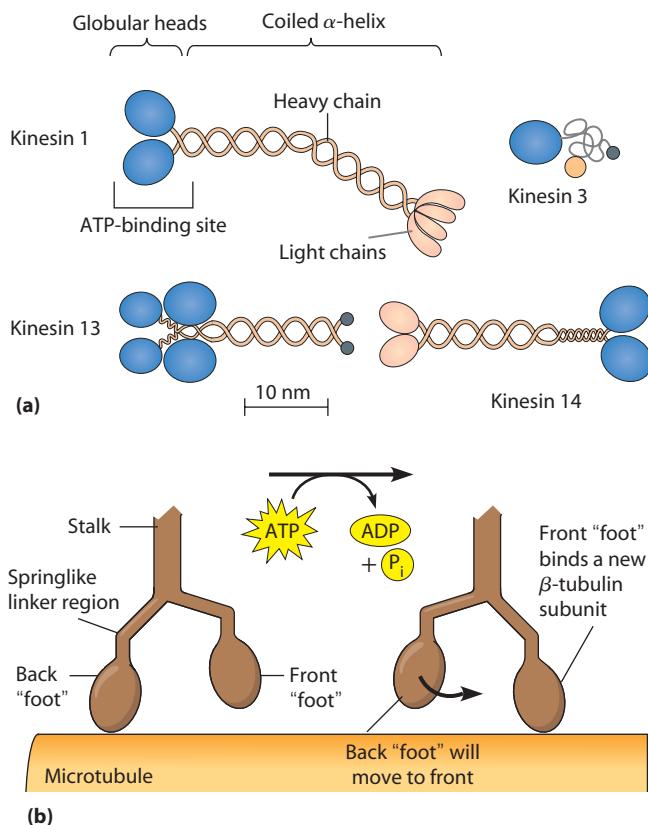

FIGURE 16-3 Movement of Kinesin. (a) The basic structure of several kinesin family members. (b) Kinesins “walk” along microtubules. The front “foot,” one of kinesin’s two globular heads, detaches from a β -tubulin subunit by hydrolyzing ATP and moves forward. The rear “foot” then releases by hydrolyzing ATP and springs forward, moving to the front.

Kinesins Are a Large Family of Proteins with Varying Structures and Functions

Since the discovery of the original kinesin involved in anterograde transport in neurons, many other kinesins have been discovered. They can be grouped into families based on their structure (Table 16-1). Some of these kinesins form dimers with another identical protein or with another, different kinesin. One family (kinesin 14) acts as minus-end-directed motors, rather than as plus-end motors. Biochemical and immunocytochemical studies, as well as analysis of mutant organisms, have shown that kinesins are involved in many different processes within cells. One important function for kinesin is moving and localizing substances within cells. These include RNAs, multiprotein complexes, and membranous organelles. (We will consider their role in organelle transport later in this chapter.) We saw another role for kinesins in Chapter 15: one family of kinesins, the catastrophins, aids depolymerization of MTs. Various kinesins localize to the mitotic or meiotic spindle or to kinetochores, where they play roles in various phases of mitosis and meiosis (see Chapter 19). Other kinesins are required for completion of mitosis and cytokinesis. For

example, cells in mutant fruit flies or nematode worms lacking one of these kinesins (called MKLP kinesins) initiate cytokinesis, but, because the cleavage furrow never deepens, cell division fails.

To attach to their cargo, kinesins often use their light chains. In some cases, the light chains attach directly to cargo. In other cases, such as mitochondria, adapter proteins allow the light chains to attach to cargo indirectly.

Dyneins Can Be Grouped into Two Major Classes: Axonemal and Cytoplasmic Dyneins

The dynein family of motor proteins consists of two basic types: cytoplasmic dynein and axonemal dynein (Table 16-1). In contrast to the kinesins, few cytoplasmic dyneins have been identified. **Cytoplasmic dynein** contains two heavy chains that interact with microtubules, two intermediate chains, two light intermediate chains, and various light chains. In contrast to most kinesins, cytoplasmic dynein moves toward the minus ends of MTs. Cytoplasmic dynein is associated with the protein complex known as **dynactin** (Figure 16-4). The dynactin complex helps to link cytoplasmic dynein to cargo (such as membranous vesicles) it transports along MTs, by binding to proteins such as spectrin attached to the membrane of its cargo.

At least four types of **axonemal dynein** have been identified. We will discuss the function of axonemal dynein in cilia and flagella in some detail later in this chapter.

Microtubule Motors Are Involved in Shaping the Endomembrane System and Vesicle Transport

In Chapter 12 we saw that the cell has an elaborate transportation system of vesicles and membranous organelles. First, recall that the endomembrane system is a complex

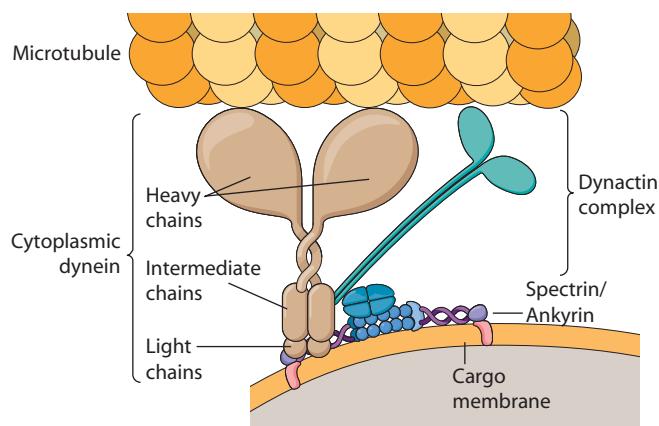

FIGURE 16-4 Schematic Representation of the Cytoplasmic Dynein/Dynactin Complex. Cytoplasmic dynein (brown) is linked with cargo membranes indirectly through the dynactin multiprotein complex (aqua). The dynactin complex binds to a complex containing spectrin and ankyrin, associated with the membrane of the cargo vesicle.

network of membrane-bounded tubules, important not only for export and processing of newly synthesized proteins but also for events such as calcium release (see Chapter 14). MT motors appear to be important for dynamically shaping this complicated network. Live imaging of MTs and endoplasmic reticulum (ER) membrane in vitro and in living cells indicates that extensions of the ER can be moved along MTs.

Second, recall that the Golgi complex is a series of flattened membrane stacks located in the region of the centrosome. The function of the Golgi is to receive proteins made in the ER and to process and package those proteins for distribution to the correct cellular destinations. At each step of this process, proteins are transported in vesicles. Thus, there is a continuous flow of vesicles to and from the Golgi. The vesicles are carried by MT motors on microtubule tracks (**Figure 16-5**).

Several experiments demonstrate that microtubule-based transport is crucial for maintenance of the Golgi stacks. For example, if MTs are depolymerized using the drug nocodazole (see Chapter 15, page 428), the Golgi complex disperses. When the nocodazole is washed out, the Golgi complex re-forms. Similarly, disruption of the function of the dynein complex by inducing cells to

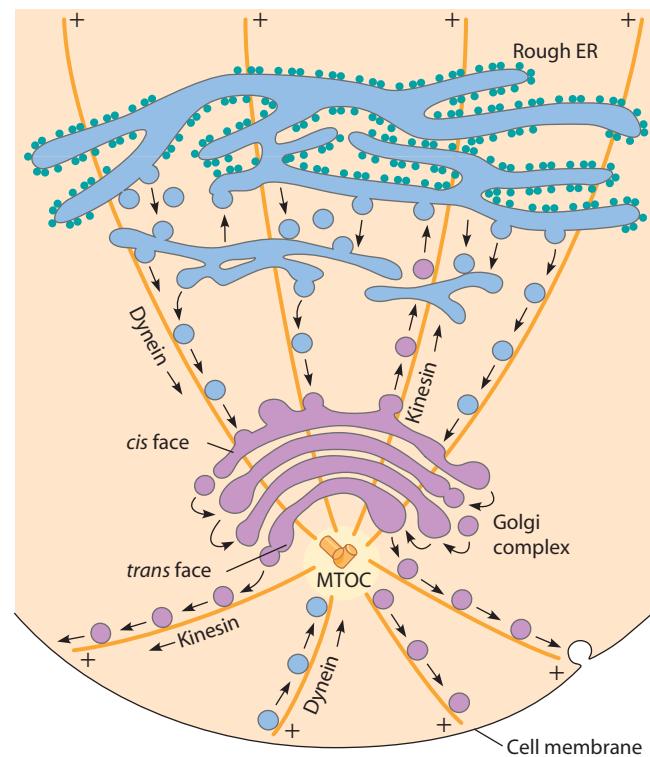

FIGURE 16-5 Microtubules and the Endomembrane System.

Vesicles going to and from the Golgi complex are attached to microtubules and carried by MT motors. Vesicles derived from either the ER or the cell membrane are carried toward the Golgi complex and microtubule-organizing center (MTOC) by dynein, whereas vesicles derived from the Golgi complex are carried toward either the ER or the cell periphery by kinesins.

produce too much of one of its subunits results in collapse of the Golgi complex and disruption of the transport of intermediates from the ER to the Golgi.

Proteins are processed as they move through the stacks of Golgi membranes. The finished proteins emerge—still packaged in vesicles—from the other side of the complex. Plus-end-directed MT motors carry the finished vesicles away from the Golgi complex toward the cell periphery. In organisms in which various kinesins are mutated, specific defects in vesicle transport have been observed, providing evidence that these motors are crucial for plus-end-directed vesicular transport.

Microtubule-Based Motility: Cilia and Flagella

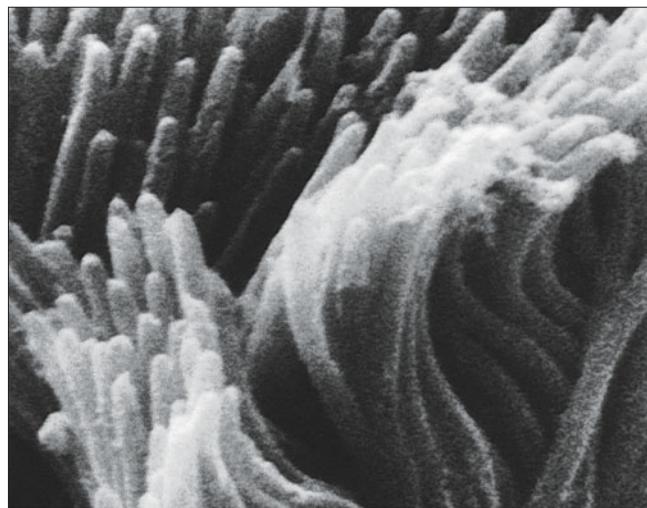

Cilia and Flagella Are Common Motile Appendages of Eukaryotic Cells

Microtubules are crucial not only for movement within cells but also for the movements of *flagella* and *cilia*, the motile appendages of eukaryotic cells. The two appendages share a common structural basis and differ only in relative length, number per cell, and mode of beating. **Cilia** (singular: **cilium**) have a diameter of about $0.25\text{ }\mu\text{m}$, are about $2\text{--}10\text{ }\mu\text{m}$ long, and tend to occur in large numbers on the surface of ciliated cells. Each cilium is bounded by an extension of the plasma membrane and is therefore an intracellular structure.

Cilia occur in both unicellular and multicellular eukaryotes. Unicellular organisms, such as *Paramecium*, a protozoan, use cilia for both locomotion and the collection of food particles. In multicellular organisms, cilia serve primarily to move the environment past the cell rather than to propel the cell through the environment. The cells that line the air passages of the human respiratory tract, for example, have several hundred cilia each, which means that every square centimeter of epithelial tissue lining the respiratory tract has about a billion cilia (**Figure 16-6a**)! The coordinated, wavelike beating of these cilia carries mucus, dust, dead cells, and other foreign matter out of the lungs. One of the health hazards of cigarette smoking lies in the inhibitory effect that smoke has on normal ciliary beating. Certain respiratory ailments can also be traced to defective cilia.

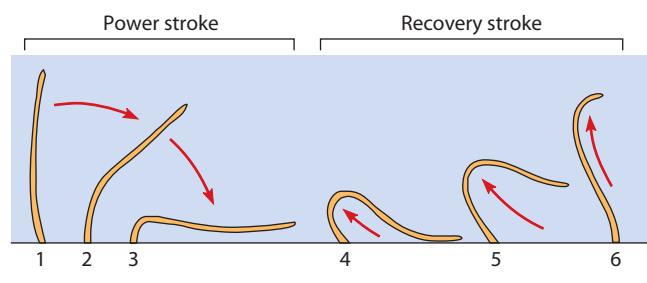

Cilia display an oarlike pattern of beating, with a power stroke perpendicular to the cilium, thereby generating a force parallel to the cell surface. The cycle of beating for an epithelial cilium is shown in Figure 16-6b. Each cycle requires about 0.1–0.2 sec and involves an active power stroke followed by a recovery stroke.

Flagella (singular: **flagellum**) move cells through a fluid environment. Although they have the same diameter as cilia, flagella are often much longer—from $1\text{ }\mu\text{m}$ to several millimeters, though usually in the range of $10\text{--}200\text{ }\mu\text{m}$ —and may be limited to one or a few per cell (Figure 16-6c). Flagella differ from cilia in the nature of their beat. Flagella

move with a propagated bending motion that is usually symmetrical and undulatory and may even have a helical pattern. This type of beat generates a force parallel to the flagellum, such that the cell moves in approximately the same direction as the axis of the flagellum. The locomotory

FIGURE 16-6 Cilia and Flagella. (a) A micrograph of cilia on a mammalian tracheal cell (SEM). (b) The beating of a cilium on the surface of an epithelial cell from the human respiratory tract. A beat begins with a power stroke that sweeps fluid over the cell surface. A recovery stroke follows, leaving the cilium poised for the next beat. Each cycle requires about 0.1–0.2 sec. (c) A micrograph of the flagellated unicellular alga *Euglena* (SEM). (d) Movement of a eukaryotic flagellated cell through an aqueous environment.

VIDEOS www.thecellplace.com Flagellum movement in swimming sperm

pattern of most flagellated cells, such as many sperm cells, involves propulsion of the cell by the trailing flagellum. Examples are also known in which the flagellum actually precedes the cell. Figure 16-6d illustrates this type of swimming movement. The flagella of bacteria (see Figure 5-3) are constructed from an entirely different set of proteins, and their mechanism of movement is completely different. These flagella are fascinating, but we will not consider them further here.

Cilia and Flagella Consist of an Axoneme Connected to a Basal Body

Cilia and flagella share a common structure, known as the **axoneme**, that is about $0.25\text{ }\mu\text{m}$ in diameter. The axoneme is connected to a **basal body** and surrounded by an extension of the cell membrane (**Figure 16-7a**). Between the axoneme and the basal body is a *transition zone* in which the arrangement of microtubules in the basal body takes on the pattern characteristic of the axoneme. Cross-sectional views of the axoneme, transition zone, and basal body are shown in Figure 16-7, parts b through d.

The basal body is identical in appearance to the centriole. A basal body consists of nine sets of tubular structures arranged around its circumference. As we saw in Chapter 15, each set is called a *triplet* because it consists of three tubules that share common walls—one complete microtubule and two incomplete tubules. As a cilium or flagellum forms, a centriole migrates to the cell surface and makes contact with the plasma membrane. The centriole then acts as a nucleation site for MT assembly, initiating polymerization of the nine outer doublets of the axoneme. After the process of tubule assembly has begun, the centriole is then referred to as a basal body.

The axonemes of the cilia used for propulsion and flagella have a characteristic “9 + 2” pattern, with nine **outer doublets** of tubules and two additional microtubules in the center, often called the **central pair**. Another, specialized group of cilia, called *primary cilia*, are used in sensory structures and play an important role in animal embryos during their development. These cilia have a “9 + 0” structure; that is, they lack the central pair.

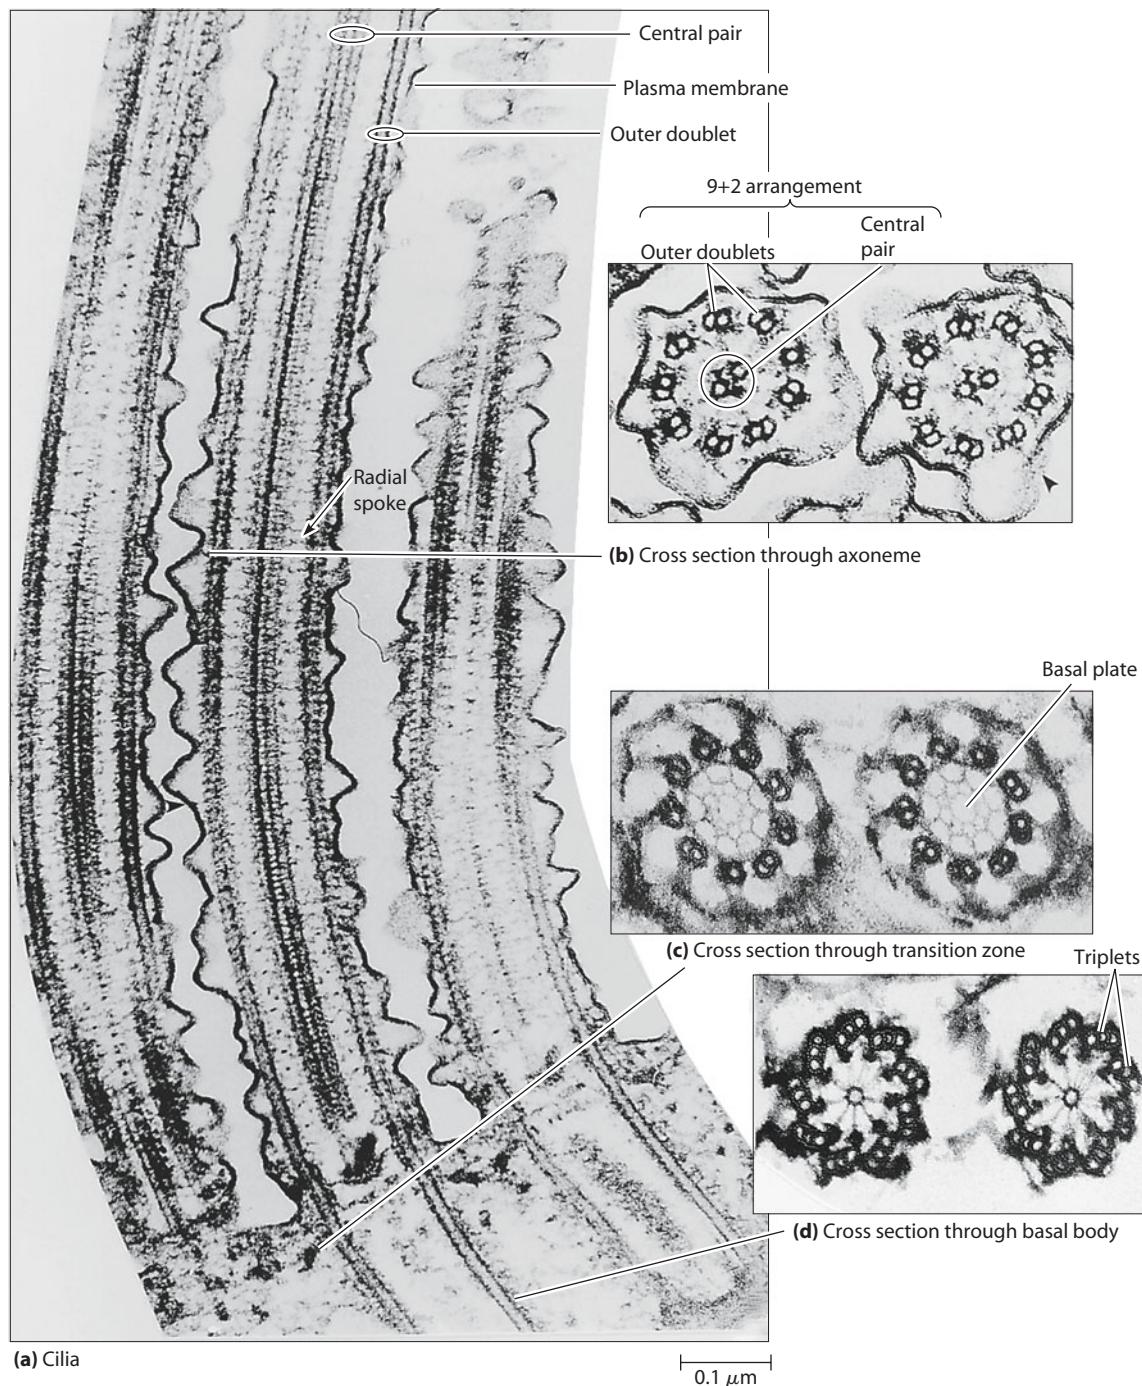

FIGURE 16-7 The Structure of a Cilium. (a) These longitudinal sections of three cilia from the protozoan *Tetrahymena thermophila* illustrate several structural features of cilia, including the central pair and outer doublet microtubules and the radial spokes. Cross-sectional views are shown for (b) axonemes, (c) the transition zone between cilia and basal bodies, and (d) basal bodies. Notice the triplet pattern of the basal body and the “9 + 2” pattern of tubule arrangement in the axoneme of the cilium. (All TEMs.)

 **ACTIVITIES** www.thecellplace.com Cilia and flagella

Defects in these cilia can result in fascinating human syndromes (see **Box 16A**).

Figure 16-8 on p. 458 illustrates these structural features of a typical “9 + 2” cilium in greater detail. The nine outer doublets of the axoneme are thought to be extensions of two of the three subfibers from each of the nine triplets

of the basal body. Each outer doublet of the axoneme therefore consists of one complete MT, called the **A tubule**, and one incomplete MT, the **B tubule** (Figure 16-8b). The A tubule has 13 protofilaments, whereas the B tubule has only 10 or 11. The tubules of the central pair are both complete, with 13 protofilaments each. All of these structures

As it has become easier to isolate genes that are defective in many human genetic disorders, researchers have identified several human disorders that are due to defects in motor proteins. We will discuss two examples: reversal of body symmetry and genetic deafness.

Dyneins, Reversal of the Left-Right Body Axis, and Ciliopathies

In at least 1 in 20,000 live human births, organs in the body cavity are completely reversed left to right. This condition, known as *situs inversus viscerum*, has no medical consequences and is often not recognized until a patient undergoes medical tests for an unrelated condition. In contrast, when only some organs are reversed (*heterotaxia*), serious health complications result. In patients suffering from an autosomal recessive condition known as *Kartagener's triad*, there is a 50% probability of the complete reversal of the left-right location of internal organs. In addition, such patients suffer from male sterility and bronchial problems. The reason for these abnormalities is a defect in the outer dynein arms of cilia and flagella. Studies in mice support the idea that microtubule motor proteins are somehow involved in left-right asymmetry in the developing mammalian embryo. In *inversus viscerum* (*iv*) mutant mice, the internal organs are reversed in half of the newborn homozygotes. Surprisingly, *iv* encodes an axonemal dynein, which is required for the activity of primary cilia ("9 + 0" cilia) that are required for left-right asymmetry. Remarkably, similar cilia have been identified in all vertebrate embryos, and it is thought that they play a similar role in all of these cases. By beating in a rotary fashion, the cilia may create a flow of secreted components that shuttle signaling molecules across the midline of the embryo, or they may serve a sensory function. Current research is aimed at clarifying the role these fascinating cilia play in early embryonic development.

In addition to *situs inversus*, a growing number of human diseases are now known to be due to defects in cilia. These diseases, known as "ciliopathies," include a number of human syndromes, including *Bardet-Biedl syndrome* (BBS) and *polycystic kidney disease* (PKD). BBS is principally characterized by obesity, retinitis pigmentosa (which results in blindness), polydactyly (more than the usual

number of fingers/toes), underdevelopment of the gonads, and mental retardation. At least twelve human genes, when mutated, can give rise to BBS. All of the proteins these genes encode localize to basal bodies or cilia. Analysis of the equivalent genes in the roundworm, *C. elegans*, has shown that BBS proteins are involved in intraflagellar transport, moving material into and along primary cilia. Retinal degeneration in BBS patients results from defects in the *connecting cilium* of rod cells. The connecting cilium carries components to rod outer segments using the same machinery as intraflagellar transport. PKD is characterized by multiple, fluid-filled cysts in the kidneys. An autosomal dominant form of PKD is associated with another protein that in worms has been shown to be involved in intraflagellar transport. How defects in such a protein lead to PKD is still poorly understood.

Myosins and Deafness

Recently, nonmuscle myosins have also been implicated in human genetic disorders. For example, mutations in a myosin VII result in *Usher's syndrome*, an autosomal recessive disorder characterized by congenital profound hearing loss, problems in the vestibular system (i.e., sensing where one is in space), and retinitis pigmentosa. Another type of deafness in humans is caused by recessive mutations in the *myosin XV* gene. The *shaker-2* mouse is a model for this condition: when mice are genetically engineered to carry a functional copy of the *myosin XV* gene, their deafness is rescued. How do defects in myosins lead to deafness? Specialized cells known as *hair cells* are found in the organ of Corti (a specialized structure within the cochlea of the inner ear) and the vestibular system; they contain special actin-rich sensory structures known as *stereocilia* (Figure 16A-1). By sensing movements of fluid within the inner ear, hair cells carry out auditory and vestibular transduction. Myosin VII is concentrated in the cell body of hair cells and in stereocilia; another myosin (myosin IC) is localized to sites where hair cells are connected laterally. Myosin XV is concentrated at the tips of stereocilia. All of these myosins are thought to be involved in linking stereocilia into a mechanically integrated vibration sensor.

contain tubulin, together with a second protein called *tektin*. Tektin is related to intermediate filament proteins (see Chapter 15) and is a necessary component of the axoneme. The A and B tubules share a wall that appears to contain tektin as a major component.

In addition to microtubules, axonemes contain several other key components (Figure 16-8b). The most important of these are the sets of **sidearms** that project out from each of the A tubules of the nine outer doublets. Each sidearm reaches out clockwise toward the B tubules of the adjacent doublet. These arms consist of axonemal dynein, which is responsible for sliding MTs within the axoneme past one

another to bend the axoneme. The dynein arms occur in pairs, one inner arm and one outer arm, spaced along the MT at regular intervals. At less frequent intervals, adjacent doublets are joined by **interdoublet links**. These links are thought to limit the extent to which doublets can move with respect to each other as the axoneme bends.

At regular intervals, **radial spokes** project inward from each of the nine MT doublets, terminating near a set of projections that extend outward from the central pair of microtubules. These spokes are thought to be important in translating the sliding motion of adjacent doublets into the bending motion that characterizes the beating of these

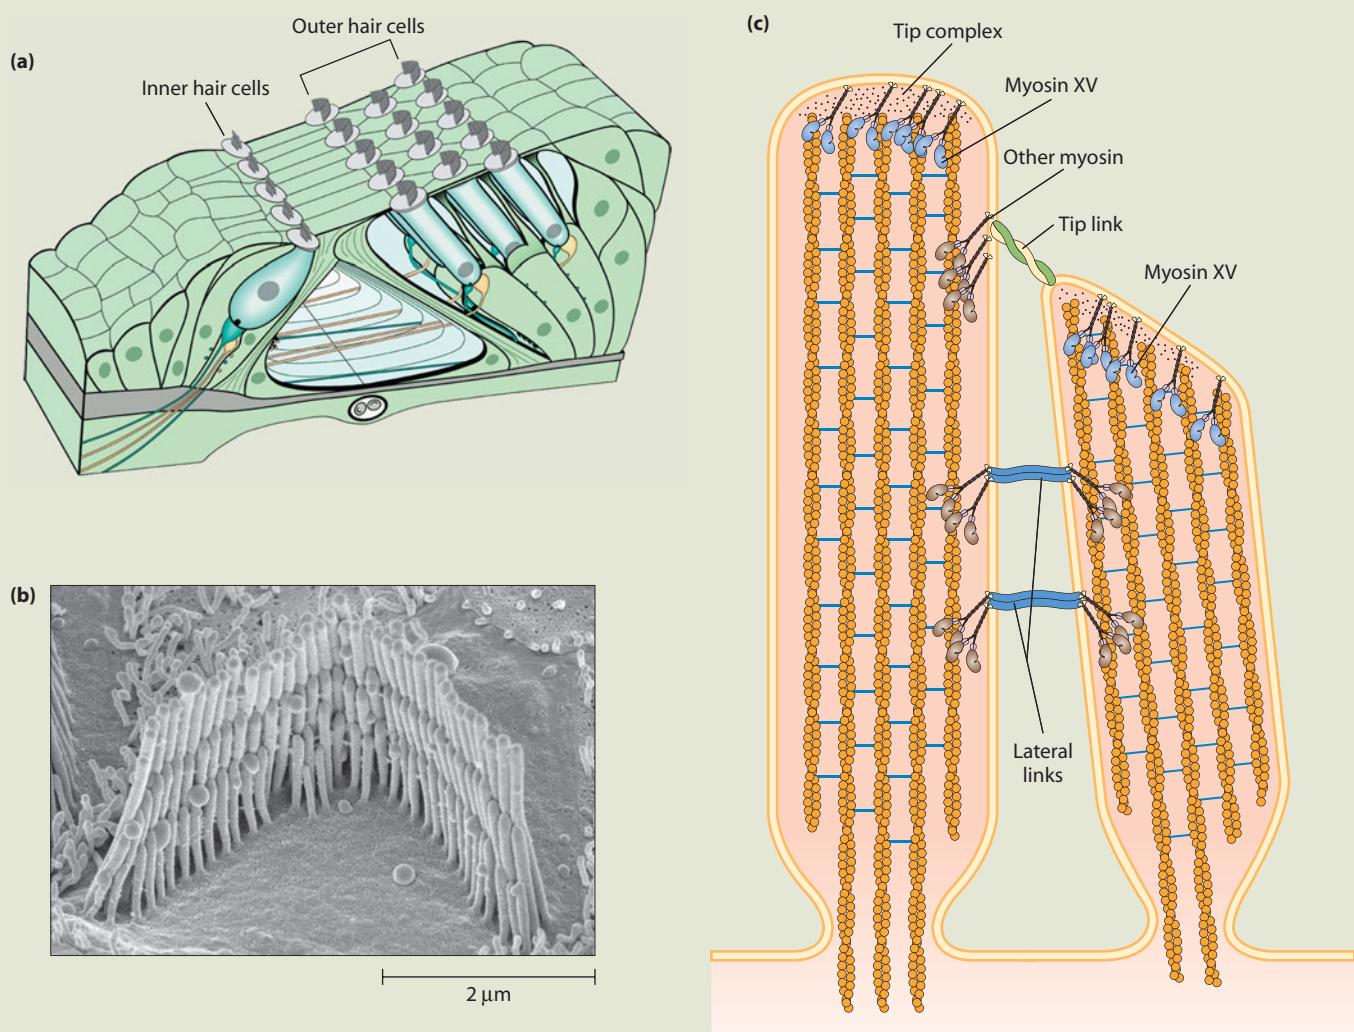

FIGURE 16A-1 Stereocilia and the Inner Ear. (a) Hair cells in the inner ear, including the organ of Corti in the cochlea, contain stereocilia. (b) A scanning electron micrograph of stereocilia in an outer hair cell. (c) Stereocilia are similar to microvilli but are much larger. They sense tiny movements caused by sound vibrations or fluid movement in the semicircular canals. Tip links, which are composed of cell surface proteins similar to cadherins (see Chapter 17), are associated with myosin XV. Lateral links are associated with other types of myosin. Such links connect one stereocilium to the next.

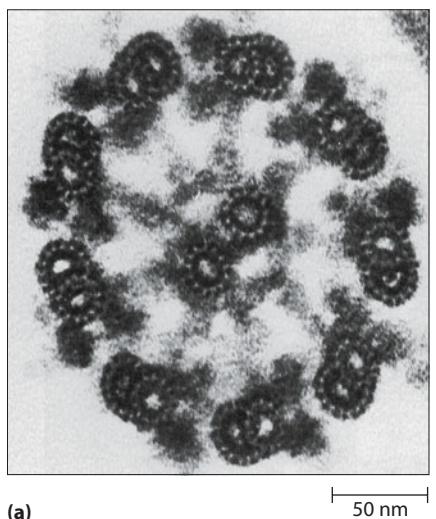

appendages. In addition to the radial spoke attachment to the central pair, a protein called **nexin** links adjacent doublets to one another and probably also plays a role in converting sliding into bending motion.

Microtubule Sliding Within the Axoneme Causes Cilia and Flagella to Bend

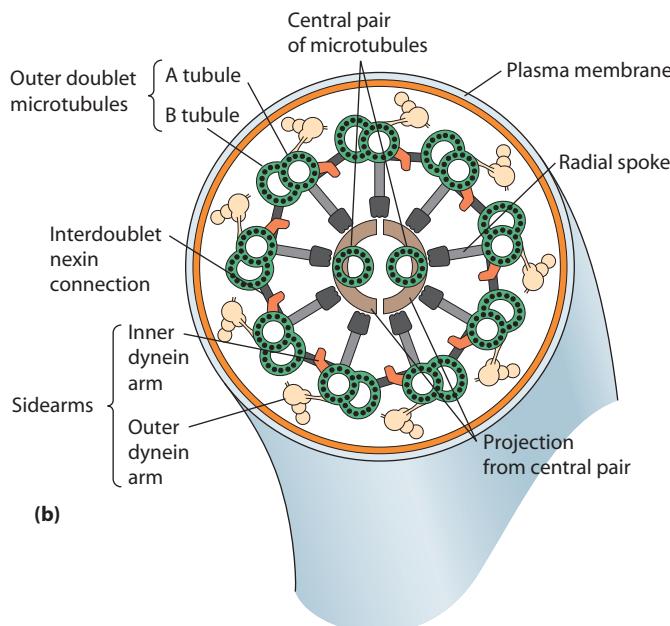

How does axonemal dynein act on this elaborate structure to generate the characteristic bending of cilia and flagella? The overall length of MTs in cilia and flagella does not change. Instead, the microtubules in adjacent outer doublets

slide relative to one another in an ATP-dependent fashion. According to the **sliding-microtubule model** for cilia and flagella, this sliding movement is converted to a localized bending because the doublets of the axoneme are connected radially to the central pair and circumferentially to one another and therefore cannot slide past each other freely. The resultant bending takes the form of a wave that begins at the base of the organelle and proceeds toward the tip.

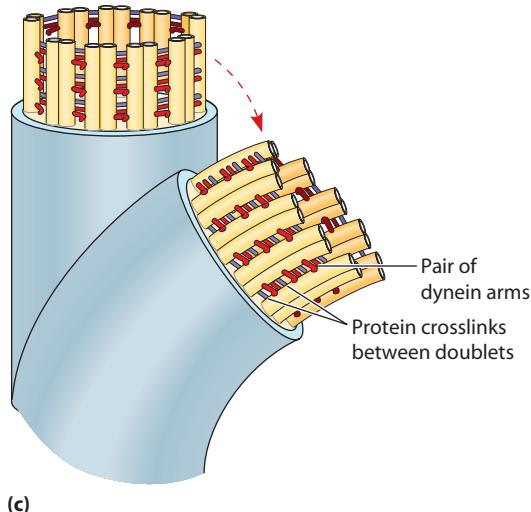

Dynein Arms Are Responsible for Sliding. The driving force for MT sliding is provided by ATP hydrolysis, catalyzed by the dynein arms. The importance of the dynein

(a)

(b)

(c)

FIGURE 16-8 Enlarged Views of an Axoneme.

(a) This micrograph shows an axoneme from a flagellum of *Chlamydomonas* (TEM). (b) Diagram of an axoneme in cross section. The microtubules of the central pair have 13 protofilaments each, as do the A tubules of the outer doublets. Each B tubule has 11 protofilaments of its own and shares 5 protofilaments with the A tubule. The dynein sidearms have ATPase activity and are thought to be responsible for the sliding of adjacent doublets. The interdoublet links (nexin connections) join adjacent doublets, and the radial spokes project inward, terminating near projections that extend outward from the central pair of MTs. (c) Bending of the axoneme by dynein. Connection of the outer doublet MTs to the central pair converts sliding of adjacent MTs into local bending of the axoneme.

arms is indicated by two kinds of evidence. First, when dynein is selectively extracted from isolated axonemes, the arms disappear from the outer doublets, and the axonemes lose both their ability to hydrolyze ATP and their capacity to beat. Furthermore, the effect is reversible: If purified dynein is added to isolated outer doublets, the sidearms reappear, and ATP-dependent sliding is restored.

A second kind of evidence comes from studies of nonmotile mutant flagella in such species as *Chlamydomonas*, a green alga. In some of these mutants, flagella are present but nonfunctional. Depending on the particular mutant, their nonmotile flagella lack dynein arms, radial spokes, or the central pair of microtubules. These structures are therefore essential for flagellar bending.

Axonemal dynein is a very large protein. It has multiple subunits, the three largest having ATPase activity and a molecular weight of about 450,000 each. During the sliding process, the stalk of the dynein arm apparently attaches to and detaches from the B tubule in a cyclic manner. Each cycle requires the hydrolysis of ATP and shifts the dynein

arm of one doublet relative to the adjacent doublet. In this way, the dynein arms of one doublet move the neighboring doublet, resulting in a relative displacement of the two.

Crosslinks and Spokes Are Responsible for Bending.

To convert the dynein-mediated displacement of doublets to a bending motion, the doublets must be restrained in a way that resists sliding but allows deformation. This resistance is provided by the radial spokes that connect the doublets to the central pair of microtubules and possibly also by the nexin crosslinks between doublets (Figure 16-8b, c). If these crosslinks and spokes are removed (by partial digestion with proteolytic enzymes, for example), the resistance that translates doublet sliding into a bending action is absent, and sliding is uncoupled from bending. Under these conditions, the free doublets move with respect to each other, and the axonemes become longer and thinner as the MTs slide apart.

In addition to their role in flagellar and ciliary beating, axonemal dyneins have been implicated in a process that

at first glance seems completely unrelated to its function in sliding microtubules: positioning the internal organs of the body (see Box 16A).

Intraflagellar Transport Adds Components to Growing Flagella. The elaborate structure of flagella and cilia raises an interesting question: How are tubulin subunits and other components added to the growing cilia or flagella? Based on the analysis of mutants in *Chlamydomonas* and nematodes, both plus- and minus-end-directed microtubule motors are involved in shuttling components to and from the tips of flagella. This process, known as **intraflagellar transport (IFT)**, is somewhat analogous to the process of axonal transport in nerve cells: Kinesins move material out to the tips of flagella, and a dynein brings material back toward the base. Several adapter proteins, which form two different major protein complexes, are required to link these motors to IFT particles. Several human disease syndromes are now known to result from mutations in components of these protein complexes (see Box 16A).

Actin-Based Cell Movement: The Myosins

Myosins Are a Large Family of Actin-Based Motors with Diverse Roles in Cell Motility

Movements of molecules and other cellular components also occurs along another major filament system in the cell—the actin cytoskeleton. As with microtubules, ATP-dependent motors exert force on actin microfilaments within cells. These motors are all members of a large superfamily of proteins known as **myosins**. Currently, there are 24 known classes of myosins (for a list of some major types of myosins, see Table 16-1). All myosins have at least one polypeptide chain, called the *heavy chain*, with a globular head group at one end attached to a tail of varying length (Figure 16-9). The globular head binds to actin and uses the energy of ATP hydrolysis to move along an actin filament. Many myosins move toward the plus (barbed) ends of actin filaments. (Myosin VI is a well-studied exception: It moves toward the minus, or pointed, ends of actin filaments.)

The structure of the tail region varies among the different kinds of myosin, giving myosin molecules the ability to bind to various molecules or cell structures. The tail structure also determines the ability of myosins to bind to other identical myosins to form dimers or large arrays. Myosins typically contain small polypeptides bound to the globular head group. These polypeptides, referred to as the *light chains*, often play a role in regulating the activity of the myosin ATPase. Some myosins are unusual in that they have a binding site for actin in their tail region, as well as in the head. In addition, some myosins, such as myosin I and myosin V, appear to bind to membranes, suggesting that these forms of myosin play a role in movement

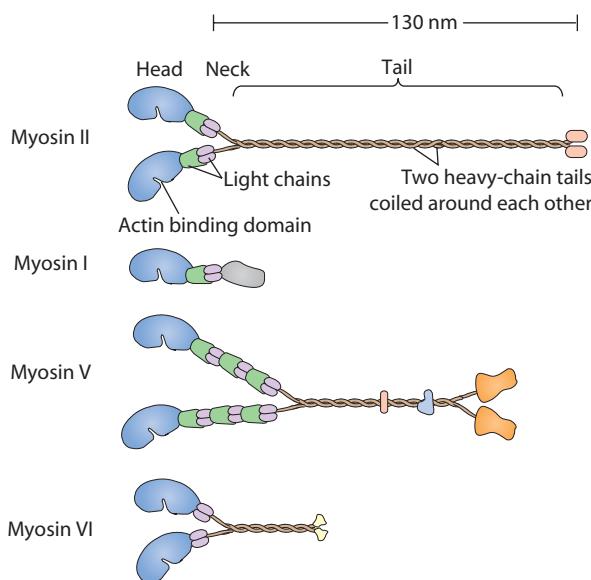

FIGURE 16-9 Myosin Family Members. All myosins have an actin- and ATP-binding heavy-chain “head” and typically have two or more regulatory light chains. Some myosins, like myosin I, have one head. Others, like myosin II, V, and VI, associate via their tails into two-stranded coils.

of the plasma membrane or in transporting membrane-enclosed organelles inside the cell.

Myosins have many functions in events as wide-ranging as muscle contraction (muscle myosin II), cell movement (nonmuscle myosin II), phagocytosis (myosin VI), and vesicle transport or other membrane-associated events (myosins I, V). One unexpected function for myosins is in maintaining the structures required for hearing in humans (see Box 16A).

The best-understood myosins are the **type II myosins**. They are composed of two heavy chains, each featuring a globular myosin head, a hinge region, a long rodlike tail, and four light chains. These myosins are found in skeletal, cardiac (heart), and smooth muscle cells, as well as in non-muscle cells. Type II myosins are distinctive in that they can assemble into long filaments such as the thick filaments of muscle cells. The basic function of myosin II in all cell types is to convert ATP hydrolysis to mechanical force that can cause actin filaments to slide past the myosin molecule, typically resulting in the contraction of a cell or group of cells. For example, in *Drosophila* embryos, analysis of mutants for a nonmuscle type II myosin indicates that it is required for the closure of tissue sheets. Non-muscle type II myosins are also involved in formation of the contractile ring during cytokinesis (see Chapter 19).

Many Myosins Move Along Actin Filaments in Short Steps

Like kinesins, myosins have been studied at the level of single molecules. These studies have shown that the force individual myosin heads exert on actin is similar to that

measured for kinesins. Like kinesin, myosin II is an efficient motor. When myosins must pull against moderate loads, they are about 50% efficient.

It is useful to compare the two best-studied types of cytoskeletal motor proteins, “classic” kinesin and myosin II, because it is now possible to see how they function as biochemical motors at the level of single molecules. Both have two heads that they use to “walk” along a protein filament, and both utilize ATP hydrolysis to change their shape. Despite these similarities, there are profound differences as well. Conventional kinesins operate alone or in small numbers to transport vesicles over large distances, and a single kinesin can move hundreds of nanometers along a single microtubule. In contrast, a single myosin II molecule slides an actin filament about 12–15 nm per power stroke. Not all myosins move such short distances. Myosin V, for example, which is involved in organelle and vesicle transport, is much more processive.

If myosin II cannot move large distances along actin, how can it be involved in movement? Myosin II molecules often operate in large arrays. In the case of myosin II filaments in muscle, these arrays can contain billions of motors working together to mediate contraction of skeletal muscle, the process to which we now turn.

Filament-Based Movement in Muscle

Muscle contraction is the most familiar example of mechanical work mediated by intracellular filaments. Mammals have several kinds of muscles, including skeletal muscle, cardiac muscle, and smooth muscle. We will first consider skeletal muscle because much of our knowledge of the contractile process grew out of early investigations of its molecular structure and function.

Skeletal Muscle Cells Contain Thin and Thick Filaments

Skeletal muscles are responsible for voluntary movement. The structural organization of skeletal muscle is shown in **Figure 16-10**. A muscle consists of bundles of parallel **muscle fibers** joined by tendons to the bones that the muscle must move. Each fiber is actually a long, thin, multinucleate cell that is highly specialized for its contractile function. The multinucleate state arises from the fusion of embryonic cells called *myoblasts* during muscle differentiation to produce a *syncytium*. This cell fusion also accounts at least in part for the striking length of muscle cells, which may be many centimeters in length.

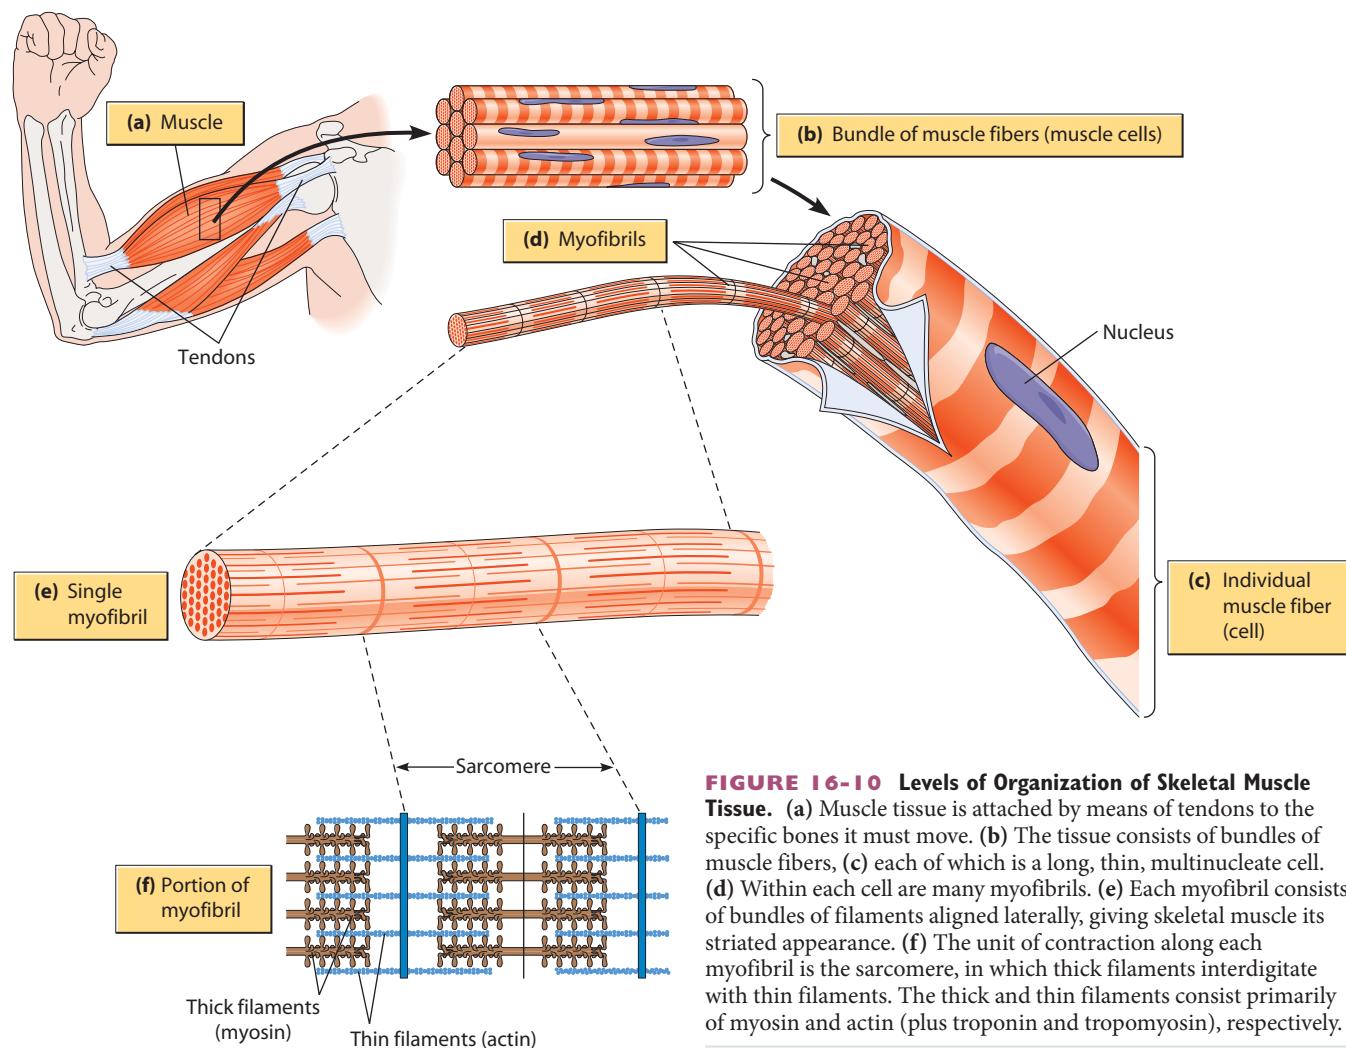

FIGURE 16-10 Levels of Organization of Skeletal Muscle Tissue. (a) Muscle tissue is attached by means of tendons to the specific bones it must move. (b) The tissue consists of bundles of muscle fibers, (c) each of which is a long, thin, multinucleate cell. (d) Within each cell are many myofibrils. (e) Each myofibril consists of bundles of filaments aligned laterally, giving skeletal muscle its striated appearance. (f) The unit of contraction along each myofibril is the sarcomere, in which thick filaments interdigitate with thin filaments. The thick and thin filaments consist primarily of myosin and actin (plus troponin and tropomyosin), respectively.

For muscles to exert force on other tissues, they use specialized structures to attach to other tissues. One such attachment is known as a *costamere*, which we will discuss in more detail in Chapter 17.

At the subcellular level, each muscle fiber (or cell) contains numerous **myofibrils**. Myofibrils are 1–2 μm in diameter and may extend the entire length of the cell. Each myofibril is subdivided along its length into repeating units called **sarcomeres**. The sarcomere is the fundamental contractile unit of the muscle cell. Each sarcomere of the myofibril contains bundles of **thick filaments** and **thin filaments**. Thick filaments consist of myosin, whereas thin filaments consist mainly of actin, tropomyosin, and troponin. The thin filaments are arranged around the thick filaments in a hexagonal pattern, as can be seen when the myofibril is viewed in cross section (Figure 16-11).

The filaments in skeletal muscle are aligned in lateral register, giving the myofibrils a pattern of alternating dark and light bands (Figure 16-12a). This pattern of bands, or *striations*, is characteristic of skeletal and cardiac muscle, which are therefore referred to as **striated muscle**. The dark bands are called **A bands**, and the light bands are called **I bands**. (The terminology for the structure and appearance of muscle myofibrils was developed from observations originally made with the polarizing light microscope. I stands for *isotropic* and A for *anisotropic*,

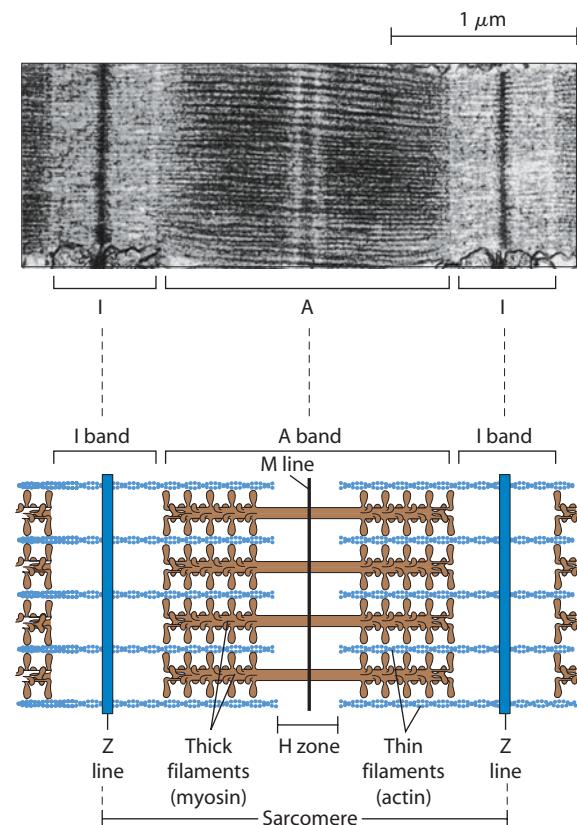

FIGURE 16-12 Appearance of and Nomenclature for Skeletal Muscle. (a) An electron micrograph of a single sarcomere (TEM). (b) A schematic diagram that can be used to interpret the repeating pattern of bands in striated muscle in terms of the interdigititation of thick and thin filaments. An A band corresponds to the length of the thick filaments, and an I band represents the portion of the thin filaments that does not overlap with thick filaments. The lighter area in the center of the A band is called the H zone; the line in the middle is known as the M line. The dense zone in the center of each I band is called the Z line. A sarcomere, the basic repeating unit along the myofibril, is the distance between two successive Z lines.

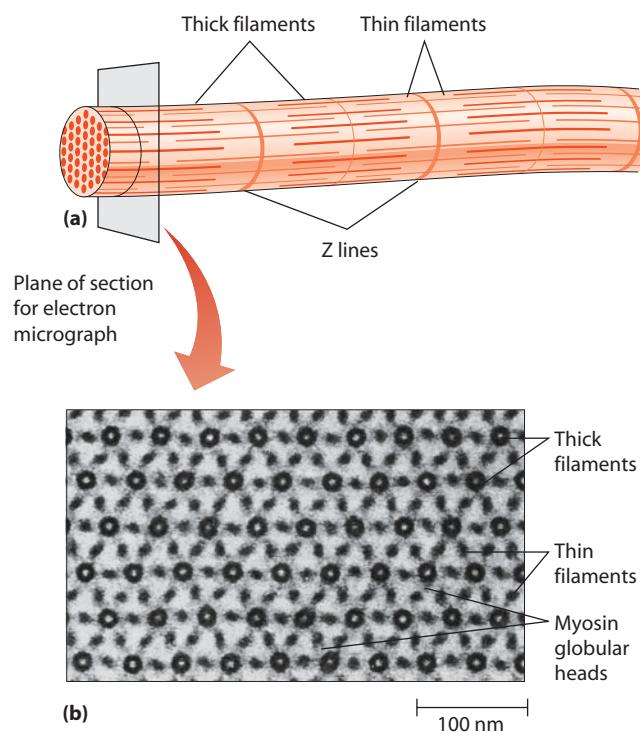

FIGURE 16-11 Arrangement of Thick and Thin Filaments in a Myofibril. (a) A myofibril consists of interdigitated thick and thin filaments. (b) The thin filaments are arranged around the thick filaments in a hexagonal pattern, as seen in this cross section of a fruit fly *Drosophila melanogaster* viewed by high-voltage electron microscopy (HVEM).

terms related to the appearance of these bands when illuminated with plane-polarized light.)

As illustrated in Figure 16-12b, the lighter region in the middle of each A band is called the **H zone** (from the German word *hell*, meaning “light”). Running down the center of the H zone is the **M line**, which contains *myomesin*, a protein that links myosin filaments together. In the middle of each I band appears a dense **Z line** (from the German word *zwischen*, meaning “between”). The distance from one Z line to the next defines a single sarcomere. A sarcomere is about 2.5–3.0 μm long in the relaxed state but shortens progressively as the muscle contracts.

Sarcomeres Contain Ordered Arrays of Actin, Myosin, and Accessory Proteins

The striated pattern of skeletal muscle and the observed shortening of the sarcomeres during contraction are due to the arrangement of thick and thin filaments in myofibrils. We will therefore look in some detail at both types of

filaments and then return to the contraction process in which they play so vital a role.

Thick Filaments. The thick filaments of myofibrils are about 15 nm in diameter and about 1.6 μm long. They lie parallel to one another in the middle of the sarcomere (see Figure 16-12). Each thick filament consists of many molecules of myosin, which are oriented in opposite directions in the two halves of the filament. Each myosin molecule is long and thin, with a molecular weight of about 525,000.

Every thick filament consists of hundreds of myosin molecules organized in a staggered array such that the heads of successive molecules protrude from the thick filament in a repeating pattern, facing away from the center (Figure 16-13). Projecting pairs of heads are spaced 14.3 nm apart along the thick filament, with each pair displaced one-third of the way around the filament from the previous pair. These protruding heads can make contact with adjacent thin filaments, forming the cross-bridges between thick and thin filaments that are essential for muscle contraction.

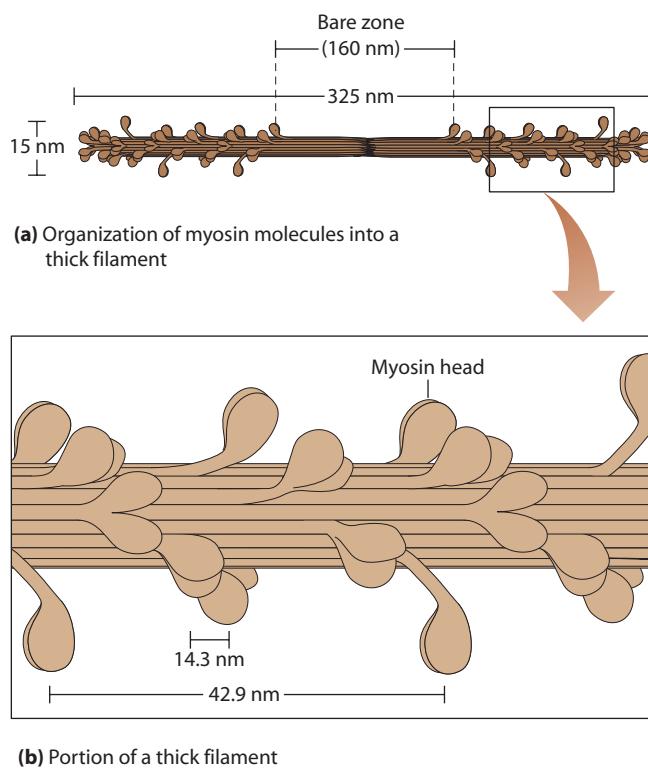

FIGURE 16-13 The Thick Filament of Skeletal Muscle. (a) The thick filament of the myofibril consists of hundreds of myosin molecules organized in a repeating, staggered array. Only a portion of such a thick filament is shown here. A typical thick filament is about 1.6 μm long and about 15 nm in diameter. Individual myosin molecules are integrated into the filament longitudinally, with their ATPase-containing heads oriented away from the center of the filament. The central region of the filament is therefore a bare zone containing no heads. (b) This enlargement of a portion of the thick filament shows that pairs of myosin heads are spaced 14.3 nm apart.

Thin Filaments. The thin filaments of myofibrils interdigitate with the thick filaments. The thin filaments are about 7 nm in diameter and about 1 μm long. Each I band consists of two sets of thin filaments, one set on either side of the Z line, with each filament attached to the Z line and extending toward and into the A band in the center of the sarcomere. This accounts for the length of almost 2 μm for I bands in extended muscle.

The structure of thin filaments is shown in Figure 16-14. A thin filament consists of at least three proteins. The most important component of thin filaments is F-actin, intertwined with the proteins **tropomyosin** and **troponin**. Tropomyosin is a long, rodlike molecule, similar to the myosin tail, that fits in the groove of the actin helix. Each tropomyosin molecule stretches for about 38.5 nm along the filament and associates along its length with seven actin monomers.

Troponin is actually a complex of three polypeptide chains, called *TnT*, *TnC*, and *TnI*. *TnT* binds to tropomyosin and is thought to be responsible for positioning the complex on the tropomyosin molecule. *TnC* binds calcium ions, and *TnI* binds to actin. (*Tn* stands for troponin, *T* for tropomyosin, *C* for calcium, and *I* for inhibitory, because *TnI* inhibits muscle contraction.) One troponin complex is associated with each tropomyosin molecule, so the spacing between successive troponin complexes along the thin filament is 38.5 nm. Troponin and tropomyosin constitute a calcium-sensitive switch that activates contraction in both skeletal and cardiac muscle.

Organization of Muscle Filament Proteins. How can the filamentous proteins of muscle fibers maintain such a precise organization when the microfilaments in other cells are relatively disorganized? First, the actin in the thin filaments is oriented such that all of the plus (barbed) ends are anchored at Z lines. Since myosin II moves toward the plus end of F-actin, this guarantees that the thick filaments will move toward the Z lines. Second, structural proteins play a central role in maintaining the architectural relationships of

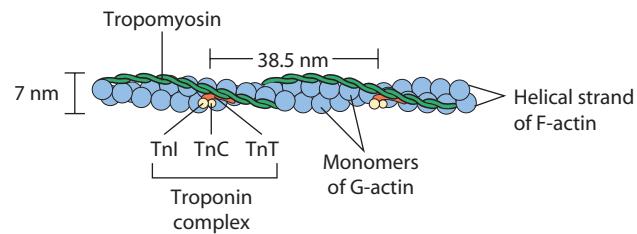

FIGURE 16-14 The Thin Filament of Striated Muscle. Each thin filament is a single strand of F-actin in which the G-actin monomers are staggered and give the appearance of a double-stranded helix. One result of this arrangement is that two grooves run along both sides of the filament. Long, ribbonlike molecules of tropomyosin lie in these grooves. Each tropomyosin molecule consists of two α helices wound about each other to form a ribbon about 2 nm in diameter and 38.5 nm long. Associated with each tropomyosin molecule is a troponin complex consisting of the three polypeptides *TnT*, *TnC*, and *TnI*.

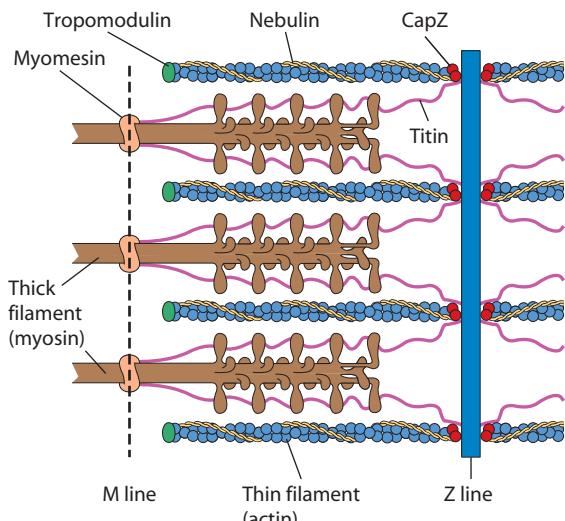

FIGURE 16-15 Structural Proteins of the Sarcomere. The thick and thin filaments require structural support to maintain their precise organization in the sarcomere. The support is provided by two proteins, α -actinin and myomesin, which bundle actin and myosin filaments, respectively. Titin attaches thick filaments to the Z line, thereby maintaining their position within the thin filament array. Nebulin stabilizes the organization of thin filaments. For clarity, tropomyosin is not shown.

muscle proteins (Figure 16-15). For instance, α -actinin keeps actin filaments bundled into parallel arrays. The capping protein, CapZ, maintains the attachment of the barbed (plus) ends of actin filaments to the Z line and simultaneously caps the actin in the thin filaments. At the other end of the thin filaments is *tropomodulin*, which helps to maintain the length and stability of thin filaments by binding their pointed (minus) ends. *Myomesin* is present at the H zone of the thick filament arrays and bundles the myosin molecules composing the arrays. A third structural protein, *titin*, attaches the thick filaments to the Z lines. Titin is highly flexible. During contraction-relaxation cycles, it can keep thick filaments in the correct position relative to thin filaments. This titin scaffolding also keeps the thick and

thin filament arrays from being pulled apart when a muscle is stretched. Another protein, *nebulin*, stabilizes the organization of thin filaments. The protein components involved in muscle contraction are summarized in Table 16-2. The contractile process involves the complex interaction of all these proteins.

The Sliding-Filament Model Explains Muscle Contraction

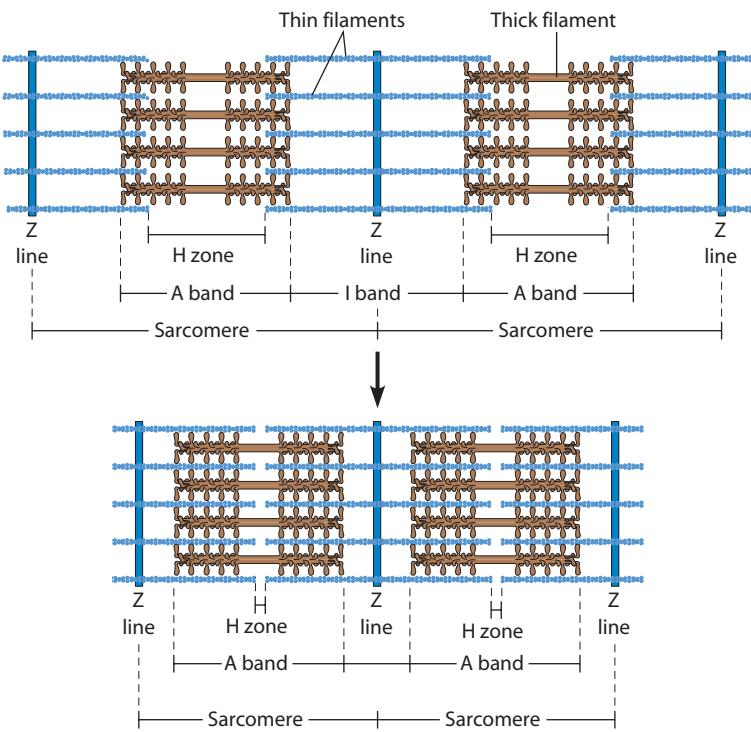

With our understanding of muscle structure, we can now consider what happens during the contraction process. Based on electron microscopic studies, it is clear that the A bands of the myofibrils remain fixed in length during contraction, whereas the I bands shorten progressively and virtually disappear in the fully contracted state. To explain these observations, the **sliding-filament model** illustrated in Figure 16-16 was proposed in 1954 independently by Andrew Huxley and Rolf Niedergerke and by Hugh Huxley and Jean Hanson. According to this model, muscle contraction is due to thin filaments sliding past thick filaments, with no change in the length of either type of filament. The sliding-filament model not only proved to be correct but was instrumental in focusing attention on the molecular interactions between thick and thin filaments that underlie the sliding process.

As Figure 16-16a indicates, contraction involves the sliding of thin filaments such that they are drawn progressively into the spaces between adjacent thick filaments, overlapping more and more with the thick filaments and narrowing the I band in the process. The result is a shortening of the individual sarcomeres and myofibrils and a contraction of the muscle cell and the whole tissue. This, in turn, causes the movement of the body parts attached to the muscle.

The sliding of the thin and thick filaments past each other as a means of generating force suggests that there should be a relationship between the force generated during contraction and the degree of shortening of the sarcomere. In fact, when the relationship between shortening and

Table 16-2 Major Protein Components of Vertebrate Skeletal Muscle

Protein	Molecular Weight	Function
Actin	42,000	Major component of thin filaments
Myosin	510,000	Major component of thick filaments
Tropomyosin	64,000	Binds along the length of thin filaments
Troponin	78,000	Positioned at regular intervals along thin filaments; mediates calcium regulation of contraction
Titin	2,500,000	Links thick filaments to Z line
Nebulin	700,000	Links thin filaments to Z line; stabilizes thin filaments
Myomesin	185,000	Myosin-binding protein present at the M line of thick filaments
α -actinin	190,000	Bundles actin filaments and attaches them to Z line
Ca^{2+} ATPase	115,000	Major protein of sarcoplasmic reticulum (SR); transports Ca^{2+} into SR to relax muscle
CapZ	68,000	Attaches actin filaments to Z line; caps actin
Tropomodulin	41,000	Maintains thin filament length and stability

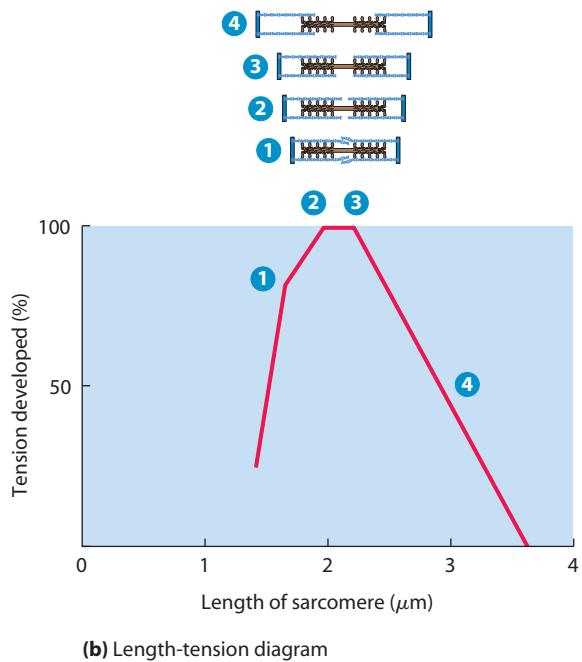

(a) Sliding filament model

FIGURE 16-16 The Sliding-Filament Model of Muscle Contraction. (a) Two sarcomeres of a myofibril during the contraction process. The extended configuration is shown at the top, while the bottom view represents a more contracted myofibril. A myofibril shortens by the progressive sliding of thick and thin filaments past each other. The result is a greater interdigitation of filaments with no change in length of individual filaments. The increasing overlap of thick and thin filaments leads to a progressive decrease in the length of the I band as interpenetration continues during contraction. (b) This graph shows that the amount of tension developed by the sarcomere is proportional to the amount of overlap between the thin filament and the region of the thick filament containing myosin heads. When the sarcomere begins to shorten, as during a muscle contraction, the Z lines move closer together, increasing the amount of overlap between thin and thick filaments. This overlap allows more of the thick filament to interact with the thin filament. Therefore, the muscle can develop more tension (see ④ to ③). This proportional relationship continues until the ends of the thin filaments move into the H zone. Here they encounter no further myosin heads, so tension remains constant (③ to ②). Any further shortening of the sarcomere results in a dramatic decline in tension (② to ①) as the filaments crowd into one another.

force is measured, it is exactly what the sliding-filament model predicts (Figure 16-16b): The amount of force the muscle can generate during a contraction depends on the number of myosin heads from the thick filament that can make contact with the thin filament. When the sarcomere is stretched, there is relatively little overlap between thin and thick filaments, so the force generated is small. As the sarcomere shortens, the region of overlap increases and the force of contraction increases. Finally, a point is reached at which continued shortening no longer increases the amount of overlap between thin and thick filaments, and the force of contraction stays the same. Any further shortening of the sarcomere results in a dramatic decline in tension as the filaments crowd into one another.

The sliding of thin filaments past thick filaments depends on the elaborate structural features of the sarcomere, and it requires energy. These basic observations raise important questions. First, by what mechanism are the thin filaments pulled progressively into the spaces between thick filaments to cause contraction? Second, how is the energy of ATP used to drive this process? These questions are answered in the next section.

(b) Length-tension diagram

Cross-Bridges Hold Filaments Together, and ATP Powers Their Movement

Cross-Bridge Formation. Regions of overlap between thick and thin filaments, whether extensive (in contracted muscle) or minimal (in relaxed muscle), are always characterized by the presence of transient **cross-bridges**. The cross-bridges are formed from links between the F-actin of the thin filaments and the myosin heads of the thick filaments (Figure 16-17). For contraction, the cross-bridges must form and dissociate repeatedly, so that each cycle of cross-bridge formation causes the thin filaments to interdigitate with the thick filaments more and more, thereby shortening the individual sarcomeres and causing the muscle fiber to contract. A given myosin head on the thick filament thus undergoes a cycle of events in which it binds to specific actin subunits on the thin filament, undergoes an energy-requiring change in shape that pulls the thin filament, and then breaks its association with the thin filament and associates with another site farther along the thin filament toward the Z line. Muscle contraction is the net result of the repeated making and breaking of many such

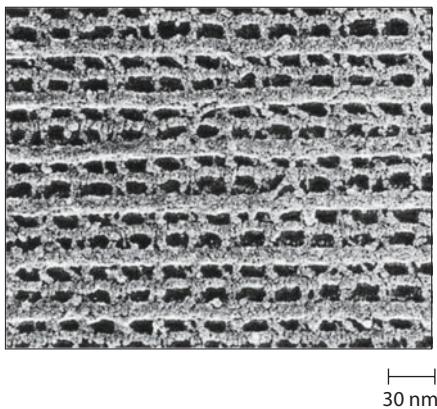

FIGURE 16-17 Cross-Bridges. The cross-bridges between thick and thin filaments formed by the projecting heads of myosin molecules can be readily seen in this high-resolution electron micrograph (TEM). 30 nm

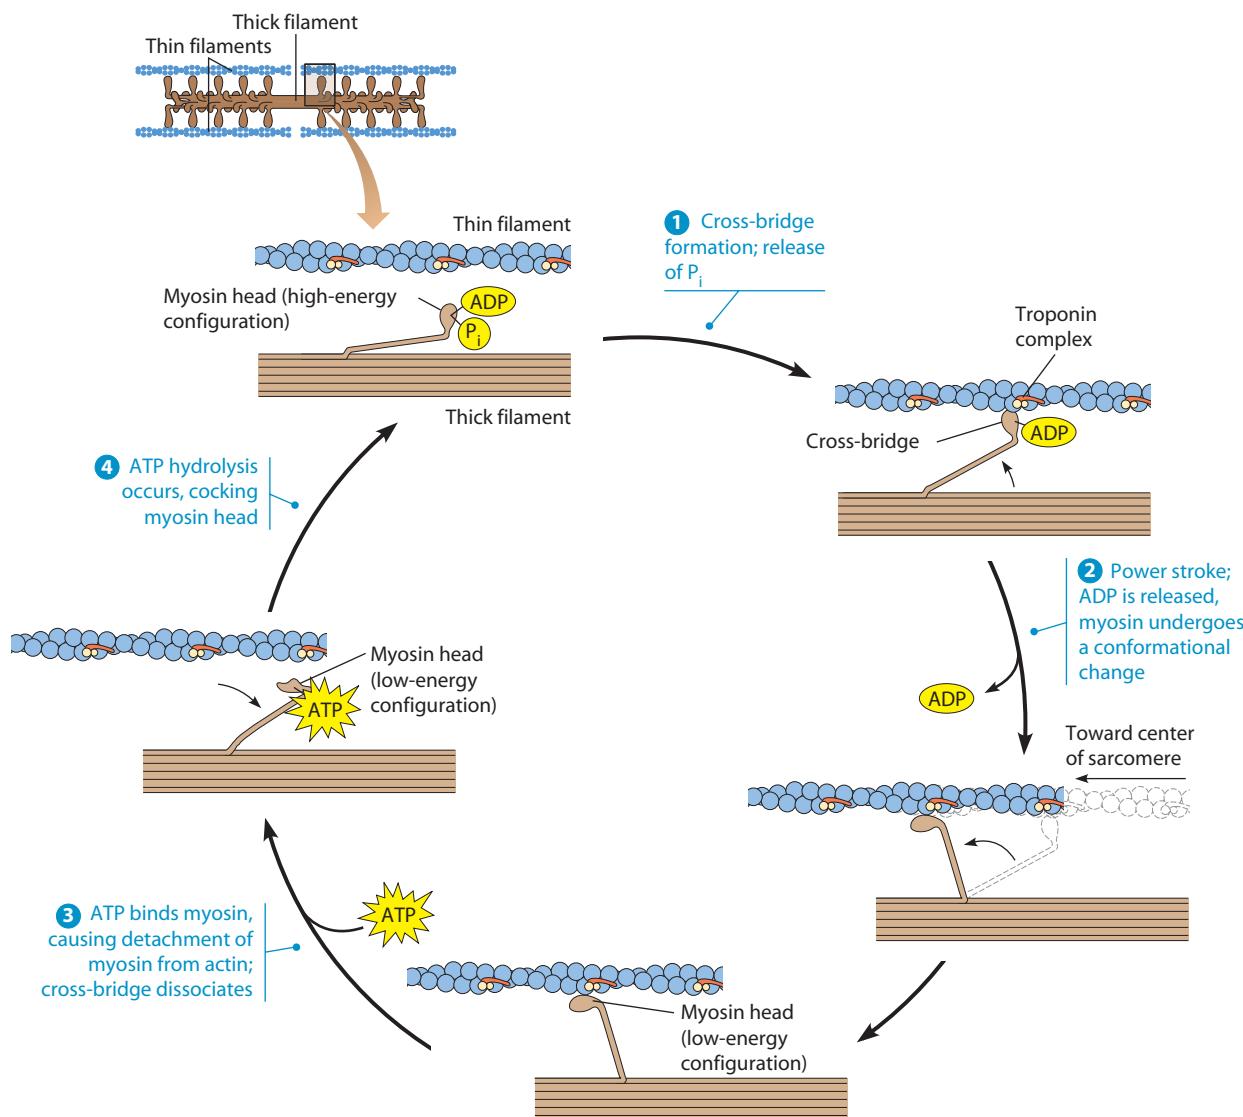

FIGURE 16-18 The Cyclic Process of Muscle Contraction. A small segment of adjacent thick and thin filaments (see the orienting inset at upper left) is used to illustrate the series of events in which the cross-bridge formed by a myosin head draws the thin filament toward the center of the sarcomere, thereby causing the myofibril to contract. Step ① shows the cross-bridge configuration of relaxed muscle, whereas the end of step ② shows the configuration of a muscle in rigor. A detailed description of all steps is given in the text.

cross-bridges, with each cycle of cross-bridge formation causing the translocation of a small length of thin filament of a single fibril in a single cell.

ATP and the Contraction Cycle. The driving force for cross-bridge formation is the hydrolysis of ATP, catalyzed by the myosin heads. The requirement for ATP can be demonstrated *in vitro* because isolated muscle fibers contract in response to added ATP.

The mechanism of muscle contraction is depicted in **Figure 16-18** as a four-step cycle. In the high-energy configuration containing an ADP and a P_i molecule (a hydrolyzed ATP, in effect) shown in step ①, a specific myosin head binds loosely to the actin filament. The myosin head then proceeds to a more tightly bound configuration that requires the loss of P_i . Step ② is the power stroke. The transition of myosin to the more tightly bound

state triggers a conformational change in myosin, which is associated with release of ADP. This conformational change is associated with a movement of the head, causing the thick filament to pull against the thin filament, which then moves with respect to the thick filament.

Cross-bridge dissociation follows in step ③, as ATP binds to the myosin head in preparation for the next step. The binding of ATP causes the myosin head to change its conformation in a way that weakens its binding to actin. In the absence of adequate ATP, cross-bridge dissociation does not occur, and the muscle becomes locked in a stiff, rigid state called *rigor*. The *rigor mortis* associated with death results from the depletion of ATP and the progressive accumulation of cross-bridges in the configuration shown at the end of step ②. Note that, once detached, the thick and thin filaments would be free to slip back to their previous positions, but they are held together at all times by the many other cross-bridges along their length at any given moment—just as at least some legs of a millipede are always in contact with the surface it is walking on. In fact, each thick filament has about 350 myosin heads, and each head attaches and detaches about five times per second during rapid contraction, so there are always many cross-bridges intact at any time.

Finally, in step ④, ATP hydrolysis is used to return the myosin head to the high-energy configuration necessary for the next round of cross-bridge formation and filament sliding. This brings us back to where we started because the myosin head is now activated and ready to form a new cross-bridge. But the new bridge will be formed with actin farther along the thin filament because the first cycle resulted in a net displacement of the thin filament with respect to the thick filament. In succeeding cycles, the particular myosin head shown in Figure 16-18 will draw the thin filament in the direction of further contraction. And what about the direction of contraction? Recall that the actin in thin filaments is uniformly oriented, with plus ends anchored at Z lines. Myosin II always walks toward the *plus* end of the thin filament, thereby establishing the direction of contraction.

The Regulation of Muscle Contraction Depends on Calcium

So far, our description of muscle contraction implies that skeletal muscle ought to contract continuously, as long as there is sufficient ATP. Yet experience tells us that most skeletal muscles spend more time in the relaxed state than in contraction. Contraction and relaxation must therefore be regulated to result in the coordinated movements associated with muscle activity.

The Role of Calcium in Contraction. Regulation of muscle contraction depends on free calcium ions (Ca^{2+}) and on the muscle cell's ability to rapidly raise and lower calcium levels in the cytosol (called the *sarcoplasm* in muscle cells) around the myofibrils. The regulatory

proteins *tropomyosin* and *troponin* act in concert to regulate the availability of myosin-binding sites on actin filaments in a way that depends critically on the level of calcium in the sarcoplasm.

To understand how this process works, we must first recognize that the myosin-binding sites on actin are normally blocked by tropomyosin. For myosin to bind to actin and initiate the cross-bridge cycle, the tropomyosin molecule must be moved out of the way. The calcium dependence of muscle contraction is due to troponin C (TnC), which binds calcium ions. When a calcium ion binds to TnC, it undergoes a conformational change that is transmitted to the tropomyosin molecule, causing it to move toward the center of the helical groove of the thin filament, out of the blocking position. The binding sites on actin are then accessible to the myosin heads, allowing contraction to proceed.

Figure 16-19 illustrates how the troponin-tropomyosin complex regulates the interaction between actin and myosin. When the calcium concentration in the sarcoplasm is low ($<0.1 \mu\text{M}$), tropomyosin blocks the binding sites on the actin filament, effectively preventing their interaction with myosin (Figure 16-19a). As a result, cross-bridge formation is inhibited, and the muscle becomes or remains relaxed. At higher calcium concentrations ($>1 \mu\text{M}$), calcium binds to TnC, causing tropomyosin molecules to shift their position, which allows myosin heads to make contact with the binding sites on the actin filament and thereby initiate contraction (Figure 16-19b).

When the calcium concentration falls again as it is pumped out of the cytosol (discussed next), the troponin-calcium complex dissociates, and the tropomyosin moves

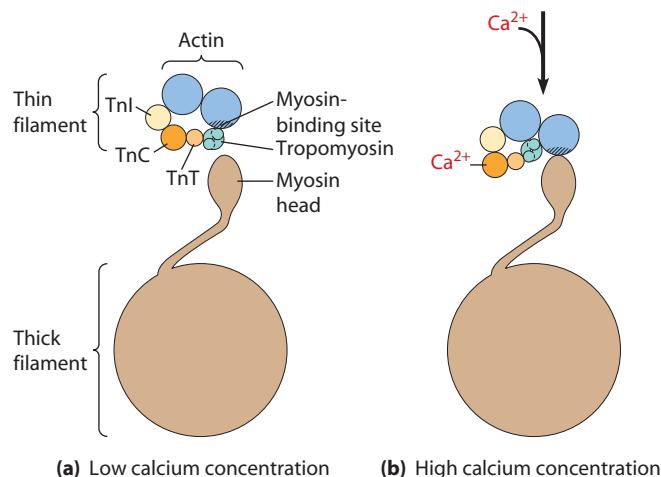

FIGURE 16-19 Regulation of Contraction in Striated Muscle. (a) At low concentrations ($<0.1 \mu\text{M} \text{ Ca}^{2+}$), calcium is not bound to the TnC subunit of troponin, and tropomyosin blocks the binding sites on actin, preventing access by myosin and thereby maintaining the muscle in the relaxed state. (b) At high concentrations ($>1 \mu\text{M} \text{ Ca}^{2+}$), calcium binds to the TnC subunit of troponin, inducing a conformational change that is transmitted to tropomyosin. The tropomyosin molecule moves toward the center of the groove in the thin filament, allowing myosin to gain access to the binding sites on actin and thereby triggering contraction.

back to the blocking position. Myosin binding is therefore inhibited, further cross-bridge formation is prevented, and the contraction cycle ends.

Regulation of Calcium Levels in Skeletal Muscle Cells.

From the previous discussion, we know that muscle contraction is regulated by the concentration of calcium ions in the sarcoplasm. But how is the level of calcium controlled? Think for a moment about what must happen when we move any part of our bodies—when we flex an index finger, for instance. A nerve impulse is generated in the brain and transmitted down the spinal column to the nerve cells, or *motor neurons*, that control a small muscle in the forearm. The motor neurons activate the appropriate muscle cells, which contract and relax, all within about 100 msec. When nerve impulses to the muscle cell cease, calcium levels decline quickly, and the muscle relaxes. Therefore, to understand how muscle contraction is regulated, we need to know how nerve impulses cause calcium levels in the sarcoplasm to change and how these changes affect the contractile machinery. Muscle cells have many specialized features that facilitate a rapid change in the sarcoplasmic concentration of calcium ions and a rapid response of the contractile machinery. We discuss these features next.

Events at the Neuromuscular Junction. Recall from Chapter 13 that the signal for a muscle cell to contract is conveyed by a nerve cell in the form of an electrical impulse called an *action potential*. The site where the nerve innervates, or makes contact with, the muscle cell is called the **neuromuscular junction**. At the neuromuscular junction, the axon branches out and forms *axon terminals* that make contact with the muscle cell. These terminals contain the transmitter chemical *acetylcholine*, which is stored in membrane-enclosed vesicles and secreted by axon terminals

in response to an action potential. The area of the muscle cell plasma membrane under the axon terminals is called the *motor end plate*. There, in the plasma membrane (called the *sarcolemma* in muscle cells), clusters of acetylcholine receptors are associated with each axon terminal. When the receptor binds acetylcholine, it opens a pore in the plasma membrane through which sodium ions can flow into the muscle cell. The sodium influx in turn causes a membrane depolarization to be transmitted away from the sarcolemma at the motor end plate.

Transmission of an Impulse to the Interior of the Muscle.

Once a membrane depolarization occurs at the motor end plate, it spreads throughout the sarcolemma via the **transverse (T) tubule system** (Figure 16-20), a series of regular invaginations of the muscle membrane that penetrates the interior of a muscle cell. The T tubules carry action potentials into the muscle cell, and they are part of the reason that muscle cells can respond so quickly to a nerve impulse.

Inside the muscle cell, the T tubule system comes into contact with the **sarcoplasmic reticulum (SR)**, a system of intracellular membranes in the form of flattened sacs or tubes. As the name suggests, the SR is similar to the endoplasmic reticulum (ER) found in nonmuscle cells except that it is highly specialized. The SR runs along the myofibrils, where it is poised to release calcium ions directly into the myofibril and cause contraction and then to remove calcium from the myofibril and cause relaxation. This close proximity of the SR to the myofibrils facilitates the rapid response of muscle cells to nerve signals.

SR Function in Calcium Release and Uptake. The SR can be functionally divided into two components, referred to as the *medial element* and the *terminal cisternae* (singular: *terminal cisterna*; see Figure 16-20). The terminal

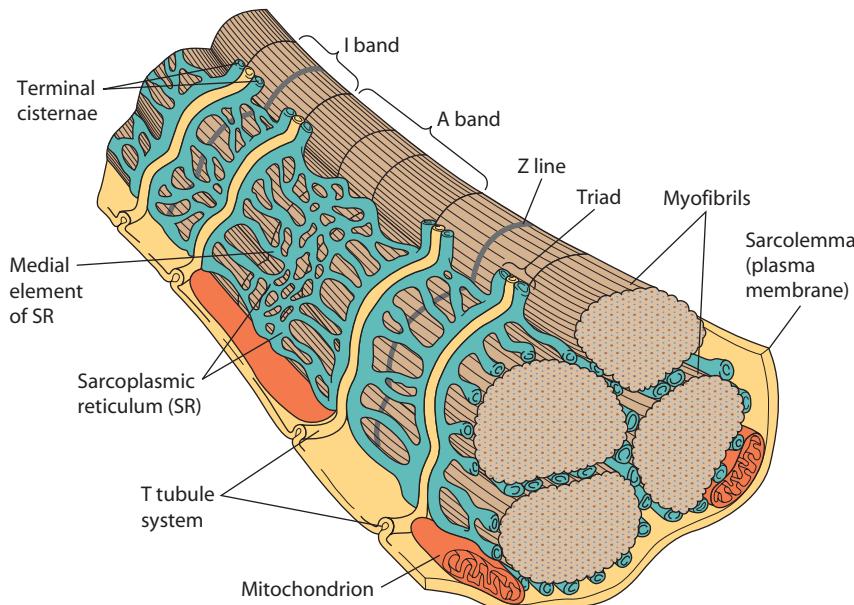

FIGURE 16-20 The Sarcoplasmic Reticulum and the Transverse Tubule System of Skeletal Muscle Cells. The sarcoplasmic reticulum (SR) is an extensive network of specialized ER that accumulates calcium ions and releases them in response to nerve signals. T tubules are invaginations of the sarcolemma (plasma membrane) that relay the membrane potential changes to the interior of the cell. Where the T tubule passes near the terminal cisternae of the SR, a triad structure is formed that appears in electron micrographs as the cross section of three adjacent tubes. The T tubule is in the middle, and on each side is one of the SR terminal cisternae. The triad contains the important junctional complex that regulates the release of calcium ions from the SR.

cisternae of the SR contain a high concentration of ATP-dependent calcium pumps that continually pump calcium into the lumen of the SR. The ability of the SR to pump calcium ions is crucial for muscle relaxation, but it is also needed for muscle contraction. Calcium pumping produces a high calcium concentration in the lumen of the SR (up to several millimolar). This calcium can then be released from the terminal cisternae of the SR when needed. Figure 16-20 shows how the terminal cisternae of the SR are positioned adjacent to the contractile apparatus of each myofibril. Terminal cisternae are typically found right next to a T tubule, giving rise to a structure called a **triad**. In electron micrographs, a triad appears as three circles in a row. The central circle is the membrane of the T tubule, and the circles on each side are the membranes of the terminal cisternae. Close inspection of the triad reveals that the terminal cisternae appear to be connected to the T tubule by material between the two membranes. This material is referred to as the *junctional complex* (to which we will return shortly).

The proximity of the T tubule, the terminal cisternae of the SR, and the contractile machinery of the myofibril provides the basis for how muscle cells can respond so rapidly to a nerve impulse. The action potential travels from the motor end plate, spreads out over the sarcolemma, and enters the T tubule (Figure 16-21). As the action potential travels down the T tubule, it activates voltage-gated calcium channels in the T tubule that are adjacent to ryanodine receptors in the terminal cisternae of the SR, causing them to open (see Figure 14-12). When the ryanodine receptor channels open, calcium rushes into the sarcoplasm immediately adjacent to the myofibrils, causing contraction.

Letting calcium out of the SR causes a muscle cell to contract. For the muscle cell to relax, calcium levels must be brought back down to the resting level. This is accom-

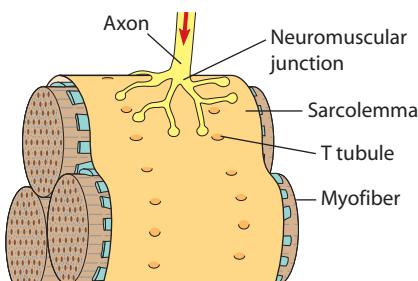

plished by pumping calcium back into the SR. The membrane of the SR contains an active transport protein, a **calcium ATPase**, which can pump calcium ions from the sarcoplasm into the cisternae of the SR. These pumps are concentrated in the medial element of the SR. The ATP-dependent mechanism by which calcium moves through the pump is similar to that discussed in Chapter 8 for the Na^+/K^+ pump (see Figure 8-11).

The pumping of calcium from the sarcoplasm back into the SR cisternae quickly lowers the sarcoplasmic calcium level to the point at which troponin releases calcium, tropomyosin moves back to the blocking position on actin, and further cross-bridge formation is prevented. Cross-bridges therefore disappear rapidly as actin dissociates from myosin and becomes blocked by tropomyosin. This leaves the muscle relaxed and free to be re-extended because the absence of cross-bridge contacts allows the thin filaments to slide out from between the thick filaments, due to passive stretching of the muscle by other tissues.

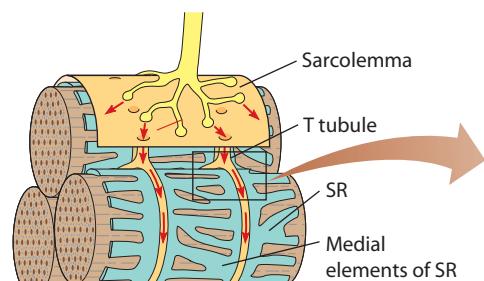

The Coordinated Contraction of Cardiac Muscle Cells Involves Electrical Coupling

Cardiac (heart) muscle is responsible for the beating of the heart and the pumping of blood through the body's circulatory system. Cardiac muscle functions continuously. In one year, your heart beats about 40 million times! Cardiac muscle is very similar to skeletal muscle in the organization of actin and myosin filaments and has the same striated appearance (Figure 16-22). In contrast to skeletal muscle, most of the energy required for the beating of the heart under resting conditions is provided not by blood glucose but by free fatty acids that are transported from adipose (fat storage) tissue to the heart by serum albumin, a blood protein.

- 1 An action potential moves down the axon of the neuron until it reaches the neuromuscular junction, where synapses exist between the neuron and the muscle cell.

- 2 Depolarization of the terminals of the axon causes the release of neurotransmitters, which bind acetylcholine receptors on the surface of the muscle cell, initiating depolarization of the muscle cell.

- 3 The depolarization spreads into the interior via the T tubules, stimulating calcium release via ryanodine receptors in the terminal cisternae of the SR.

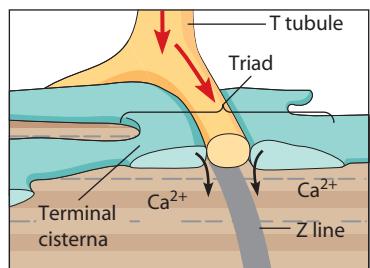

FIGURE 16-21 Stimulation of a Muscle Cell by a Nerve Impulse. The nerve causes a depolarization of the muscle cell, which spreads into the interior via the T tubule system, stimulating calcium release from the terminal cisternae of the sarcoplasmic reticulum (SR).

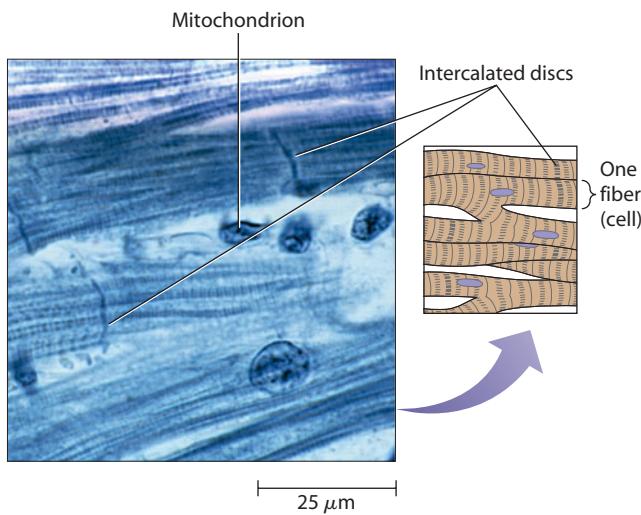

FIGURE 16-22 Cardiac Muscle Cells. Cardiac muscle cells have a contractile mechanism and sarcomeric structure similar to those of skeletal muscle cells. However, unlike skeletal muscle cells, cardiac muscle cells are joined together end to end at intercalated discs, which allow ions and electrical signals to pass from one cell to the next. This ionic permeability enables a contraction stimulus to spread evenly to all the cells of the heart (LM).

 [VIDEOS www.thecellplace.com](http://www.thecellplace.com) Cardiac muscle contraction

A second difference between cardiac and skeletal muscle is that heart muscle cells are not multinucleate. Instead, cells are joined end to end through structures called **intercalated discs**. The discs have a high density of desmosomes and gap junctions (see Chapter 17); the gap junctions electrically couple neighboring cells, allowing depolarization waves to spread throughout the heart during its contraction cycle. The heart is not activated by nerve impulses, as skeletal muscle is, but contracts spontaneously once every second or so. The heart rate is controlled by a “pacemaker” region in an upper portion of the heart (right atrium). The depolarization wave initiated by the pacemaker then spreads to the rest of the heart to produce the heartbeat.

Smooth Muscle Is More Similar to Nonmuscle Cells than to Skeletal Muscle

Smooth muscle is responsible for involuntary contractions such as those of the stomach, intestines, uterus, and blood vessels. In general, such contractions are slow, taking up to five seconds to reach maximum tension. Smooth muscle contractions are also of greater duration than those of skeletal or cardiac muscle. Though smooth muscle is not able to contract rapidly, it is well adapted to maintain tension for long periods of time, as is required in these organs and tissues.

The Structure of Smooth Muscle. Smooth muscle cells are long and thin, with pointed ends. Unlike skeletal or heart muscle, smooth muscle has no striations (Figure 16-23a). Smooth muscle cells do not contain Z lines, which are

responsible for the periodic organization of the sarcomeres found in skeletal and cardiac muscle cells. Instead, smooth muscle cells contain **dense bodies**, plaque-like structures in the cytoplasm and on the cell membrane (Figure 16-23b), that contain intermediate filaments. Bundles of actin filaments are anchored at their ends to these dense bodies. As a result, actin filaments appear in a crisscross pattern, aligned obliquely to the long axis of the cell. Cross-bridges connect thick and thin filaments in smooth muscle but not in the regular, repeating pattern seen in skeletal muscle.

Regulation of Contraction in Smooth Muscle Cells.

Smooth muscle cell contraction and nonmuscle cell contraction are regulated in a manner distinct from that of skeletal muscle cells. Although skeletal and smooth muscle cells are both stimulated to contract by an increase in the sarcoplasmic concentration of calcium ions, the mechanisms involved are quite different. When sarcoplasmic calcium concentrations increase in smooth muscle and nonmuscle cells, a cascade of events takes place

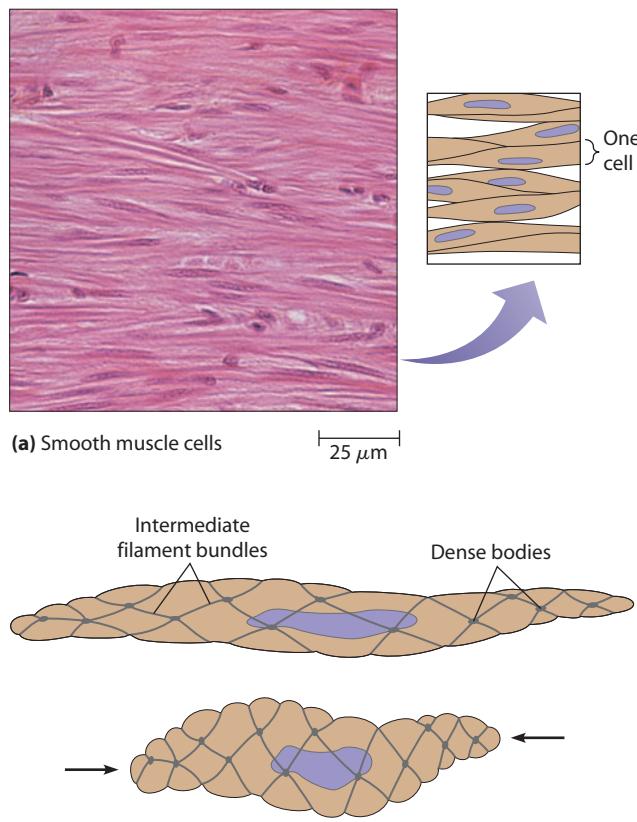

FIGURE 16-23 Smooth Muscle and Its Contraction. (a) Individual smooth muscle cells are long and spindle shaped, with no Z lines or sarcomeric structure (LM). (b) In the smooth muscle cell, contractile bundles of actin and myosin appear to be anchored to plaque-like structures called dense bodies. The dense bodies are connected to each other by intermediate filaments, thereby orienting the actin and myosin bundles obliquely to the long axis of the cell. When the actin and myosin bundles contract, they pull on the dense bodies and intermediate filaments, producing the cellular contraction shown here.

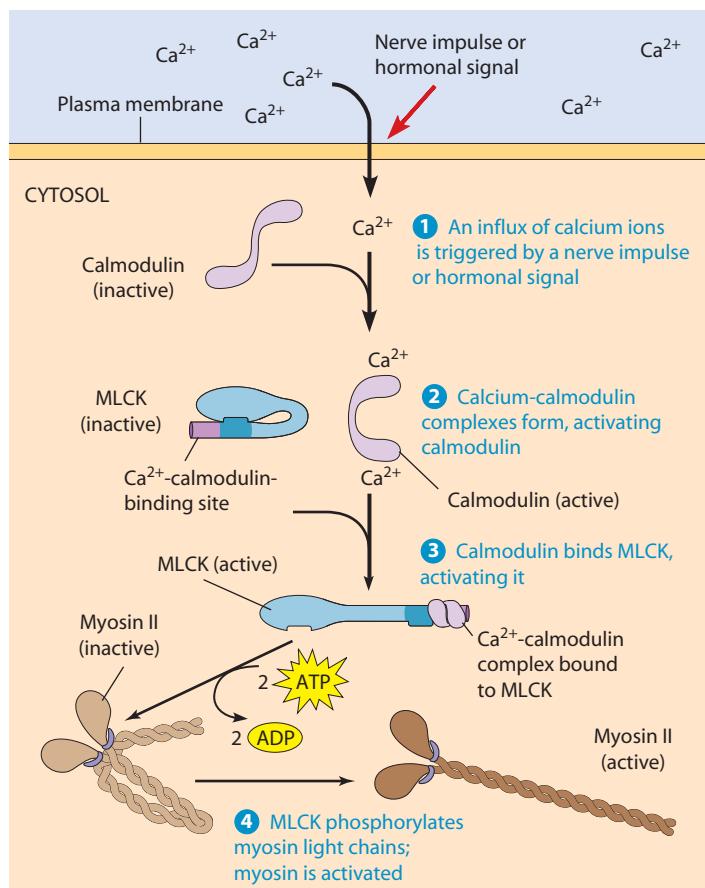

that includes the activation of **myosin light-chain kinase (MLCK)**. Activated MLCK then phosphorylates one type of myosin light chain known as a **regulatory light chain** (see Figure 16-9, myosin II).

Myosin light-chain phosphorylation affects myosin in two ways. First, some myosin molecules are curled up so that they cannot assemble into filaments. When the myosin light chain is phosphorylated, the myosin tail uncurls and becomes capable of assembly. Second, the phosphorylation of the light chains activates myosin, enabling it to interact with actin filaments to undergo the cross-bridge cycle.

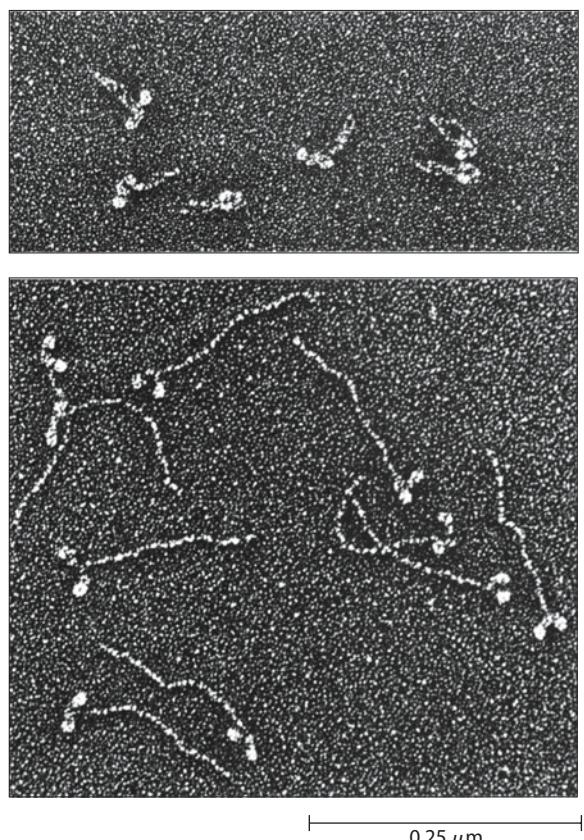

The cascade of events involved in the activation of smooth muscle and nonmuscle myosin is shown in **Figure 16-24a**. In response to a nerve impulse or hormonal signal reaching the smooth muscle cell, an influx of extracellular calcium ions occurs, increasing the intracellular calcium concentration and causing contraction. Recall from Chapter 14 that elevation of intracellular calcium can activate the protein *calmodulin*. The resulting *calcium-calmodulin complex* can bind to myosin light-chain kinase,

activating the enzyme. As a result, myosin light chains become phosphorylated, and myosin can interact with actin to cause contractions. In addition, the tails of the myosins straighten out and can assemble with other myosin molecules into filaments (Figure 16-24b). As the calcium levels within smooth muscle cells drop again, the MLCK is inactivated, and a second enzyme, *myosin light-chain phosphatase*, removes the phosphate group from the myosin light chain. Since the dephosphorylated myosins can no longer bind to actin, the muscle cell relaxes.

Thus, both skeletal muscle and smooth muscle are activated to contract by calcium ions but from different sources and by different mechanisms. In skeletal muscle, the calcium comes from the sarcoplasmic reticulum. Its effect on actin-myosin interaction is mediated by troponin and is very rapid because it depends on conformational changes only. In smooth muscle, the calcium comes from outside the cell, and its effect is mediated by calmodulin. The effect is much slower in this case because it involves a covalent modification (phosphorylation) of the myosin molecule.

(a) Phosphorylation of myosin II by myosin light-chain kinase (MLCK)

(b) Curled and uncurred myosin II molecules

FIGURE 16-24 Phosphorylation of Smooth Muscle and Nonmuscle Myosin. (a) The functions of both smooth muscle and nonmuscle myosin II are regulated by phosphorylation of the regulatory light chains. An influx of calcium ions into the cell, triggered by a nerve impulse or a hormonal signal, allows the calcium-calmodulin complex to bind myosin light-chain kinase (MLCK), which in turn phosphorylates the myosin light chains. The activated (and uncurled) myosin can then bind to actin. (b) Electron micrographs of curled and uncurred myosin II molecules (TEMs).

Actin-Based Motility in Nonmuscle Cells

Actin and myosin are best known as the major components of the thin and thick filaments of muscle cells. In fact, muscle cells represent only one specialized case of cell movements driven by the interactions of actin and myosin. Actins and myosins have now been discovered in almost all eukaryotic cells and are known to play important roles in various types of nonmuscle motility. One example of actin-dependent, nonmuscle motility occurs during cytokinesis (see Chapter 19). In this section, we examine several other examples.

Cell Migration via Lamellipodia Involves Cycles of Protrusion, Attachment, Translocation, and Detachment

Actin microfilaments (MFs) are required for the movement of most nonmuscle cells in animals. Many nonmuscle cells, such as fibroblasts, the growth cones of neurons, and many embryonic cells in animals, are capable of crawling over a substrate using lamellipodia and/or filopodia, whose internal structure we explored in Chapter 15. (A scanning electron micrograph of a crawling cell in vitro is shown in **Figure 16-25**.) In this section, we will consider such cell crawling in more detail. In a later section, we will

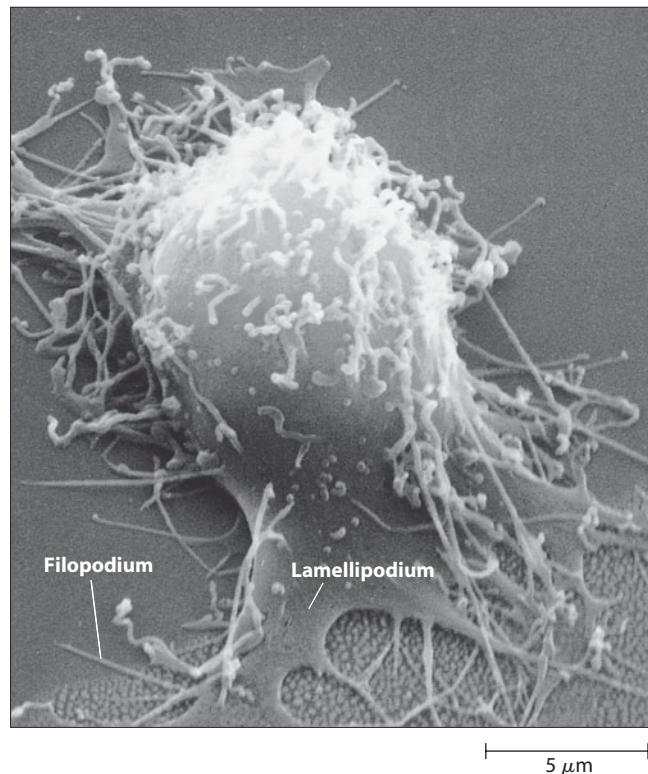

FIGURE 16-25 A Crawling Cell. A mouse fibroblast displays a lamellipodium and numerous filopodia extending from the cell surface (SEM).

[VIDEOS www.thecellplace.com](http://www.thecellplace.com) *Lamellipodia in cell migration*

consider a specialized form of crawling known as amoeboid movement.

Cell crawling involves several distinct events: (1) extension of a protrusion at the cell's leading edge; (2) attachment of the protrusion to the substrate; and (3) generation of tension, which pulls the cell forward as its "tail" releases its attachments and retracts. These events are summarized in **Figure 16-26**.

Extending Protrusions. To crawl, cells must produce specialized extensions, or *protrusions*, at their front or *leading edge*. One type of protrusion is a thin sheet of cytoplasm called a **lamellipodium** (plural: **lamellipodia**). Another type of protrusion is a thin, pointed structure known as a **filopodium** (plural: **filopodia**). Crawling cells often exhibit interconversion of these two types of protrusions as they migrate.

Fundamental to the dynamics of protrusions is the phenomenon of **retrograde flow** of F-actin. During normal retrograde flow, there is bulk movement of microfilaments toward the rear of the protrusion as it extends. Retrograde flow appears to result from two simultaneous processes: *actin assembly* at the tip of the growing lamellipodium or filopodium and *rearward translocation* of actin filaments toward the base of the protrusion. In a typical cell, forward assembly and rearward translocation balance one another; as one or the other occurs, a protrusion can be extended or retracted.

Actin polymerization, especially in lamellipodia, is driven by Arp2/3-dependent dendritic branching, a process we examined in some detail in Chapter 15. As actin polymerizes at the tip of a protrusion, the protrusion pushes forward. At the same time that extension of the tip of a protrusion is occurring, the polymerized actin is drawn toward the base of the protrusion, where it is disassembled. Released actin monomers are then available for addition to the barbed ends of new or growing microfilaments as the cell continues to crawl forward.

Microtubules are also involved in the polarized production of protrusions. Although how MTs are involved is not entirely clear, in cultured cells MTs can be seen polymerizing near the leading edge. Moreover, treating some cells with MT depolymerizing agents causes them to lose their polarized appearance, and they make protrusions simultaneously all around their perimeter.

Cell Attachment. If cells only polymerized actin at the tips of protrusions, pulled it rearward, and then depolymerized it, they would not be able to move. Something must couple retrograde flow to forward movement of the cell as a whole. Attachment, or adhesion of the cell to its substrate, is also necessary for cell crawling. New sites of attachment must be formed at the front of a cell, and contacts at the rear must be broken. Attachment sites between the cell and the substrate are complex structures involving the attachment of transmembrane proteins to other proteins both outside and inside the cell. One family of such

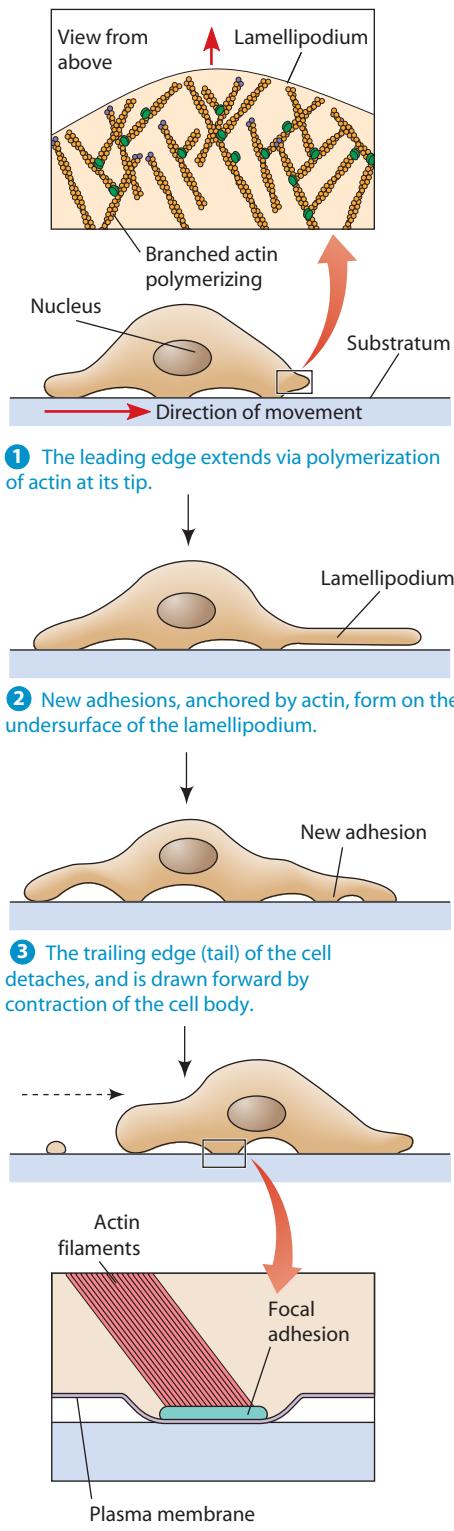

FIGURE 16-26 The Steps of Cell Crawling. Several different processes are involved in cell crawling, including cell protrusion, attachment, and contractile activities. Protrusion is accompanied by Arp2/3-dependent actin polymerization at the leading edge. Attachment connects actin to the cell surface, typically via integrins, which cluster at focal adhesions.

attachment proteins is the *integrins*. On the outside of the cell, integrins attach to extracellular matrix proteins. Inside the cell, integrins are connected to actin filaments through linker proteins. Such integrin-dependent attachments are

known as *focal contacts* and are crucial for cell migration. We will discuss focal contacts in more detail in Chapter 17.

How firmly a cell is attached to the underlying substrate helps to determine whether a cell will move forward. In this sense, actin polymerization at the leading edge is analogous to a car with its transmission in neutral. Once the car is shifted into a forward gear, it rapidly moves forward. In the same way, firm attachment of the leading edge shifts the balance in favor of forward movement.

Translocation and Detachment. Cell crawling coordinates protrusion formation and attachment with forward movement of the entire cell body. Contraction of the rear of the cell squeezes the cell body forward and releases the cell from attachments at its rear. Evidence suggests that contraction is due to interactions between actin and myosins, and that contraction is under the control of the protein Rho. Rho is thought to regulate activation of non-muscle myosin II, which is localized toward the rear of the cell. In mutant cells from the cellular slime mold *Dictyostelium* that lack myosin II, the ability of the trailing edge of the cell to retract is reduced. Similarly, when Rho activity is impaired in migrating monocytes, they are unable to withdraw attachments at their rear and contract their trailing edge. These and other results support the idea that Rho and myosin II are involved in tail retraction.

Contraction of the cell body must be linked to detachment of the trailing edge of the cell. Detachment requires breaking adhesive contacts. Interestingly, contacts at the rear of the cell are sometimes too tight to be detached, and the tail of the cell actually breaks off as the cell pulls the rear forward (see Figure 16-26). In general, how firmly a cell attaches to a substrate affects how quickly that cell can crawl. If cells adhere too tightly to the underlying substrate, they cannot dynamically make and break connections to the substrate, and motility is actually impeded. Thus for movement to occur, new attachments must be balanced by loss of old ones.

Chemotaxis Is a Directional Movement in Response to a Graded Chemical Stimulus

A key feature of migrating cells in the body and in embryos is *directional* migration. One way that directional migration occurs is through the formation of protrusions predominantly on one side of the cell. In this case, cells must be able to regulate not only whether they form protrusions but where they form them. Diffusible molecules can act as important cues for such directional migration. When a migrating cell moves toward a greater or lesser concentration of a diffusible chemical, the response is known as **chemotaxis**. The molecule(s) that elicit this response are called *chemoattractants* (when a cell moves toward higher concentrations of the molecule) or *chemorepellants* (when a cell moves away from higher concentrations of the molecule). In eukaryotes, chemotaxis has been studied most intensively in white blood cells and in the *Dictyostelium* amoeba. In both cases, increasing the local concentration of a chemoattractant (small peptides in the

case of white blood cells and cyclic AMP in the case of *Dictyostelium*) results in dramatic changes in the actin cytoskeleton, including biochemical changes in actin-binding proteins and migration of the cell toward the source of chemoattractant. These changes occur through local activation of chemoattractant (or repellent) receptors on the cell surface. These receptors are G protein-linked receptors, which we discussed in Chapter 14. Activation of these receptors leads to local accumulation of phosphoinositides (see Chapter 15), which in turn is thought to result in polarized recruitment of the cell's cytoskeletal machinery to form a protrusion in the direction of migration.

Amoeboid Movement Involves Cycles of Gelation and Solation of the Actin Cytoskeleton

Amoebas and white blood cells exhibit a type of crawling movement referred to as **amoeboid movement** (Figure 16-27). This type of movement is accompanied by protrusions of the cytosol called **pseudopodia** (singular: **pseudopodium**, from the Greek for “false foot”). Cells that undergo amoeboid movement have an outer layer of thick, gelatinous, actin-rich cytosol (“gel”) and an inner, more fluid layer of cytosol (“sol”). In an amoeba, for example, as a pseudopodium is extended, more fluid material streams forward in the direction of extension and congeals at the tip of the pseudopodium (this event is often called gelation). Meanwhile, at the rear of the moving cell, gelatinous cytosol changes into a more fluid state and streams toward the pseudopodium (solation). Proteins such as gelsolin that are present within these gels may be activated by calcium to convert the gel to a more fluid state. Experiments have shown that the forward streaming in the pseudopodium does not require squeezing from the rear of the cell: When a pseudopodium’s cell membrane is removed using detergent, the remaining components can still stream forward if the

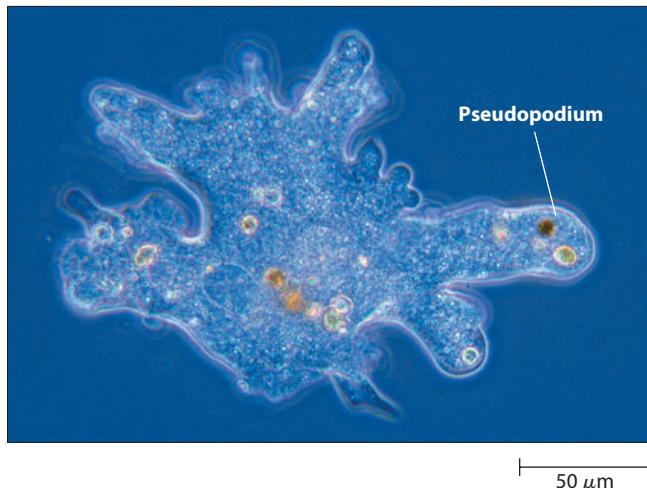

FIGURE 16-27 Amoeboid Movement. A micrograph of *Amoeba proteus*, a protozoan that moves by extension of pseudopodia (LM).

www.thecellplace.com A crawling amoeba

appropriate mixture of ions and other chemicals is added. Pressure exerted on the endoplasm, possibly due to contraction of an actomyosin network in the trailing edge of the cell, may also squeeze the endoplasm forward, aiding formation of a protrusion at the leading edge.

Actin-Based Motors Move Components Within the Cytoplasm of Some Cells

Cytoplasmic streaming, an actomyosin-dependent movement of the cytosol within a cell, is seen in a variety of organisms that do not display amoeboid movement. In slime molds such as *Physarum polycephalum*, for example, cytosol streams back and forth in the branched network that constitutes the cell mass.

Many plant cells display a circular flow of cell contents around a central vacuole. This streaming process, called **cyclosis**, has been studied most extensively in the giant algal cell *Nitella*. In this case, the movement seems to circulate and mix cell contents (Figure 16-28a). Cytoplasmic streaming requires actin filaments, as it is inhibited in cells treated with cytochalasin. In *Nitella*, a dense set of aligned microfilaments are found near sites where cyclosis occurs (Figure 16-28b). Cyclosis involves specific myosins that provide the force for movement of components within the

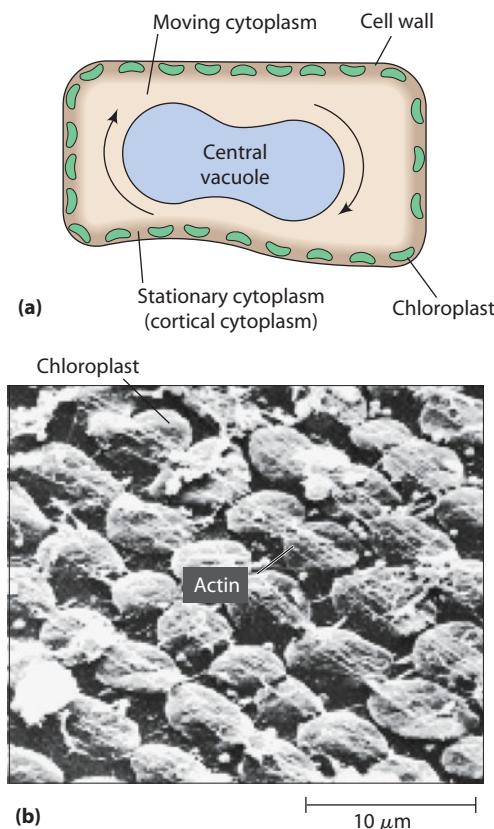

FIGURE 16-28 Cytoplasmic Streaming. (a) Cyclosis in an algal cell. The cytoplasm moves in a circular path around a central vacuole, driven by myosin motors that interact with actin anchored to chloroplasts near the cell wall. (b) Chloroplasts and actin filaments in an algal cell. Actin filaments are arranged in parallel tracks (SEM).

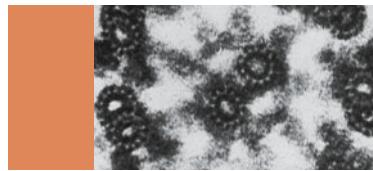

www.thecellplace.com Cytoplasmic streaming

cytosol. When latex beads coated with various types of myosin are added to *Nitella* cells that have been broken open, the beads move along the actin filaments in an ATP-dependent manner in the same direction as normal organelle movement.

In animal cells, myosins may also be involved in vesicular transport. For example, by carefully observing vesicles from the cytoplasm of squid giant axons in vitro, it is clear that individual vesicles can jump from microtubules to microfilaments. This means that the vesicles have both MT motors, such as kinesins, and myosins attached to their

surfaces. Myosin V may be particularly important for such actin-based vesicle movement. Myosin V may be able to physically interact with kinesins on the surface of such vesicles, and myosin V has been shown to interact with the plus ends of MTs, making it well suited to such a “handoff” between MTs and MF-based vesicle trafficking. A human disorder called *Griselli's disease*, which involves partial albinism and neurological defects, has been shown to result from a mutation in this class of myosins.

SUMMARY OF KEY POINTS

Motile Systems

- Cell motility and intracellular movements of cellular components are driven by motor proteins, which couple ATP hydrolysis to movements along microtubules (MTs) or microfilaments (MFs). ATP hydrolysis is coupled to conformational changes in the motor that allow the motor to move along a cytoskeletal element.

Microtubule-Based Movement

- Kinesins generally move toward the plus ends of MTs; dyneins move toward the minus ends.
- There are many families of kinesins, which can act as highly processive motors, moving great distances along MTs. One major function for kinesins is moving intracellular cargo. Kinesins connect to adapter proteins and/or their cargo mainly via their light chains.
- There are relatively few dyneins, which fall into two basic classes: cytoplasmic and axonemal. Cytoplasmic dyneins bind to the dynactin complex, which serves as an adapter between dyneins and their cargo.
- MT motors are important for the shaping and transport of the endomembrane system within cells and for intraflagellar transport.
- Axonemal dyneins mediate the bending of cilia and eukaryotic flagella. Dynein arms project out from one MT doublet to the next and slide one set of microtubules past the next. The nine outer doublets of the axoneme are connected

laterally to one another and radially to the central pair of single MTs. These connections allow the sliding movement powered by dynein to be converted into bending of the cilium or flagellum.

Microfilament-Based Movement

- There are many families of myosins, and many of them move toward the plus ends of MFs. The best studied is myosin II, one form of which is found in skeletal muscle. Other myosins are involved in events as diverse as cytokinesis, vesicular trafficking, and endocytosis.
- Skeletal muscle contraction involves progressive sliding of thin filaments that contain actin past thick myosin filaments, driven by the interaction between the ATPase head of the myosins and successive myosin-binding sites on actin filaments. Contraction is triggered by the release of calcium from the sarcoplasmic reticulum (SR), which binds troponin, causing a conformational change in tropomyosin that in turn opens myosin-binding sites on the thin filament. Contraction ceases again as calcium is actively pumped back into the SR.
- In smooth muscle, the effect of calcium is mediated by calmodulin, which activates myosin light-chain kinase, leading to the phosphorylation of myosin.
- Actin and myosin are involved in various sorts of motility, including cell crawling, amoeboid movement, cytoplasmic streaming, and cytokinesis. In crawling cells, polymerization of actin extends cellular protrusions; attachment of the protrusions to the substrate and contraction of the cell drive forward movement.

MAKING CONNECTIONS

In Chapter 15 we saw how cytoskeletal polymers assemble and disassemble under tight control. In this chapter, we have examined how motor proteins move along these polymers. To accomplish cell movement, cells use cytoskeletal

motor proteins. Like other mechanoenzymes we examined, such as the F1 subunit of the mitochondrial ATP synthase (Chapter 10), eukaryotic motility is driven by a set of motor molecules (dyneins and kinesin in the case of

microtubules, myosin in the case of actin) that also act as mechanoenzymes. In this case, movement is coupled to ATP hydrolysis. Cytoskeletal motors move intracellular components, such as the vesicles and endomembrane system we examined in Chapter 12, along cytoskeletal elements. Cell movements are also mediated by cytoskeletal motors. Indeed, motility is a major theme in cell biology.

PROBLEM SET

More challenging problems are marked with a •.

16-1 Kartegener's Triad. Sterility in human males with Kartegener's triad is due to nonmotile sperm. Upon cytological examination, the sperm of such individuals are found to have tails (that is, flagella) that lack one or more of the normal structural components. Such individuals are also likely to have histories of respiratory tract disease, especially recurrent bronchitis and sinusitis, caused by an inability to clear mucus from the lungs and sinuses.

- (a) What is a likely mechanistic explanation for nonmotility of sperm in such cases of sterility?
- (b) Why is respiratory tract disease linked with sterility in affected individuals?

16-2 A Moving Experience. For each of the following statements, indicate whether it is true of the motility system that you use to lift your arm (A), to cause your heart to beat (H), to move ingested food through your intestine (I), or to sweep mucus and debris out of your respiratory tract (R). More than one response may be appropriate in some cases.

- (a) It depends on muscles that have a striated appearance when examined with an electron microscope.
- (b) It would probably be affected by the same drugs that inhibit motility of a flagellated protozoan.
- (c) It requires ATP.
- (d) It involves calmodulin-mediated calcium signaling.
- (e) It involves interaction between actin and myosin filaments.
- (f) It depends heavily on fatty acid oxidation for energy.
- (g) It is under the control of the voluntary nervous system.

16-3 Muscle Structure. Frog skeletal muscle consists of thick filaments that are about $1.6 \mu\text{m}$ long and thin filaments about $1 \mu\text{m}$ long.

- (a) What is the length of the A band and the I band in a muscle with a sarcomere length of $3.2 \mu\text{m}$? Describe what happens to the length of both bands as the sarcomere length decreases during contraction from 3.2 to $2.0 \mu\text{m}$.
- (b) The H zone is a specific portion of the A band. If the H zone of each A band decreases in length from 1.2 to $0 \mu\text{m}$ as the sarcomere length contracts from 3.2 to $2.0 \mu\text{m}$, what can you deduce about the physical meaning of the H zone?
- (c) What can you say about the distance from the Z line to the edge of the H zone during contraction?

16-4 Rigor Mortis and the Contraction Cycle. At death, the muscles of the body become very stiff and inextensible, and the corpse is said to go into rigor.

In the case of smooth muscle and chemotaxis, we saw that such events are tightly controlled by cell signaling, which we examined in Chapter 14. In the case of skeletal muscle, movement is controlled by neuronal activity, a major topic of Chapter 13. Efficient cell movement requires cells to be attached to one another or the extracellular matrix, the topic of the next chapter.

(a) Explain the basis of rigor. Where in the contraction cycle is the muscle arrested? Why?

(b) Would you be likely to go into rigor faster if you were to die while racing to class or while sitting in lecture? Explain.

(c) What effect do you think the addition of ATP might have on muscles in rigor?

• 16-5 AMPPNP and the Contraction Cycle. AMPPNP is the abbreviation for a structural analogue of ATP in which the third phosphate group is linked to the second by a CH_2 group instead of an oxygen atom. AMPPNP binds to the ATP-binding site of virtually all ATPases, including myosin. It differs from ATP, however, in that its terminal phosphate cannot be removed by hydrolysis. When isolated myofibrils are placed in a flask containing a solution of calcium ions and AMPPNP, contraction is quickly arrested.

(a) Where in the contraction cycle will contraction be arrested by AMPPNP? Draw the arrangement of the thin filament, the thick filament, and a cross-bridge in the arrested configuration.

(b) Do you think contraction would resume if ATP were added to the flask containing the AMPPNP-arrested myofibrils? Explain.

(c) What other processes in a muscle cell do you think are likely to be inhibited by AMPPNP?

16-6 Pulled in Two Directions. The following questions deal with the arrangement of actin and myosin in contractile structures.

(a) In skeletal muscle sarcomeres, the H zone is in the middle and bounded on each side by a Z line. During contraction, the Z lines on either side move in opposite directions toward the H zone. Myosin, however, can crawl along an actin filament in only one direction. How can you reconcile movements of Z lines in opposite directions with the unidirectional movement of myosin along an actin filament?

(b) Stress fibers of nonmuscle cells contain contractile bundles of actin and myosin II. For stress fibers to contract or develop tension, how would actin and myosin have to be oriented within the stress fibers?

16-7 Nervous Twitching. Recent military conflicts have involved discussions of “weapons of mass destruction,” including nerve gas. One such nerve gas contains the chemical sarin. Sarin inhibits reuptake of the neurotransmitter acetylcholine. What effect would you expect sarin to have on muscle function in individuals exposed to the nerve gas, and why? In your answer, discuss in detail how sarin would be expected to affect the neuromuscular junction, and how it

would affect signaling and cytoskeletal events within affected muscle cells.

- **16-8 Tipped Off.** Polarized cytoskeletal structures and intraflagellar transport (IFT) are involved in formation of cilia and flagella.

- (a) Observation of flagella in the biflagellate alga, *Chlamydomonas reinhardtii*, indicates that particles move toward the tips of flagella at a rate of $2.5 \mu\text{m}/\text{min}$., but the particles moving back toward the base of flagella move at $4 \mu\text{m}/\text{min}$. How do you explain this difference in rate of movement?
- (b) Temperature-sensitive mutations in a kinesin II required for intraflagellar transport (IFT) have been identified in *Chlamydomonas*. Such mutations only lead to defects when the temperature is raised above a certain threshold, called the *restrictive temperature*. When algae with fully formed flagella are grown at the restrictive temperature, their flagella degenerate. What can you conclude about the necessity of IFT from this experiment?

- (c) Based on your knowledge of the directionality of microtubule motors and the information in (b), where would you predict that the plus ends of flagellar microtubules are? State your reasoning.

- 16-9 **AMPPNP Again.** AMPPNP can be used to study microtubule (MT) motors as well as myosins.

- (a) What effects would you predict on a sperm flagellum to which AMPPNP was added? In your explanation, please be specific about what molecule's function would be inhibited and what the effect on overall flagellar function would be.
- (b) When researchers incubated purified vesicles, nerve cytosol from squid giant axons, and MTs in the presence of AMPPNP, the vesicles bound tightly to the microtubules but did not move. Scientists then used AMPPNP to promote its tight binding to MTs, and the MTs with bound proteins were collected by centrifugation. The main protein purified in this way promotes movement of vesicles away from the cell body, where the nucleus resides. What was this protein?

Beyond the Cell: Cell Adhesions, Cell Junctions, and Extracellular Structures

In the preceding chapters, we have treated cells as if they exist in isolation and as if they “end” at the plasma membrane. However, most organisms are multicellular: They consist of many—sometimes trillions—of cells. Many kinds of cells—including most of those in your own body—spend all their lives linked to neighboring cells. It is the organization of cells into tissues that allows multicellular organisms to adopt complex structures. These tissues, in turn, are arranged in precise ways to generate the form of an organism. How do these tissues achieve their structures? Consider the two types of animal tissues shown in **Figure 17-1**. One is a sheet of cells known as an epithelium, such as the cells that line the small intestine. Such cells are clearly polarized—that is, they contain discrete functional domains at opposite ends of the cell. The end of the cell in contact with the external environment (for example, the lumen of the small intestine) is often called the apical side of the cell. The parts on the other side of the tight junction, including the surfaces in contact with the basal lamina, are called the basolateral side of the cell. The other cell type in Figure 17-1 is from a more loosely organized connective tissue, such as might be found in the dermis of the skin. In each case, cells must be attached to one another, to a mechanically rigid scaffolding, or to both. Thus, in order to understand how multicellular organisms are constructed, we will need to consider both connections between cells, or cell-cell adhesions, and the extracellular structures to which cells attach. Cells use a variety of elaborate molecular complexes, or junctions, to attach to one another, and most of these involve transmembrane proteins that link the cell surface to the cytoskeleton (which we learned about in Chapters 15 and 16). Cells use other types of molecular complexes to attach to extracellular structures, and these also involve specific linkages between the cell surface and the cytoskeleton.

The extracellular structures themselves consist mainly of macromolecules that are secreted by the cell. Animal cells

have an extracellular matrix that takes on a variety of forms and plays important roles in cellular processes as diverse as division, motility, differentiation, and adhesion. Epithelial cells, such as the ones shown in Figure 17-1, produce a specialized extracellular matrix called a basal lamina. Connective tissues, on the other hand, produce a more loosely organized matrix. In plants, fungi, algae, and prokaryotes, the extracellular structure is a cell wall—although its chemical composition differs considerably among these organisms. Cell walls confer rigidity on the cells they encase, serve as permeability barriers, and protect cells from physical damage and from attack by viruses and infectious organisms.

Most of our attention in this chapter is devoted to the adhesions animal cells make with one another, the junctions that characterize these adhesions, and how animal cells interact with the extracellular matrix. Then we will turn to the walls that surround plant cells and the specialized structures that allow direct cell-to-cell communication between plant cells, despite the presence of a cell wall.

Cell-Cell Recognition and Adhesion

The ability of individual cells to associate in precise patterns to form tissues, organs, and organ systems requires that individual cells be able to recognize, adhere to, and communicate with each other. We discuss *cell-cell contact* in this section and consider *intercellular junctions* later in the chapter.

Transmembrane Proteins Mediate Cell-Cell Adhesion

Animal cells use specialized adhesion receptors to attach to one another. Many of these adhesion proteins are transmembrane proteins, which means the extracellular portion of these proteins can interact with the extracellular

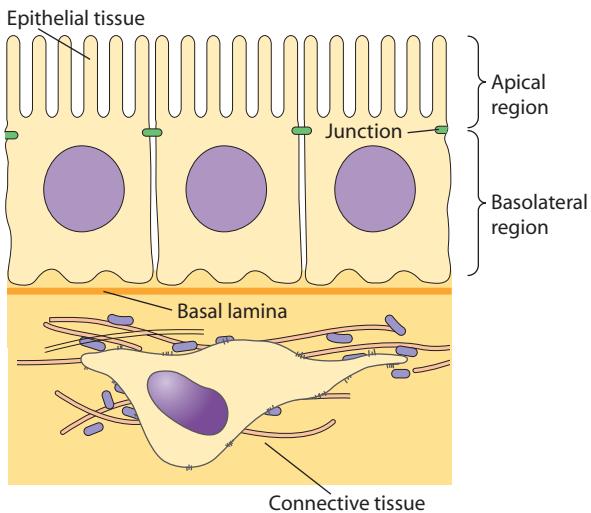

FIGURE 17-1 Different Types of Tissues in Animals. Tissues are multicellular structures that include cells linked together with extracellular material. In a polarized epithelium (top), such as the cells lining the small intestine in a mammal, cells are connected together by cell-cell adhesions. The apical surfaces of these cells are very different from the basal surfaces, which lie on top of an extracellular matrix known as a basal lamina. In a connective tissue (bottom), such as the dermis of the skin, loosely organized cells are embedded in extracellular matrix fibers.

portion of similar proteins on the surface of a neighboring cell. Although diagrams of adhesive structures may suggest that they are static once assembled, they are anything but. Cells can dynamically assemble and disassemble adhesions in response to a variety of events. Many adhesion proteins are continuously recycled: Protein at the cell surface is internalized by endocytosis, and new protein is deposited at the surface via exocytosis. In addition, adhesion proteins serve as key sites for assembly of signaling complexes in cells and for dynamically assembling cytoskeletal structures at sites of cell adhesion. In this way, cell adhesion is coordinated with other major processes, including cell signaling, cell movement, cell proliferation, and cell survival.

We now know that cell-cell adhesion receptors fall into a relatively small number of classes. They include *immunoglobulin superfamily (IgSF)* proteins, *cadherins*, *selectins*, and, in a few cases, *integrins* (Figure 17-2). In each case, the adhesion protein on the surface of one cell binds to the appropriate ligand on the surface of a neighboring cell. In some cases, such as many cadherins and immunoglobulin superfamily members, cells interact with identical molecules on the surface of the cell that they adhere to. Such interactions are said to be **homophilic interactions** (from the Greek *homo*, meaning “like,” and *philia*, meaning “friendship”). In other cases, such as the selectins and integrins, a cell adhesion receptor on one cell interacts with a different molecule on the surface of the cell to which it attaches. Such interactions are said to be **heterophilic interactions** (from the Greek *hetero*, meaning “different”). Many transmembrane adhesion receptors

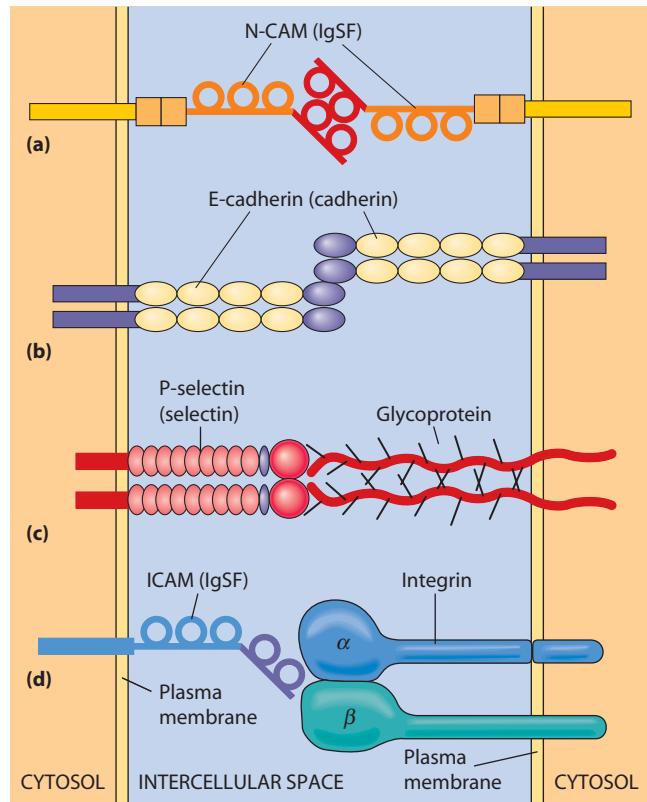

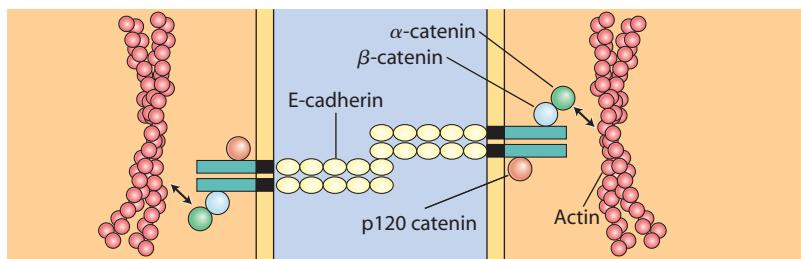

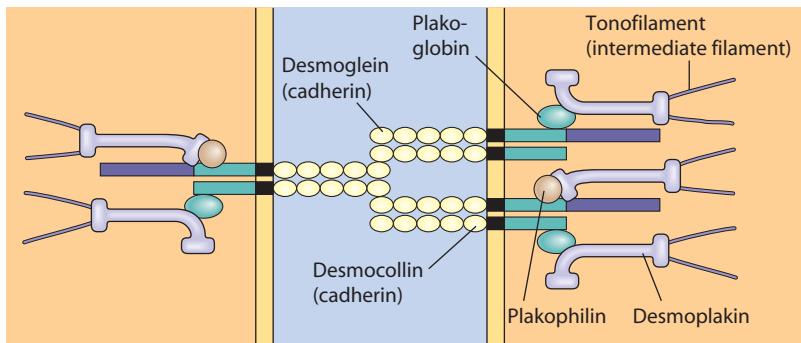

FIGURE 17-2 Different Types of Cell-Cell Adhesion Proteins. Cells adhere to other cells using transmembrane proteins that fall into a few main classes. These include (a) immunoglobulin superfamily (IgSF) proteins, such as N-CAM; (b) cadherins, such as E-cadherin; (c) selectins, which bind to the carbohydrates of glycoproteins on other cells; and (d) in a few cases such as leukocytes, integrins, which bind to IgSF proteins such as ICAM on the surface of endothelial cells.

attach to the cytoskeleton via linker proteins, which differ depending on the class of molecule and its location within the cell. In the next few sections, we consider examples of each of these major classes of cell-cell adhesion molecules.

Cell Adhesion Molecules (CAMs). CAMs are members of the **immunoglobulin superfamily (IgSF)**. The founding member of this family, called *neural cell adhesion molecule (N-CAM)*, was identified using an antibody that disrupted cell-cell adhesion between isolated neuronal cells. Proteins in this large superfamily are so named because they contain domains, characterized by well-organized loops, that are similar to those in the immunoglobulin subunits that constitute antibodies. CAMs, such as N-CAM, on one cell interact homophilically with CAMs on an adjacent cell via these domains. Other IgSF members interact heterophilically with their ligands. IgSF members participate in a wide range of adhesion events. In the embryonic nervous system, CAMs, such as N-CAM and L1-CAM, are involved in the outgrowth and bundling of neurons. Humans with mutations in the L1-CAM gene show defects in the corpus callosum (a region that interconnects the

(a) Adherens junction

(b) Desmosome

two hemispheres of the brain), mental retardation, and other defects.

Cadherins. The use of antibodies that block cell adhesion also led to the discovery of the **cadherins**, an important group of adhesive glycoproteins found in the plasma membranes of most animal cells. Like CAMs, cadherins play a crucial role in cell-cell recognition and adhesion. The two groups of proteins can be distinguished from each other because cadherins, but not CAMs, require calcium to function. Ca^{2+} binds to and stabilizes the conformation of cadherins that allows them to mediate cell-cell adhesion.

Cadherins are characterized by a series of structurally similar domains (or “repeats”) in their extracellular domain. Members of the cadherin superfamily have widely varying numbers of these repeats, and they vary in the structure of their cytosolic ends. The best-characterized cadherin, E-cadherin (*E* is for “epithelial”), has five such repeat domains. E-cadherin molecules associate in pairs in the plasma membrane. Their extracellular domains have a structure that allows them to “zip” together in a homophilic fashion, as cadherins from one cell interlock with those from a neighboring cell (Figure 17-3). At their cytosolic ends, cadherins associate with the cytoskeleton, thereby linking the cell surface to the cytoskeleton. These linkages differ for different types of cadherins, as we will see when we discuss the structure of cell-cell junctions later in this chapter.

Different cadherins are expressed in specific tissues. Their regulated expression is a particularly striking feature of embryonic development and contributes to the ability of different tissues to separate from one another as

FIGURE 17-3 Cadherin Structure. Cadherins are found at sites of cell-cell adhesion. (a) “Classical” cadherins, such as E-cadherin, mediate cell-cell adhesion at adherens junctions. E-cadherin molecules associate as pairs (homodimers) in the plasma membrane and interact with homodimers in the neighboring cell through their extracellular domains. Their cytosolic tail binds to the linker protein, β -catenin. β -catenin in turn binds α -catenin, which recruits actin to the junction. (b) The cadherins in desmosomes, called desmocollins and desmogleins, probably interact in pairs. Neighboring cells probably attach to one another via their desmogleins. In the cytosol, desmosomal cadherins interact with proteins in the desmosomal plaque (plakoglobin, plakophilin, and desmoplakin) that anchors desmosomes to intermediate filaments.

Cadherins and tissue organization

embryos change their shape. The role of different cadherins in cell-cell adhesion has been investigated in cultured fibroblasts called *L cells*, which bind poorly to one another and contain little cadherin. When purified DNA encoding E-cadherin or P-cadherin (*P* is for “placental,” where this cadherin was first described) is introduced into L cells, the cells begin to produce cadherins and to bind more tightly to one another. Moreover, L cells that produce E-cadherin bind preferentially to other cells producing E-cadherin. Similarly, cells that produce P-cadherin bind selectively to other cells that are also producing P-cadherin (Figure 17-4). Such observations suggest that the amount and types of cadherin molecules on cell surfaces help to segregate cells into specific tissues.

Cadherins have especially important roles during embryonic development, where the dynamic assembly and disassembly of cadherin-based adhesions is tightly regulated. For example, when frog embryos are depleted of mRNA for the main type of cadherin found in the early embryo, they lose their normal organization (Figure 17-5). Other cadherins are involved in helping neuronal cells to form bundles and to establish synaptic connections. One particularly important event that occurs frequently in embryos is the breakdown of an epithelium into loosely organized, migratory cells called mesenchymal cells. This *epithelial-mesenchymal transition (EMT)* is accompanied by changes in cadherin expression. Changes in cadherin expression also occur in cancer cells. Cancer cells often stop expressing cadherins, such as E-cadherin, on their surfaces. As a result, they undergo an EMT that healthy cells would not, and these cells spread to other parts of the body by a process known as metastasis (see Chapter 24).

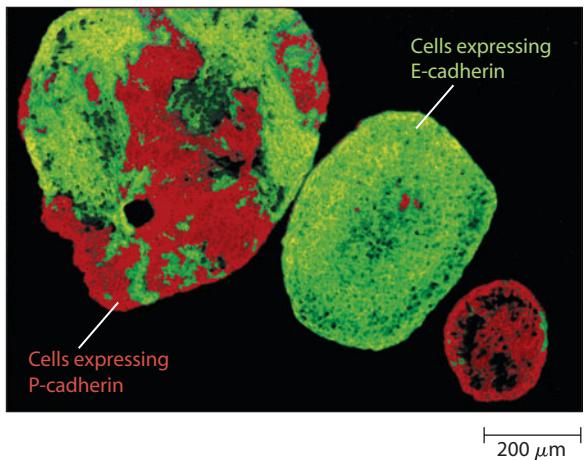

FIGURE 17-4 The Effect of Cadherins on Cell Adhesions. Cultured L cells do not normally adhere to one another. When DNA coding for E-cadherin or P-cadherin is introduced into these cells, cadherin is produced, and cell-cell adhesion occurs. Cells producing P-cadherin (red) and those producing E-cadherin (green) can be stained with fluorescent antibodies specific for each cadherin. The staining pattern shows that cells producing P-cadherin are located in different areas from the cells producing E-cadherin. This indicates that cells making E-cadherin bind preferentially to other cells producing E-cadherin. Similarly, cells making P-cadherin bind preferentially to other cells producing P-cadherin.

Carbohydrate Groups Are Important in Cell-Cell Recognition and Adhesion

Like other glycoproteins, the carbohydrate side chains of CAMs and cadherins likely affect their adhesion properties. In addition, there are several well-studied examples of how carbohydrates on the cell surface affect cell adhesion.

Lectins. A role for carbohydrate groups in cell adhesion is also suggested by the fact that many animal and plant cells secrete carbohydrate-binding proteins called **lectins**, which promote cell-cell adhesion by binding to a specific sugar or sequence of sugars exposed at the outer cell surface. Because lectins usually have more than one carbohydrate-binding site, they can bind to carbohydrate groups on two different cells, thereby linking the cells together.

Selectins and Leukocyte Adhesion. Carbohydrate recognition also plays an important role during the interactions of leukocytes with endothelial cells lining blood vessels or with platelets. Cell surface glycoproteins called **selectins** mediate these interactions. A different selectin is expressed by each cell type (*L-selectin* on leukocytes, *E-selectin* on the endothelial cells of blood vessels, and *P-selectin* on platelets and endothelial cells). Leukocytes roll along the walls of blood vessels. During inflammation, they attach to the wall of a blood vessel in the vicinity of the inflammation and then migrate through the blood vessel to the inflammation site. The initial attachment of leukocytes is mediated by binding of selectins on the leukocyte to carbohydrates on the surface of the endothelial cells and vice versa. When leukocytes stop rolling and begin to invade the blood vessel, they make more stable adhesions, which are mediated by a specific integrin on the surface of the leukocyte and immunoglobulin superfamily proteins, called *ICAMs*, on the surfaces of endothelial cells (Figure 17-6).

Carbohydrates and the Survival of Erythrocytes. One especially well-known example of the importance of carbohydrates at the cell surface is the determination of the human blood types A, B, AB, and O by a specific carbohydrate side chain present on a glycolipid of the erythrocyte plasma membrane. The *ABO blood group* involves differences in carbohydrate side chains on the surface of red blood cells that can be detected by antibodies present in the blood, leading to clumping of red blood cells and likely to the patient's death if the wrong blood type is used in transfusion.

The four blood types in the ABO system depend on genetically determined differences in the structure of a branched-chain carbohydrate attached to a specific glycolipid in the erythrocyte plasma membrane. Individuals with blood type A have the amino sugar *N*-acetylgalactosamine (GalNAc) at the ends of this carbohydrate, whereas individuals with blood type B have galactose (Gal) instead. Individuals with blood type AB have both *N*-acetylgalactosamine and galactose present; and, in individuals with type O blood, these terminal sugars are missing entirely.

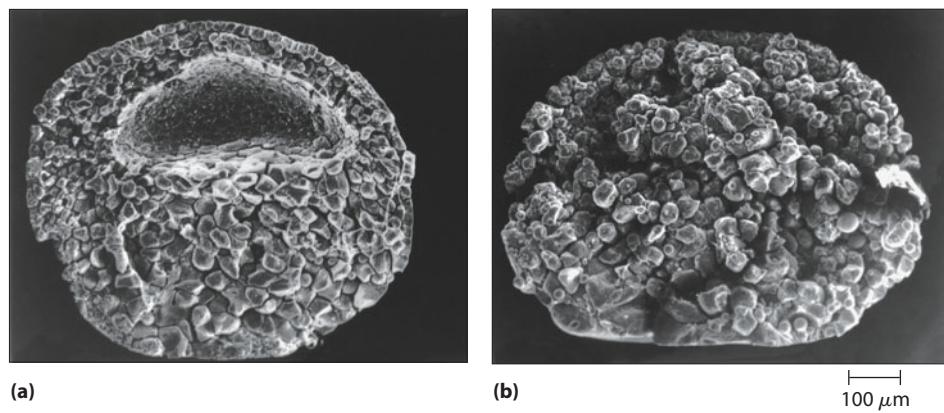

FIGURE 17-5 Cadherins During Embryonic Development. After many rounds of cell division, frog embryos form a blastula, which contains a fluid-filled space lined by cells. When embryos are depleted of mRNA for a cadherin known as EP-cadherin, they fail to make EP-cadherin protein, and compared with control embryos (a), they lose their normal organization (b).

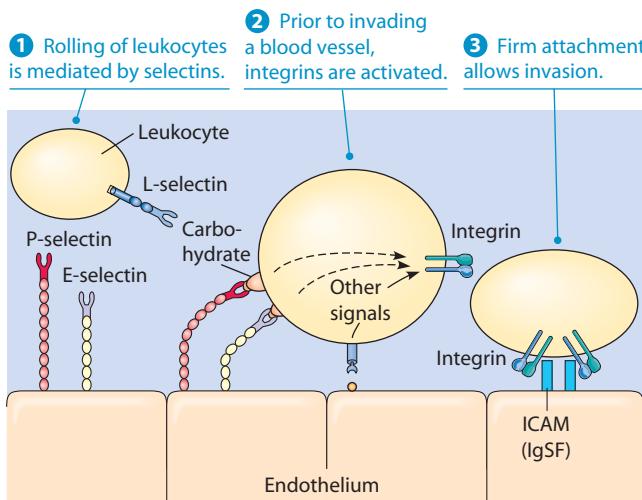

FIGURE 17-6 Leukocyte Adhesion and Selectins. The initial attachment of leukocytes, which allows them to roll along endothelial cells that line blood vessels, is mediated by selectins. Strong adhesion, mediated by integrins, allows leukocytes to stop and to pass between cells in the blood vessel wall to sites of inflammation. Adapted from D. Vestweber and J. E. Blanks, “Mechanisms That Regulate the Function of the Selectins and Their Ligands,” *Physiological Reviews* 79 (1), January 1999:181–213, Fig. 1. Am Physiol Soc, used with permission.

These minor differences have major effects on the compatibility of blood transfusions because people with blood types A, B, or O have antibodies in their bloodstream that recognize and bind to the respective terminal sugars of this specific glycolipid. An individual whose blood contains antibodies against one or both sugars (GalNAc or Gal) cannot accept blood containing the glycolipid with that terminal sugar. Individuals with type A blood have antibodies against carbohydrate chains ending in galactose, which occur in type B and type AB blood. They therefore cannot be transfused with type B or AB blood, but they can accept blood from type A or O donors. Conversely, individuals with type B blood have antibodies against carbohydrate chains ending in GalNAc, which occur in blood of types A and AB. They therefore cannot be transfused with type A or AB blood but can accept blood from B or O donors. Individuals with type O blood are called universal donors because their erythrocytes do not generate an immune response when transfused into individuals of any blood type.

Cell-Cell Junctions

By definition, unicellular organisms have no permanent associations between cells (although they can form temporary associations, such as during bacterial swarming or the aggregation of slime mold amoebae). Whereas a single cell is an entity unto itself, multicellular organisms have specific means of joining cells in long-term associations to form tissues and organs. Such associations usually involve specialized modifications of the plasma membrane at the point where two cells come together. These specialized structures are called **cell-cell junctions**. In animals, the

three most common kinds of cell junctions are *adhesive junctions*, *tight junctions*, and *gap junctions*. **Figure 17-7** illustrates each of these kinds of junctions.

In plants, the presence of a cell wall between the plasma membranes of adjacent cells precludes the kinds of cell junctions that link animal cells. However, the cell wall and special structures called *plasmodesmata* carry out similar functions, as we will see a bit later in the chapter.

Polarity Proteins Regulate the Positioning of Cell-Cell Junctions

Both migrating single cells and sheets of epithelial cells display polarity: They have defined regions that have

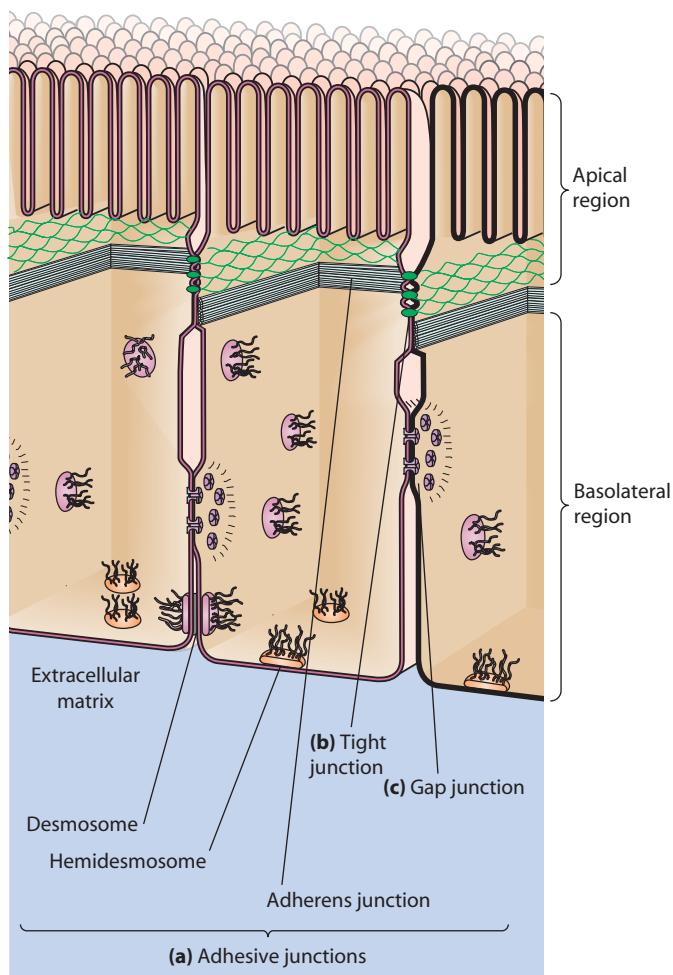

FIGURE 17-7 Major Types of Cell Junctions in Animal Cells.

(a) Adhesive junctions are specialized for cell-cell and cell-ECM adhesion. Desmosomes and hemidesmosomes bind to intermediate filaments within the cell, whereas adherens junctions and focal adhesions bind to actin microfilaments. (b) Tight junctions create an impermeable seal between cells, thereby preventing fluids, molecules, or ions from crossing a cell layer via the intercellular space. (c) Gap junctions provide direct chemical and electrical communication between cells by allowing the passage of small molecules and ions from one cell to another. Note that, like adherens junctions, tight junctions can also recruit actin, but for clarity this is not shown.

obviously different activities. Epithelial cells in particular have a striking polarity that separates apical from basolateral regions of the cell surface (see Figure 17-1). Numerous studies, including key work in the nematode worm, *C. elegans*, and the fruit fly, *Drosophila*, have identified proteins that help to establish and maintain epithelial polarity. One important protein complex, localized at the apical ends of epithelial cells, is the *Par3/Par6/atypical protein kinase C (aPKC) complex*. The Par proteins get their name from mutations in *C. elegans* that result in defective partitioning of materials in the one-cell embryo. In conjunction with the Rho family proteins Cdc42 or Rac, the Par3/Par6//aPKC complex is important for recruiting other protein complexes to the apical ends of epithelial cells. Par proteins also play important roles in non-epithelial cells, which are less well understood.

Adhesive Junctions Link Adjoining Cells to Each Other

One of the three main kinds of junctions in animal cells is the **adhesive (or anchoring) junction** (**Table 17-1**). Adhesive junctions link cells together into tissues, thereby enabling the cells to function as a unit. All junctions in this category anchor the cytoskeleton to the cell surface. The resulting interconnected cytoskeletal network helps to maintain tissue integrity and to withstand mechanical stress.

The two main kinds of cell-cell adhesive junctions are *adherens junctions* and *desmosomes* (Figure 17-7). Despite structural and functional differences, adhesive junctions all contain two distinct kinds of proteins: *intracellular attachment proteins*, which link the junction to the appropriate cytoskeletal filaments on the inside of the plasma membrane, and *cadherins*, which protrude on the outer surface of the membrane and bind cells to each other.

Adherens Junctions. Cadherin-mediated adhesive junctions that interact with actin are called **adherens junctions**

(Table 17-1). At adherens junctions, the space between the adjacent membranes is about 20–25 nm. Adherens junctions are especially prominent in epithelial cells. In these cells adherens junctions form a continuous belt that encircles the cell near the apical end of the lateral membrane (Figure 17-7).

Adherens junctions are points of attachment between the cell surface and the cytoskeleton (see Figure 17-3a). A protein known as β -catenin binds to the cytosolic tail of the cadherin. β -catenin plays multiple roles in the cell: In addition to its role in cell adhesion, it also functions in the Wnt pathway, a cell signaling pathway that is important in cancer (see Chapter 24). β -catenin in turn is bound by a second protein called α -catenin, which can recruit actin to the junction. Although normally thought of as a desmosomal protein (see below), in some adherens junctions another β -catenin family member, plakoglobin, is present alongside β -catenin. A final core component of adherens junctions is *p120catenin* (*p120ctn*). This protein binds to the cytoplasmic tail of cadherins near the plasma membrane; p120ctn regulates stability of cadherin at the surface, as well as the activity of Rho, an actin regulator we examined in Chapter 15.

We have seen that cell-cell and cell-extracellular matrix adhesions are important for the normal functions of cells and tissues in the body. A surprising finding of modern microbiology is that many pathogens, such as those responsible for several types of food poisoning, infect the body by using these very same adhesion systems to gain entry into healthy cells. These mechanisms of infection are discussed in more detail in **Box 17A**.

Desmosomes. **Desmosomes** are button-like points of strong adhesion between adjacent cells in a tissue. Desmosomes give the tissue structural integrity, enabling cells to function as a unit and to resist stress. Desmosomes are found in many tissues but are especially abundant in skin, heart muscle, and the neck of the uterus.

Table 17-1 Junctions Between Animal Cells

Type of Junction	Main Function	Intermembrane Features	Space	Associated Structures
Adhesive junctions				
Focal adhesion	Cell-ECM adhesion	Localized points of attachment	20–25 nm	Actin microfilaments
Hemidesmosome	Cell-basal lamina adhesion	Localized points of attachment	25–35 nm	Intermediate filaments (tonofilaments)
Adherens junction	Cell-cell adhesion	Continuous zones of attachment	20–25 nm	Actin microfilaments
Desmosome	Cell-cell adhesion	Localized points of attachment	25–35 nm	Intermediate filaments (tonofilaments)
Tight junction	Sealing spaces between cells	Membranes joined along ridges	None	Transmembrane junctional proteins, actin
Gap junction	Exchange of ions and molecules between cells	Connexons (transmembrane protein complexes with 3-nm pores)	2–3 nm	Connexins in one membrane align with those in another to form channels between cells

Food Poisoning and “Bad Bugs”: The Cell Surface Connection

Cell adhesion and cell recognition play important roles during the construction and maintenance of tissues in the human body. Surprisingly, foreign invaders that attack the human body can use the very same proteins that healthy cells require for cell adhesion to gain entry into the body. Here, we consider one example of how bacteria attach to and infect human cells: enteropathogenic bacteria.

Enteropathogenic Bacteria Use Normal Cell Adhesion Proteins to Infect Host Cells

One good example of this sort of “molecular hijacking” of normal cell adhesion processes occurs when pathogenic bacteria enter the digestive tract (such bacteria are called enteropathogenic bacteria; *entero* comes from the Greek word for “intestine”). Such bacteria are responsible for several types of food poisoning, and their combined effects have a substantial impact on public health. Although some pathogenic bacteria can use multiple methods for gaining entry into the gut, in several well-studied cases, they attach to cell adhesion molecules such as integrins or cadherins.

One of the best-studied examples of such subversion of cell adhesion is the enteric pathogen *Yersinia pseudotuberculosis*. Infection by bacteria of the genus *Yersinia*, which usually occurs via contaminated water and food, typically results in gastroenteritis with diarrhea and vomiting 24–48 hours after exposure. *Y. pseudotuberculosis* uses a 986-amino acid outer membrane protein, called *invasin*, to penetrate mammalian cells. Surprisingly, the cellular receptors for invasin are integrins that contain β_1 subunits on the

surface of cells lining the gut (Figure 17A-1). Identification of the cellular receptor for *Yersinia* was an important discovery because it showed that bacteria could invade cells by targeting common mammalian cell surface proteins.

As the molecular pathways used by other bacteria to invade host cells have been identified, such co-opting of normal cell surface proteins has emerged as a common theme in pathogenesis. A second enteropathogenic bacterium, *Shigella flexneri*, also attaches to an integrin ($\alpha_5\beta_1$) via proteins on its surface. *Shigella* infection results in dysentery and is usually caused by contamination of raw foods by food handlers. Approximately 300,000 cases of shigellosis occur annually in the United States, making it a significant health problem.

Another well-studied example of subversion of cell adhesion is *Listeria monocytogenes*. *Listeria* infection can occur through exposure to improperly prepared raw foods, such as raw milk and hamburger. Although the incidence of listeriosis in the United States is not high (about 2000 people annually develop symptoms), once infection occurs, it is very serious. Approximately 25% of those infected die, and many of these people contract bacterial meningitis. *Listeria* expresses a protein called *internalin A* on its surface that can bind to E-cadherin on the surface of cells in the gut (Figure 17A-1). We now know that just as these bacteria “hijack” the normal cell adhesion machinery of gut cells, they can do the same with the cytoskeleton once they are inside an infected cell (see Box 15A, page 441).

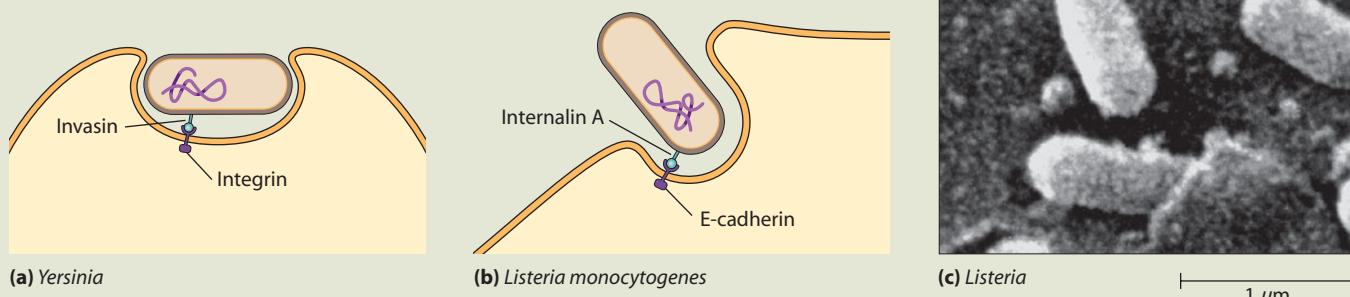

FIGURE 17A-1 Bacterial Pathogens and Cell Adhesion Proteins. Bacteria that invade the lining of the human digestive tract attach to cell adhesion receptors on the surface of intestinal cells. (a) Species in the genus *Yersinia* express a protein called invasin that attaches to integrins on gut cells that have β_1 subunits. (b) *Listeria monocytogenes* expresses a protein called internalin A that binds to E-cadherin on intestinal cells. (c) *Listeria* attached to the surface of cultured epithelial cells (SEM).

The structure of a typical desmosome is shown in Figure 17-8. The plasma membranes of the two adjacent cells are aligned in parallel, separated by a space of about 25–35 nm. The extracellular space between the two membranes is called the *desmosome core*. The desmosome core consists of the desmosomal cadherins, *desmocollin* and *desmoglein* (see Figure 17-3b). Unlike E-cadherin, desmocollins and desmogleins probably interact het-

erophilically across the intercellular space. Like other cadherins, linker proteins bind to their cytosolic tail and link them to the cytoskeleton. The β -catenin family protein *plakoglobin* binds to desmocollin. Plakoglobin in turn binds to a protein called *desmoplakin*. Desmoplakin in turn attaches to *tonofilaments*, which are composed of intermediate filaments such as *vimentin*, *desmin*, or *keratin*. A thick *plaque* containing these linker proteins

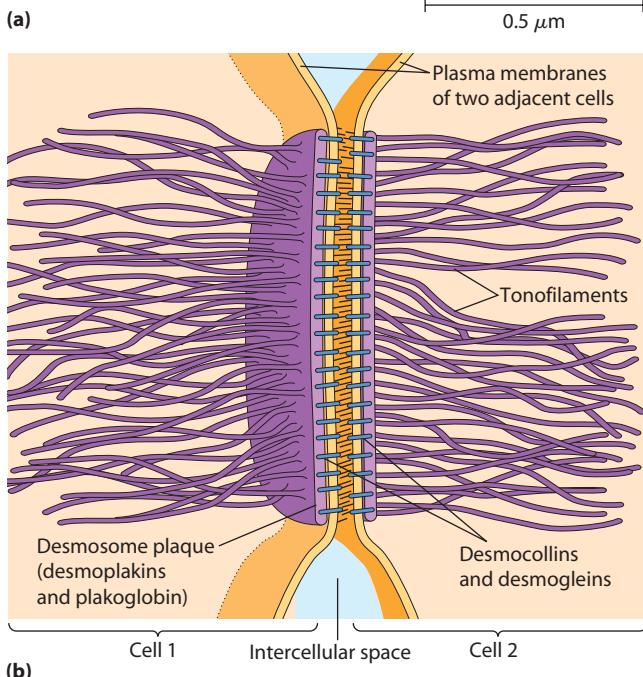

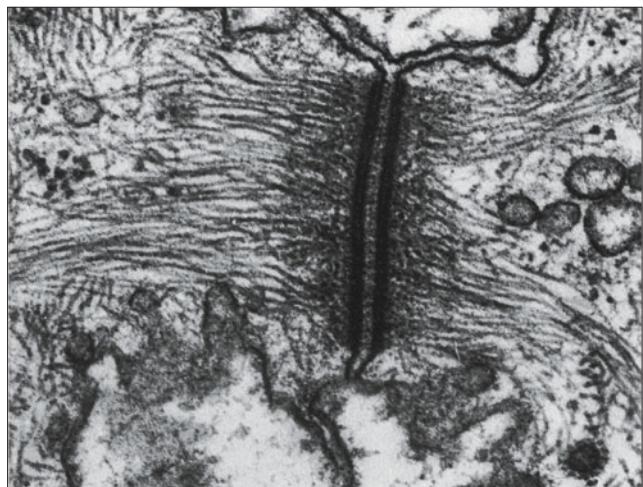

FIGURE 17-8 Desmosome Structure. (a) An electron micrograph of a desmosome joining two cells in the skin of a newt (TEM). (b) A schematic diagram of a desmosome. The distance between cells in the desmosome region is 25–35 nm, about that for a nonjunction region. The desmosome core between the two membranes is filled with cadherins (desmocollins and desmogleins). The plaque on the cytoplasmic side of the membrane contains desmoplakins and plakoglobin, and it is linked to tonofilaments, which are intermediate filaments consisting of keratin, desmin, or vimentin, depending on the cell type. By connecting tonofilaments from adjacent cells together, desmosomes help provide mechanical strength to epithelial sheets.

and tonofilaments is found just beneath the plasma membrane of each of the two adjoining cells.

Loss of desmosomal components can be devastating. For example, mice lacking plakoglobin die with heart failure and skin defects. Similarly, mutations in desmocollins expressed in the heart can lead to damage to the heart muscle in adult human patients. Human patients

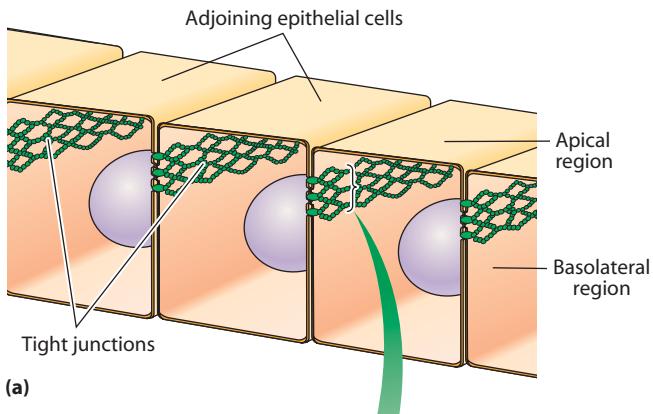

who develop autoimmune reactions against components of their desmosomes develop blistering diseases of the skin known as *pemphigus*. Some patients develop antibodies against desmogleins, while others generate antibodies against linker proteins, such as desmoplakin. Similar blistering disorders arise when human patients have mutations in the genes encoding desmosomal proteins.

Tight Junctions Prevent the Movement of Molecules Across Cell Layers

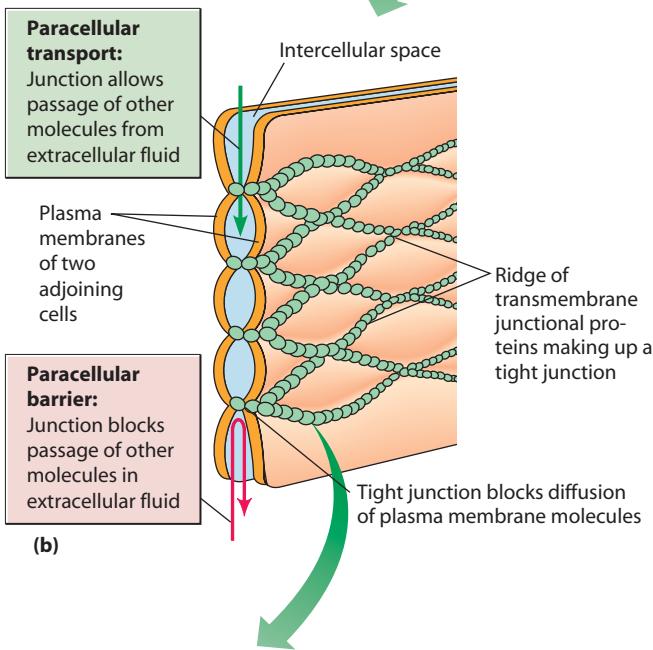

A key feature of epithelial tissues is that they form barriers between the internal cells of the body and the outside world. For example, intestinal cells must seal off the fluids that pass through the digestive tract from the internal fluids of the body. Epithelial cells, therefore, need specialized structures that serve to seal them tightly together. **Tight junctions** serve this function. As their name implies, they leave no space at all between the plasma membranes of adjacent cells (Figure 17-9). The tight junctions between adjacent cells in an epithelium lining an organ or body cavity form a continuous belt around the apical ends of the lateral surfaces of each cell, just apical to the adherens junction. These belts together form a formidable barrier (Figure 17-9a), so that molecules must typically cross the cell layer by passing through the cells themselves. Tight junctions are especially prominent in intestinal epithelial cells. Tight junctions are also abundant in the ducts and cavities of glands that connect with the digestive tract, such as the liver and pancreas, as well as in the urinary bladder, where they ensure that the urine stored in the bladder does not seep out between cells.

Tight junctions seal the membranes of adjacent cells together very effectively. However, the membranes are not actually in close contact over broad areas. Rather, they are connected along sharply defined ridges (Figure 17-9b). Tight junctions can be seen especially well by freeze-fracture microscopy, which reveals the inner faces of membranes. Each junction appears as a series of ridges that form an interconnected network extending across the junction (Figure 17-9c). Each ridge consists of a continuous row of tightly packed transmembrane junctional proteins about 3–4 nm in diameter. The result is rather like placing two pieces of corrugated metal together so that their ridges are aligned and then fusing the two pieces lengthwise along each ridge of contact. The fused ridges eliminate the intercellular space and effectively seal the junction, creating a barrier that prevents the passage of extracellular fluid through the spaces between adjacent cells. Not surprisingly, the number of such ridges across a junction correlates well with the tightness of the seal made by the junction. In addition to these close membrane appositions, scaffolding proteins at tight junctions recruit cytoskeletal proteins, such as F-actin, to tight junctions.

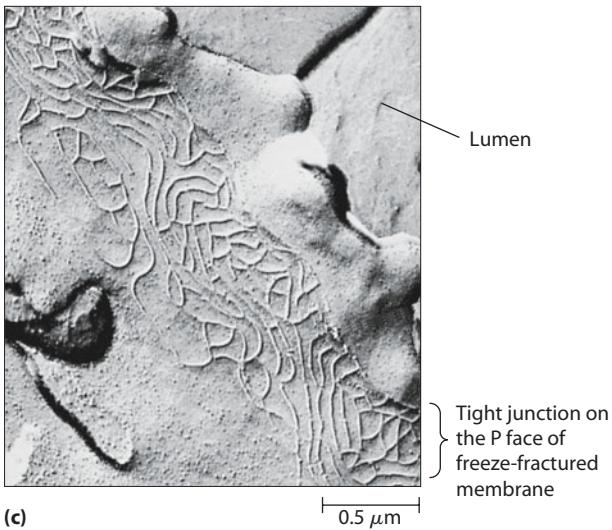

The properties of tight junctions have been studied by incubating tissues in the presence of electron-opaque tracer molecules and then using electron microscopy to

(a)

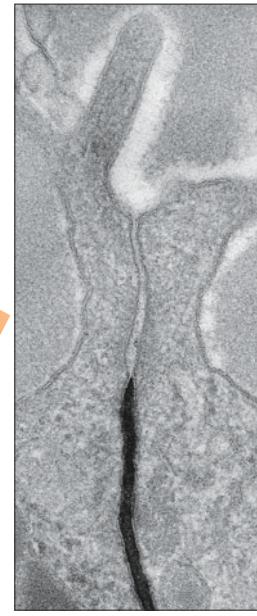

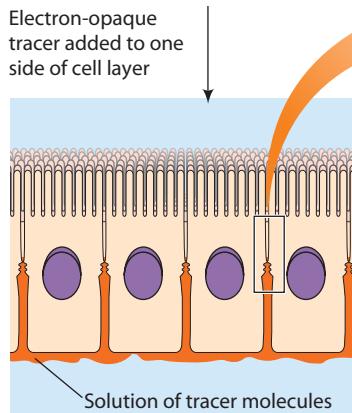

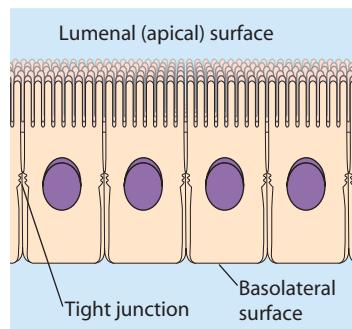

(b)

(c)

FIGURE 17-9 Tight Junction Structure. (a) A schematic representation of several adjoining epithelial cells connected by tight junctions. (b) Transmembrane junctional proteins in the plasma membranes of two adjacent cells are clustered along the points of contact, forming ridges of protein particles that join the two plasma membranes together tightly. Tight junctions prevent the passage of extracellular molecules through the spaces between cells (red arrows) and also block lateral movement of transmembrane proteins. (c) This electron micrograph illustrates tight junctions between cells in a frog bladder, as revealed by the freeze-fracture technique. Tight junctions appear as raised ridges on the protoplasmic (P) face of the membrane. The lumen is the cavity of the bladder (TEM).

(a)

FIGURE 17-10 Experimental Evidence Demonstrating That Tight Junctions Create a Permeability Barrier. (a) When an electron-opaque tracer is added to the extracellular space on one side of an epithelial cell layer, tracer molecules penetrate into the space between adjacent cells only to the point where they encounter a tight junction. (b) Because the tracer molecules are electron opaque, their penetration into the intercellular space can be visualized by electron microscopy (TEM).

observe the movement of the tracer through the extracellular space. As **Figure 17-10** illustrates, tracer molecules diffuse into the narrow spaces between adjacent cells until they encounter a tight junction, which blocks further movement.

Role of Tight Junctions in Blocking Lateral Movement of Membrane Proteins. Tight junctions act like “gates,” preventing the movement of fluids, ions, and molecules between cells. In addition, tight junctions act like “fences,” blocking the lateral movement of lipids and proteins

within the membrane. Lipid movement is blocked in the outer monolayer only, but the movement of integral membrane proteins is blocked entirely. As a result, different kinds of integral membrane proteins can be maintained in the portions of a plasma membrane on opposite sides of a tight junction belt.

Claudins Form a Seal at Tight Junctions

Tight junctions contain several major transmembrane proteins. These include a transmembrane protein known as *occludin* and immunoglobulin superfamily proteins known as *junctional adhesion molecules (JAMs)*. In addition, tight junctions contain **claudins**. Claudins have four membrane-spanning domains; the largest extracellular loop contains charged amino acids that are thought to allow passage of specific ions (**Figure 17-11**). Claudins in the plasma membrane of adjacent cells are thought to interlock to form a tight seal. Charged amino acids in the large extracellular loop of claudins are thought to form ion-selective pores that allow passage of specific ions through the epithelium. Because in this case ions move between cells, rather than through them, this type of transport is termed **paracellular transport** (see Figure 17-9). When cells that do not make tight junctions are forced to express claudins, they form junctions that look

very similar to tight junctions. In addition to their functions in assembling tight junctions, claudins appear to regulate paracellular transport of ions across epithelia (see below). Different claudins are expressed in different epithelial tissues and are thought to confer on these tissues different permeability properties. Mutations in one claudin (claudin-16) result in *familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC)*, an autosomal recessive disease characterized by severe Mg^{2+} and Ca^{2+} imbalance.

Gap Junctions Allow Direct Electrical and Chemical Communication Between Cells

A **gap junction** is a region where the plasma membranes of two cells are aligned and brought into intimate contact, with a gap of only 2–3 nm in between, spanned by small molecular “pipelines.” The gap junction thus provides a point of cytoplasmic contact between two adjacent cells through which ions and small molecules can pass. It allows adjacent cells to be in direct electrical and chemical communication with each other.

The structure of gap junctions is illustrated in **Figure 17-12**. At a gap junction, the two plasma membranes from adjacent cells are joined by tightly packed, hollow cylinders called **connexons**. A single gap junction may consist of just a few or as many as thousands of clustered connexons. In vertebrates, each connexon is a circular assembly of six subunits of the protein *connexin*. Invertebrates do not have connexins. Instead, they produce proteins called *innexins* that appear to serve the same function.

Many different connexins (more than a dozen types) are found in different tissues, but each one functions similarly in forming connexons. The assembly spans the membrane and protrudes into the space, or gap, between the two cells (Figure 17-12a). Each connexon has a diameter of about 7 nm and a hollow center that forms a very thin hydrophilic channel through the membrane. The channel is about 3 nm in diameter at its narrowest point—just large enough to allow the passage of ions and small molecules but too small to allow proteins, nucleic acids, and organelles through. Included in this range are single sugars, amino acids, and nucleotides—most of the molecules involved in cellular metabolism. By injecting fluorescent molecules into cells connected by gap junctions, researchers have shown that gap junctions allow the passage of solutes with molecular weights up to about 1200.

Although they are formed in a closed state initially, once connexons from adjacent cells meet, the cylinders in the two membranes join end to end. They form direct channels of communication between the two cells that can be seen with an electron microscope (Figure 17-12, parts b and c). Once fully formed, conditions inside of the cell, including electrical potential, concentration of second

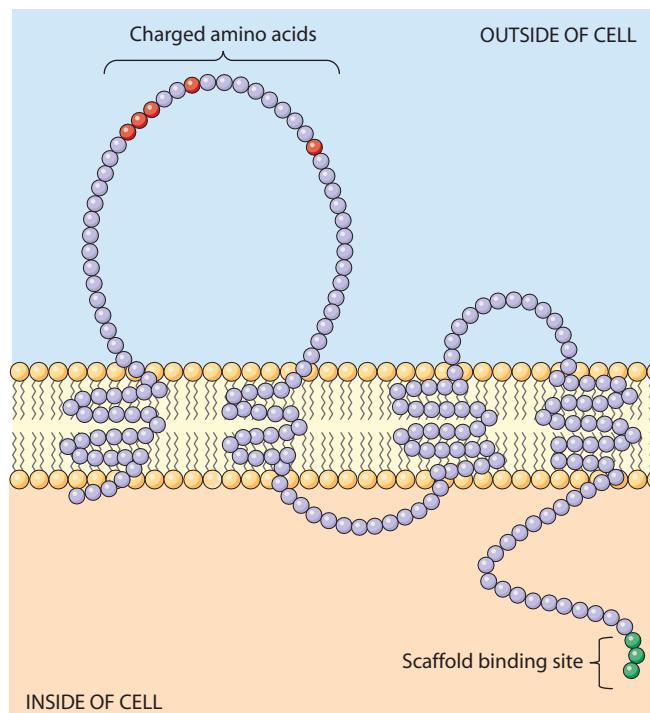

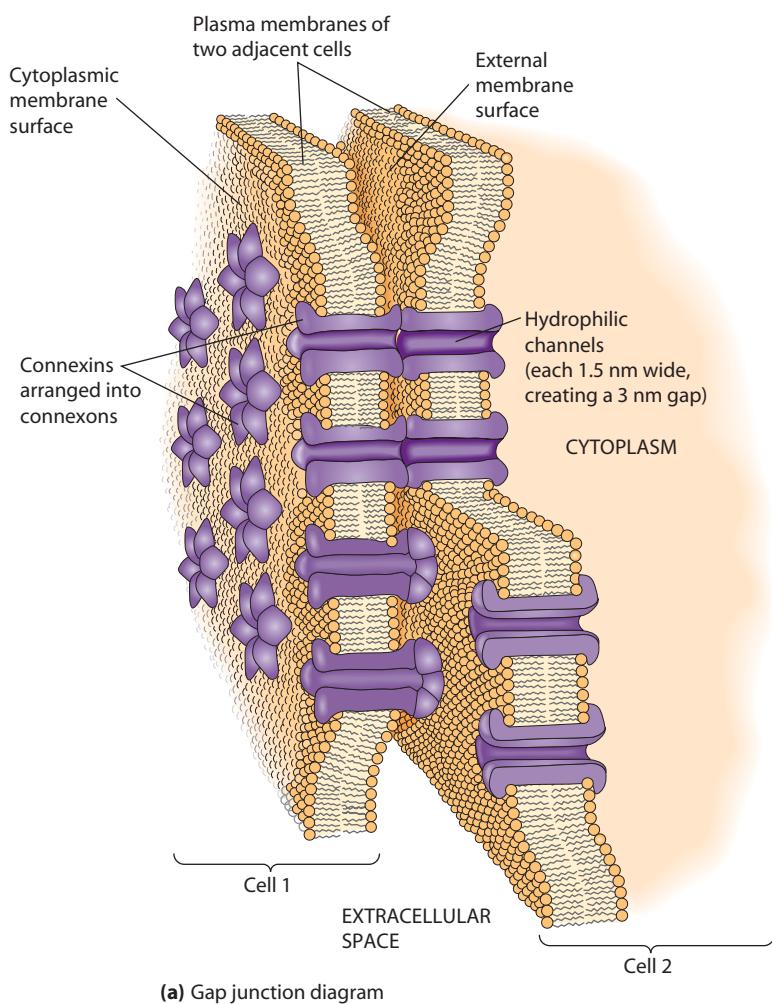

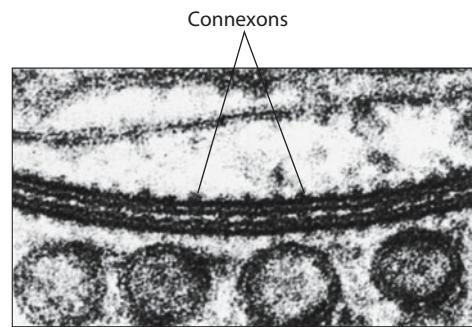

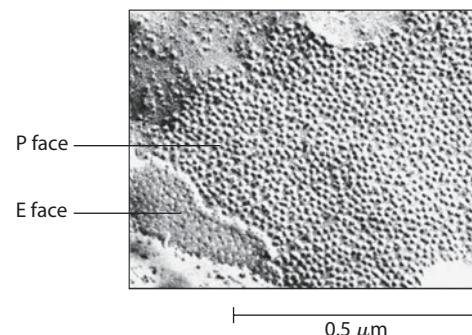

FIGURE 17-11 Claudin Structure. Claudins have four transmembrane domains and characteristic extra- and intracellular loops. The largest extracellular loop contains charged amino acids that are thought to interact with claudins on a neighboring cell to create a paracellular pore through which ions can pass. The C-terminus of claudins can bind scaffolding proteins in the cytosol.

The junction appears as an aggregation of intramembranous particles on the protoplasmic (P) face and as a series of pits on the exterior (E) face of the membrane (TEM).

 [VIDEOS www.thecellplace.com](http://www.thecellplace.com) Connexon structure

messengers, and other conditions, can influence whether gap junctions are open or closed.

Gap junctions occur in most vertebrate and invertebrate cells. They are especially abundant in tissues such as muscle and nerve, where extremely rapid communication between cells is required (e.g., in electrical synapses; see Chapter 13). In heart tissue, gap junctions facilitate the flow of electrical current that causes the heart to beat. These roles are confirmed by analyzing mutations in connexins and innexins. For example, mice lacking one type of connexin have defects in conducting electrical impulses in the heart. Several human disorders have been directly linked to defects in gap junctions. These include several types of demyelinating neurodegenerative diseases, various skin disorders, formation of cataracts, and some types of deafness.

The Extracellular Matrix of Animal Cells

Tissues are not simply composed of cells. Cells interact with extracellular materials that are crucial for tissue structure and function. In animal cells, this **extracellular matrix (ECM)** takes on a remarkable variety of forms in different tissues. **Figure 17-13** illustrates just three examples. **Bone** consists largely of a rigid extracellular matrix that contains a tiny number of interspersed cells. **Cartilage** is another tissue constructed almost entirely of matrix materials, although the matrix is much more flexible than in bone. In contrast to bone and cartilage, the *connective tissue* surrounding glands and blood vessels has a relatively gelatinous extracellular matrix containing numerous interspersed fibroblast

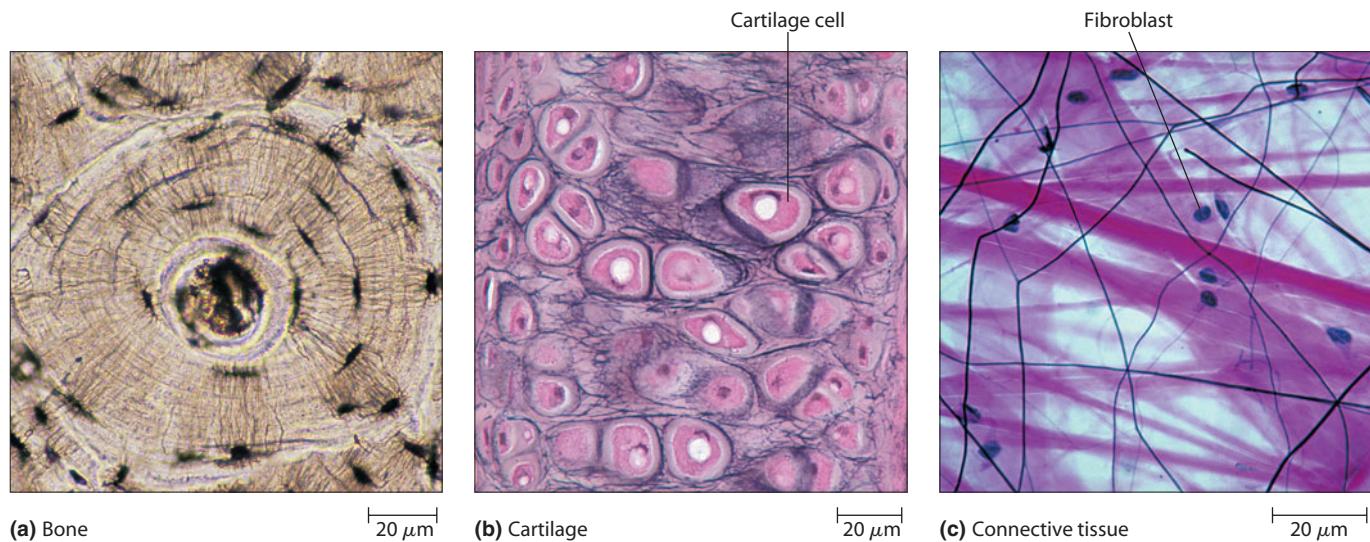

FIGURE 17-13 Different Kinds of Extracellular Matrix. The ECM takes on different forms in different tissues, as these images illustrate. (a) In bone tissue, a hard, calcified ECM is laid down in concentric rings around central canals. The small elliptical depressions are regions where bone cells are found. (b) In cartilage, the cells are embedded in a flexible matrix that contains large amounts of proteoglycans. (c) In the connective tissue found under skin, fibroblasts are surrounded by an ECM that contains large numbers of collagen fibers.

cells. As we have already seen, epithelial cells produce a specialized ECM known as a basal lamina.

These examples illustrate the diverse roles that the ECM plays in determining the shape and mechanical properties of organs and tissues. Despite this diversity of function, the ECM of animal cells almost always consists of the same three classes of molecules: (1) structural proteins such as *collagens* and *elastins*, which give the ECM its strength and flexibility; (2) protein-polysaccharide complexes called *proteoglycans* that provide the matrix in which the structural molecules are embedded; and (3) adhesive glycoproteins such as *fibronectins* and *laminins*, which allow cells to attach to the matrix (Table 17-2). The considerable variety in the properties of the ECM in different tissues results not only from differences in the types of structural proteins and the kinds of proteoglycans present but also from variations in the ratio of structural proteins—collagen, most commonly—to proteoglycans and in the kinds and amounts of adhesive glycoproteins present. We will consider each of these classes of ECM constituents in turn.

Collagens Are Responsible for the Strength of the Extracellular Matrix

The most abundant component of the ECM in animals is a large family of closely related proteins called **collagens**,

which form fibers with high tensile strength and thus account for much of the strength of the ECM. Considered collectively, collagen is the most abundant protein in vertebrates, accounting for as much as 25–30% of total body protein. Collagen is secreted by several types of cells in connective tissues, including *fibroblasts*. Without collagen, cells in these and other tissues would not have sufficient adhesive strength to maintain a given form. Indeed, several human diseases result from mutations in collagens. For example, Ehlers–Danos syndrome is a group of inherited disorders characterized by excessive looseness (laxity) of the joints, hyperelastic skin that is fragile and bruises easily, and/or easily damaged blood vessels. These disorders arise from mutations in collagens. Vitamin C is an essential cofactor for collagen synthesis. Vitamin C deficiency leads to scurvy, which was a historically important disease among sailors.

Two defining characteristics are shared by all collagens: their occurrence as a rigid *triple helix* of three intertwined polypeptide chains and their unusual amino acid composition. Specifically, collagens are high in both the common amino acid glycine and the unusual amino acids hydroxylysine and hydroxyproline, which rarely occur in other proteins. (For the structures of hydroxylysine and hydroxyproline, see Figure 7-25c.) The high glycine content makes the triple helix possible because the spacing of the glycine

Table 17-2 **Extracellular Structures of Eukaryotic Cells**

Kind of Organism	Extracellular Structure	Structural Fiber	Components of Hydrated Matrix	Adhesive Molecules
Animals	Extracellular matrix (ECM)	Collagens and elastins	Proteoglycans	Fibronectins and laminins
Plants	Cell wall	Cellulose	Hemicelluloses and extensins	Pectins

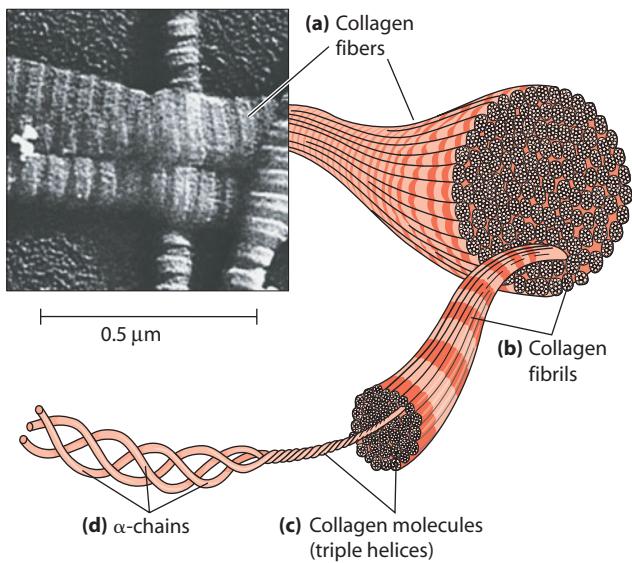

FIGURE 17-14 The Structure of Collagen. (a) Collagen fibers as seen by SEM. (b) A collagen fiber contains many fibrils, each of which is a bundle of collagen molecules, also called tropocollagen. (c) Each collagen molecule is a triple helix consisting of (d) three entwined α chains. The repeating bands visible on the fibers in the SEM partially reflect the regular but offset way that collagen molecules associate laterally to form fibrils; see Figure 17-15 for details of collagen assembly.

residues places them in the axis of the helix, and glycine is the only amino acid small enough to fit in the interior of a triple helix.

In most animal tissues, **collagen fibers** can be seen in bundles throughout the extracellular matrix when viewed by scanning electron microscopy (**Figure 17-14a**). One of the most striking features of collagen fibers is their enormous physical strength. For example, it takes a load of more than 20 pounds (about 9 kg) to tear a collagen fiber just 1 millimeter in diameter! As illustrated in Figure 17-14b, each collagen fiber is composed of numerous *fibrils*. A fibril, in turn, is made up of many collagen molecules, each consisting of three polypeptides called α chains that are twisted together into a rigid, right-handed triple helix (Figure 17-14, parts c and d). Collagen molecules are about 270 nm in length and 1.5 nm in diameter and are aligned both laterally and end to end within the fibrils. A typical collagen fiber has about 270 collagen molecules in cross section.

A Precursor Called Procollagen Forms Many Types of Tissue-Specific Collagens

Given the complexity of a collagen fiber, it is important to ask how such an elaborate structure is generated (**Figure 17-15**). In the lumen of the endoplasmic reticulum (ER), three α chains assemble to form a triple helix called

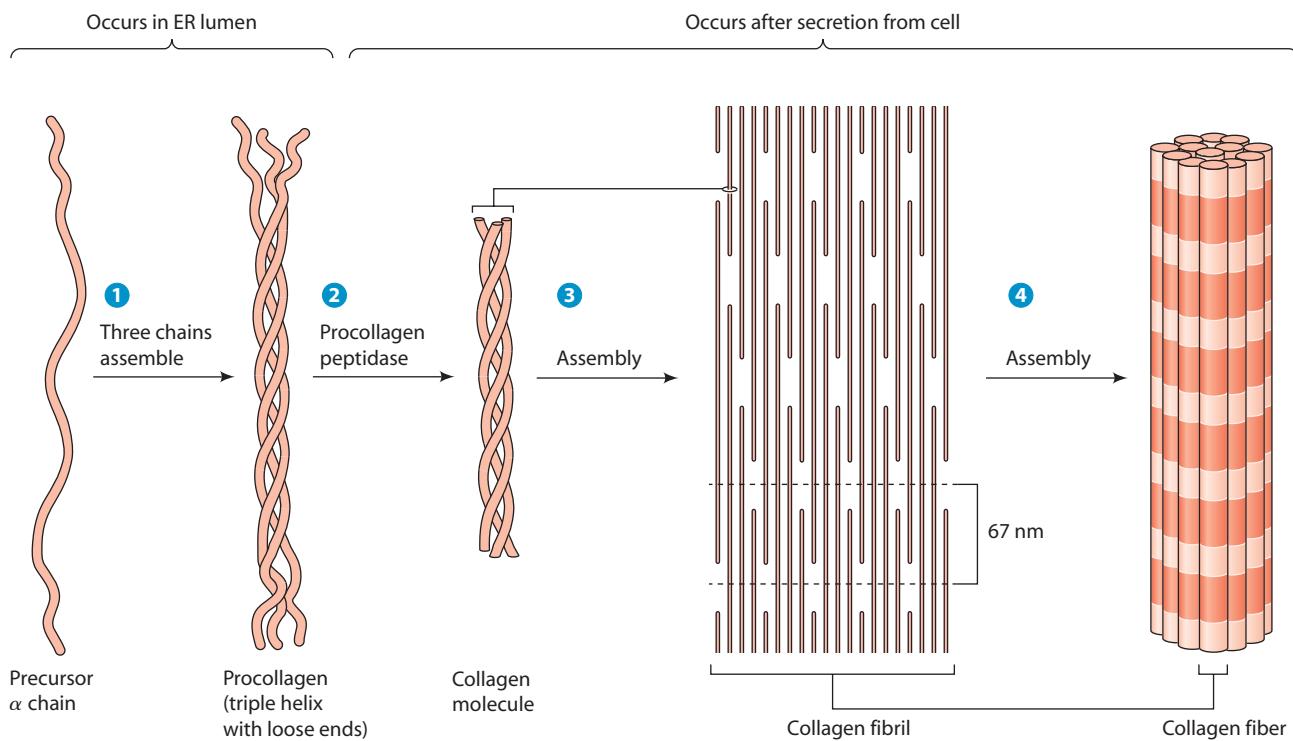

FIGURE 17-15 Collagen Assembly. ① Collagen precursor chains are assembled in the ER lumen to form triple-helical procollagen molecules. ② After secretion from the cell, procollagen is converted to collagen in a peptide-cleaving reaction catalyzed by the enzyme procollagen peptidase. ③ The molecules of collagen, also called tropocollagen, then bind to each other and self-assemble into collagen fibrils. ④ The fibrils assemble laterally into collagen fibers. In striated collagen, the 67-nm repeat distance is created by packing together rows of collagen molecules in which each row is displaced by one-fourth the length of a single molecule.

Table 17-3 Types of Collagens, Their Occurrence, and Their Structure

Type of Structure	Collagen Type(s)	Representative Tissues
Long fibrils	I, II, III, V, XI	Skin, bone, tendon, cartilage, muscle
Fibril-associated, with interrupted triple helices	IX, XII, XIV	Cartilage, embryonic skin, tendon
Fibril-associated, forms beaded filaments	VI	Interstitial tissues
Sheets	IV, VIII, X	Basal laminae, cartilage growth plates
Anchoring fibrils	VII	Epithelia
Transmembrane	XVII	Skin
Other	XIII, XV, XVI, XVIII, XIX	Basement membranes, assorted tissues

procollagen. At both ends of the triple-helical structure, short nonhelical sequences of amino acids prevent the formation of collagen fibrils, as long as the procollagen remains within the cell. Once procollagen is secreted from the cell into the intercellular space, it is converted to collagen by *procollagen peptidase*, an enzyme that removes the extra amino acids from both the N- and C-terminal ends of the triple helix. The resulting collagen molecules spontaneously associate to form mature collagen fibrils, which then assemble laterally into fibers.

The stability of the collagen fibril is reinforced by hydrogen bonds that involve the hydroxyl groups of hydroxyproline and hydroxylysine residues in the α chains. These hydrogen bonds form crosslinks both within and between the individual collagen molecules in a fibril. In addition, specialized types of collagen are often present on the surface of collagen fibrils. The triple-helical structure of these specialized collagens is interrupted at intervals, allowing the molecules to bend and hence to serve as flexible bridges between adjacent collagen fibrils or between collagen fibrils and other matrix components.

Vertebrates have about 25 kinds of α chains, each encoded by its own gene and having its own unique amino acid sequence. These different α chains combine in various ways to form at least 15 types of collagen molecules, most of which are found in specific tissues. **Table 17-3** lists the types and the tissues where they are found. Types I, II, and III are the most abundant forms. Type I alone makes up about 90% of the collagen in the human body.

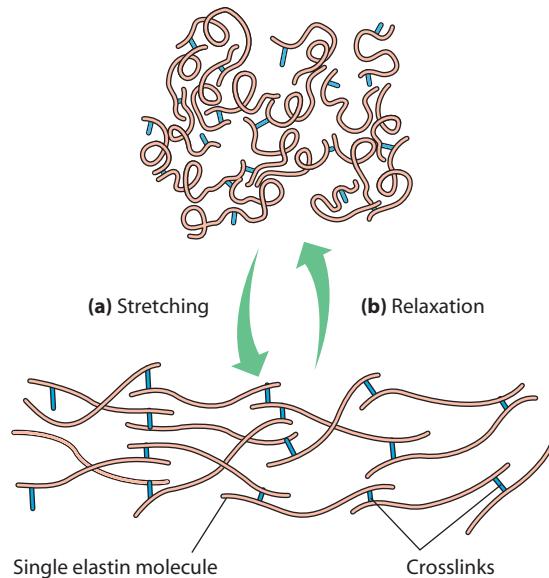

When fibrils containing type I, II, III, or V collagen molecules are examined with an electron microscope, they exhibit a characteristic pattern of dark crossbands, or *striations*, that repeat at intervals of about 67 nm (see Figure 17-14a). These bands reflect the regular but offset way that triple helices associate laterally to form fibrils (Figure 17-15, ③). Type IV collagen forms very fine, unstriated fibrils. The structures of other collagen types are less well characterized.

Elastins Impart Elasticity and Flexibility to the Extracellular Matrix

Although collagen fibers give the ECM great tensile strength, their rigid, rodlike structure is not particularly

suited to the elasticity and flexibility required by some tissues, such as lungs, arteries, skin, and the intestine, which change shape continuously. Elasticity is provided by stretchable elastic fibers, whose principle constituent is a family of ECM proteins called **elastins**. Like collagens, elastins are rich in the amino acids glycine and proline. However, the proline residues are not hydroxylated, and no hydroxylysine is present. Elastin molecules are crosslinked to one another by covalent bonds between lysine residues. Tension on an elastin network causes the overall network to stretch (**Figure 17-16a**). When the tension is released, the individual molecules relax, returning to their normal, less extended conformations. The crosslinks between molecules then cause the network to recoil to its original shape (**Figure 17-16b**).

The important roles of collagens and elastins are clearly demonstrated as people age. Over time, collagens become increasingly crosslinked and inflexible, and elastins are lost from tissues like skin. As a result, older

**FIGURE 17-16** Stretching and Recoiling of Elastin Fibers.

Each elastin molecule in the crosslinked network can assume either an extended (bottom) or compact (top) configuration. The fiber (a) stretches to its extended form when tension is exerted on it and (b) recoils to its compact form when the tension is released.

people often find that their bones and joints are less flexible, and their skin becomes wrinkled.

Collagen and Elastin Fibers Are Embedded in a Matrix of Proteoglycans

The hydrated, gel-like network in which the collagen and elastin fibrils of the ECM are enmeshed consists primarily of proteoglycans, glycoproteins in which a large number of glycosaminoglycans are attached to a single protein molecule.

Glycosaminoglycans (GAGs) are large carbohydrates characterized by repeating disaccharide units, as illustrated in **Figure 17-17** for the three most common types: *chondroitin sulfate*, *keratan sulfate*, and *hyaluronate*. In each case, one of the two sugars in the disaccharide repeating unit is an amino sugar, either *N-acetylglucosamine* (*GlcNAc*) or *N-acetylgalactosamine* (*GalNAc*). The other sugar in the disaccharide repeating unit is usually a sugar or a sugar acid, commonly *galactose* (*Gal*) or *glucuronate* (*GlcUA*). In most cases, the amino sugar has one or more sulfate groups attached. Of the GAG repeating units shown in Figure 17-17, only hyaluronate contains no sulfate groups. Because GAGs are hydrophilic molecules with many negatively charged sulfate and carboxyl groups, they attract both water and cations, thereby forming the hydrated, gelatinous matrix in which collagen and elastin fibrils become embedded.

Most glycosaminoglycans in the ECM are covalently bound to protein molecules to form **proteoglycans**. Each proteoglycan consists of numerous GAG chains attached along the length of a **core protein**, as shown in Figure 17-17. Many kinds of proteoglycans can be formed by the combination of different core proteins and GAGs of varying types and lengths. Proteoglycans vary greatly in size, depending on the molecular weight of the core protein (which ranges from about 10,000 to over 500,000) and the number and length of the carbohydrate chains (1–200 per molecule, with an average length of about 800 monosaccharide units). Most proteoglycans are huge. They have molecular weights in the range of 0.25–3 million. Proteoglycans are linked directly to collagen fibers to make up the fiber/network structure of the ECM.

In some cases, the proteoglycans are themselves integral components of the plasma membrane, with their core polypeptides embedded within the membrane. In other cases, proteoglycans are linked covalently to membrane phospholipids. Alternatively, either proteoglycans or collagen may bind to specific receptor proteins on the outer surface of the plasma membrane.

In many tissues, proteoglycans are present as individual molecules. In cartilage, however, numerous proteoglycans become attached to long molecules of hyaluronate, forming large complexes as shown in Figure 17-17. A single such complex can have a molecular weight of many millions and may exceed several micrometers in length.

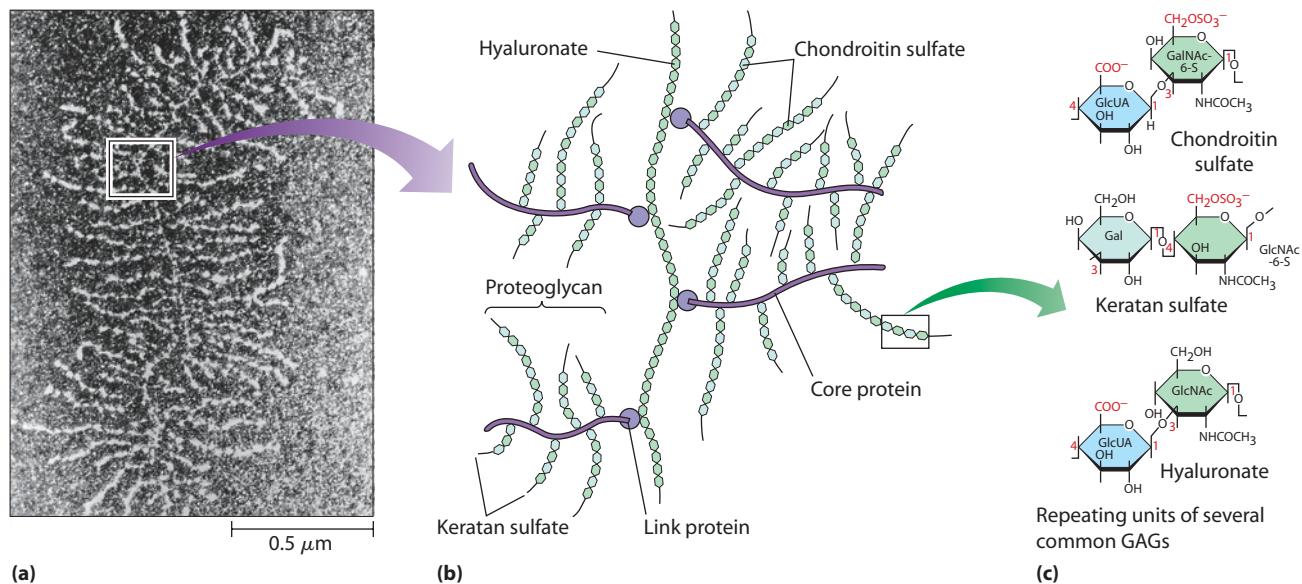

FIGURE 17-17 Proteoglycan Structure in Cartilage. In cartilage, many proteoglycans associate with a hyaluronate backbone to form a complex that is readily visible with an electron microscope. (a) A hyaluronate-proteoglycan complex isolated from bovine cartilage (TEM). (b) A diagram of a small portion of the structure showing core proteins of proteoglycans attached via linker proteins to a long hyaluronate molecule. Short keratan sulfate and chondroitin sulfate chains are linked covalently along the length of the core proteins. Proteoglycans have a carbohydrate content of about 95%. (c) Structures of the disaccharide repeating units in three common extracellular glycosaminoglycans (GAGs) found in the extracellular matrix of animal cells. The repeating unit of chondroitin sulfate (top) consists of glucuronate, the ionized form of glucuronic acid (GlcUA), and *N*-acetylgalactosamine (GalNAc). The repeating unit of keratan sulfate (middle) is galactose (Gal) and *N*-acetylglucosamine (GlcNAc). Hyaluronate (bottom) has a repeating unit consisting of GlcUA and GlcNAc.

The remarkable resilience and pliability of cartilage are due mainly to the properties of these complexes. Smaller proteoglycans are also known to be involved in facilitating growth factor signaling, which we learned about in Chapter 14. For example, a proteoglycan called *syndecan* is a modulator of fibroblast growth factor signaling.

Free Hyaluronate Lubricates Joints and Facilitates Cell Migration

Although most of the GAGs found in the extracellular matrix exist only as components of proteoglycans and not as free glycosaminoglycans, **hyaluronate** is an exception. In addition to its role as the backbone of the proteoglycan complex in cartilage, hyaluronate occurs as a free molecule consisting of hundreds or even thousands of repeating disaccharide units. Hyaluronate molecules have lubricating properties and are most abundant in places where friction must be reduced, such as the joints between movable bones.

Adhesive Glycoproteins Anchor Cells to the Extracellular Matrix

Direct links between the ECM and the plasma membrane are reinforced by a family of *adhesive glycoproteins* that bind proteoglycans and collagen molecules to each other and to receptors on the membrane surface. These proteins typically have multiple domains, some with binding sites for macromolecules in the ECM and others with binding sites for membrane receptors. The two most common kinds of adhesive glycoproteins are the *fibronectins* and *laminins*. Many of the membrane receptors to which these glycoproteins bind belong to a family of transmembrane proteins called *integrins*. In the following sections, we discuss each family of proteins.

Fibronectins Bind Cells to the ECM and Guide Cellular Movement

Fibronectins are a family of closely related adhesive glycoproteins in the ECM and are widely distributed in vertebrates. Fibronectins occur in soluble form in blood and other body fluids, as insoluble fibrils in the extracellular matrix, and as an intermediate form loosely associated with cell surfaces. These different forms of the protein are generated because the RNA transcribed from the fibronectin gene is processed to generate many different mRNAs.

A fibronectin molecule consists of two very large polypeptide subunits that are linked near their carboxyl ends by a pair of disulfide bonds (Figure 17-18). Each subunit has about 2500 amino acids and is folded into a series of rodlike domains connected by short, flexible segments of the polypeptide chain. Several of the domains bind to one or more specific kinds of macromolecules located in the ECM or on cell surfaces, including several

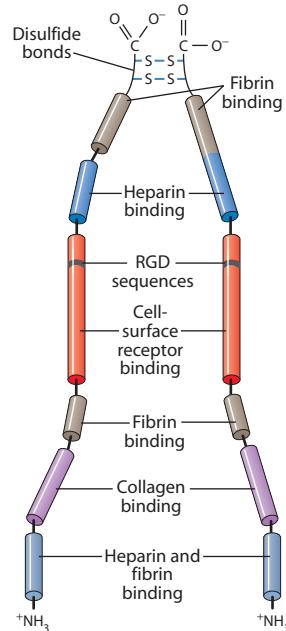

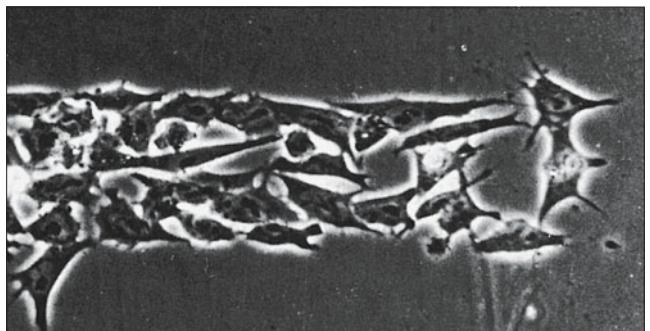

FIGURE 17-18 Fibronectin Structure. A fibronectin molecule consists of two nearly identical polypeptide chains joined by two disulfide bonds near their carboxyl ends. Each polypeptide chain is folded into a series of domains linked by short, flexible segments. These domains have binding sites for ECM components or for specific receptors on the cell surface. The receptor-binding domain contains the tripeptide sequence RGD (arginine-glycine-aspartate), which is recognized by fibronectin receptors. Besides the binding activities noted, fibronectin has binding sites for heparan sulfate, hyaluronate, and gangliosides (glycosphingolipids that contain sialic acid groups).

types of collagen (I, II, and IV), heparin, and the blood-clotting protein fibrin. Other domains recognize and bind to cell surface receptors. The receptor-binding activity of these domains has been localized to a specific tripeptide sequence, RGD (arginine-glycine-aspartate). This *RGD sequence* is a common motif among extracellular adhesive proteins and is recognized by various integrins on the cell surface (see the following section).

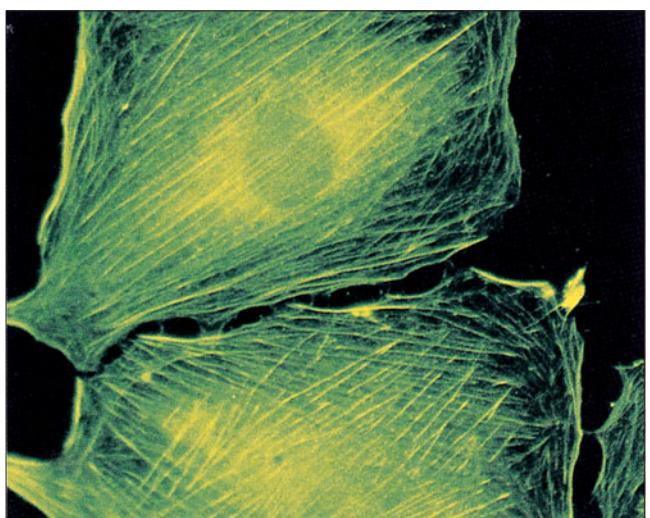

Effects of Fibronectin on Cell Shape and Cell Movement. Fibronectin binds to cell surface receptors as well as to ECM components such as collagen and heparin. It thus functions as a bridging molecule that attaches cells to the ECM. This anchoring role can be demonstrated experimentally by placing cells in a culture dish coated on the inside with fibronectin. Under these conditions, the cells attach to the surface of the dish more efficiently than they do in the absence of fibronectin. After attaching, the cells flatten out (Figure 17-19a), and components of the actin cytoskeleton become aligned with the fibronectin located outside the cell (Figure 17-19b, c). In some cases such alignment occurs because the cell remodels the ECM, dragging it into new arrangements. In other cases the cell aligns itself with the ECM.

Fibronectin is also involved in cellular movement. For example, when migratory embryonic cells are grown on

(c) Fibronectin

FIGURE 17-19 Interaction Between Fibronectin and Migrating Cells. (a) Cells from the neural crest (a type of migratory embryonic cell) preferentially migrate along a strip of fibronectin in vitro (phase contrast micrograph). (b and c) Fluorescence micrographs show the same cultured cells stained with fluorescent antibodies specific for either (b) actin or (c) fibronectin. Note that the extracellular fibronectin network and the intracellular actin microfilaments are aligned in a similar pattern.

www.thecellplace.com Fibronectin fibrils

fibronectin, they adhere readily to it (Figure 17-19a). The pathways followed by migrating cells are rich in fibronectin, suggesting that such cells are guided by binding to fibronectin molecules along the way. More direct evidence for the importance of fibronectin in embryos comes from studying genetically engineered mice that cannot produce fibronectin. Such mice have severe defects in some cells that make the musculature and the vasculature. These defects highlight the crucial importance of fibronectin during embryonic development.

A possible involvement of fibronectin in cancer is suggested by the observation that many kinds of cancer cells do not synthesize fibronectins, with an accompanying loss of normal cell shape and detachment from the ECM. If such cells are supplied with fibronectin, they often return to a more normal shape, recover their ability to bind to the ECM, and no longer appear malignant.

Effects of Fibronectin on Blood Clotting. The soluble form of fibronectin present in the blood, called *plasma fibronectin*, is involved in blood clotting. Fibronectin promotes blood clotting because it has several binding domains that recognize *fibrin*, the blood-clotting protein, and it can attach blood platelets to fibrin as the blood clot forms.

Laminins Bind Cells to the Basal Lamina

Another major adhesive glycoprotein present in the ECM is a family of proteins called **laminins**, which are conserved from simple invertebrates to humans. Unlike fibronectins, which occur widely throughout supporting tissues and body fluids, laminins are found mainly in the **basal lamina**. This thin sheet of specialized extracellular material, typically about 50 nm thick, underlies epithelial cells, thereby separating them from connective tissues (Figure 17-20). Basal laminae also surround muscle cells, fat cells, and the Schwann cells that form myelin sheaths around nerve cells.

Properties of the Basal Lamina. The basal lamina serves as a structural support that maintains tissue organization and as a permeability barrier that regulates the movement of molecules as well as cells. In the kidney, for example, an extremely thick basal lamina functions as a filter that allows small molecules but not blood proteins to move from the blood into the urine. The basal lamina beneath epithelial cells prevents the passage of underlying connective tissue cells into the epithelium but permits the migration of the white blood cells needed to fight infections. The effect of the basal lamina on cell migration is of special interest because some cancer cells show increased binding to the basal lamina. The resulting increase in the ability of cancer cells to bind to the basal lamina may facilitate their movement through it and allow them to migrate from one region of the body to another.

Despite differences in function and specific molecular composition from tissue to tissue, all forms of basal

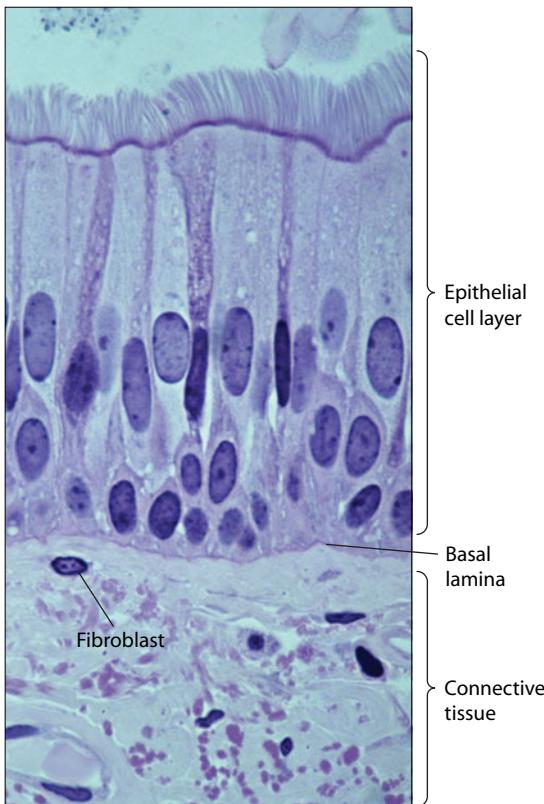

FIGURE 17-20 The Basal Lamina. The basal lamina is a thin sheet, typically about 50 nm, of matrix material that separates an epithelial cell layer from underlying connective tissue (TEM).

lamina contain type IV collagen, proteoglycans, laminins, and another glycoprotein called *entactin*, or *nidogen*. Fibronectins may be present, but laminins are the most abundant adhesive glycoproteins in the basal lamina. Laminins are thought to be localized mainly on the surface of the lamina that faces the overlying epithelial cells, where they help bind the cells to the lamina. Fibronectins, on the other hand, are located on the other side of the lamina, where they help anchor cells of the connective tissue.

Cells can alter the properties of the basal lamina by secreting enzymes that catalyze changes in the basal lamina. One important class of such enzymes is *matrix metalloproteinases (MMPs)*. These enzymes, which require metal ions as cofactors, degrade the ECM locally, allowing cells to pass through the ECM. Such activity is important for cells such as leukocytes to invade injured tissues during inflammation. MMPs are also involved in abnormal invasive behavior. The MMP activity of invasive cancer cells, such as metastatic melanoma cells, is very high. We will discuss these enzymes in more detail in Chapter 24.

Properties of Laminin. Laminin, a very large protein with a molecular weight of about 850,000, consists of three long polypeptides, denoted α , β , and γ . There are several types of each of the three subunits, which can combine to form many types of laminin. Disulfide bonds hold the polypep-

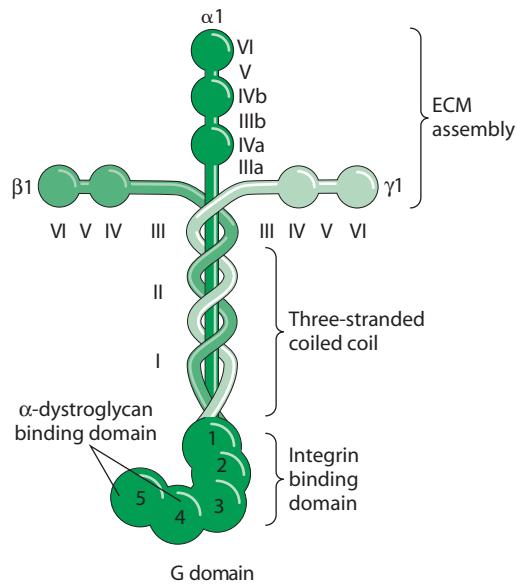

FIGURE 17-21 Laminin Structure. A laminin molecule consists of three large polypeptides— α , β , and γ —joined by disulfide bonds into a crosslinked structure. A portion of the long arm consists of a three-stranded coil. The functional domains on the ends of the α chain bind to organ-specific cell surface receptors, whereas those at the ends of the two arms of the cross are specific for type IV collagen. The cross-arms also contain laminin-laminin binding sites, thereby enabling laminin molecules to bind to each other and form large aggregates. Laminin also contains binding sites for heparin and heparan sulfate, as well as for entactin (not shown). Reprinted by permission from Macmillan Publishers Ltd: Fig. 1 from M. P. Marinkovich, "Laminin 332 in Squamous-Cell Carcinoma," *Nature Reviews Cancer* 7:370-380. Copyright 2007.

tide chains together in the shape of a cross, with part of the long arm wound into a three-stranded coil (Figure 17-21). Like fibronectin, laminin consists of several domains that include binding sites for type IV collagen, heparin, heparan sulfate, and entactin, as well as for laminin receptor proteins on the surface of overlying cells. Its binding sites allow laminin to serve as a bridging molecule that attaches cells to the basal lamina. Entactin molecules have binding sites for both laminin and type IV collagen and are therefore thought to reinforce the binding of type IV collagen and laminin networks in the basal lamina.

Integrins Are Cell Surface Receptors That Bind ECM Constituents

Fibronectins and laminins can bind to animal cells because the plasma membranes of most cells have specific receptors on their surfaces that recognize and bind to specific regions of the fibronectin or laminin molecule. These receptors—and those for a variety of other ECM constituents—belong to a large family of transmembrane proteins that are called **integrins** because of their role in *integrating* the cytoskeleton with the extracellular matrix. Integrins are important receptors because they are the primary means by which cells bind to ECM proteins such as collagen, fibronectin, and laminin.

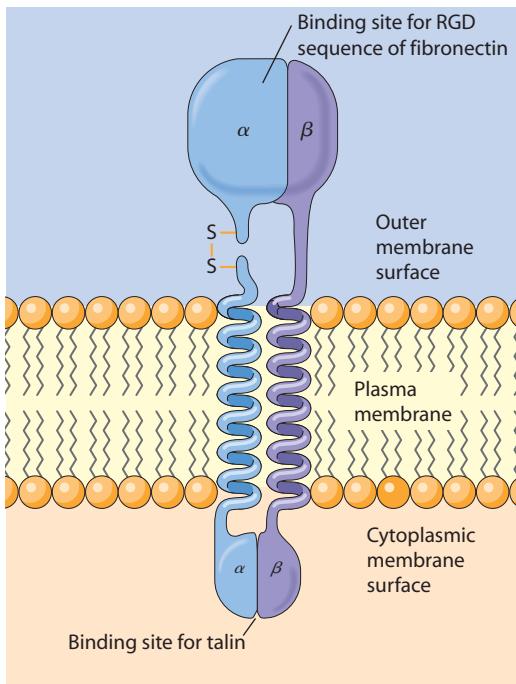

FIGURE 17-22 An Integrin: The Fibronectin Receptor. An integrin consists of α and β subunits, transmembrane polypeptides that associate with each other noncovalently to form a binding site for the ligand on the outer membrane surface and a binding site for a specific cytoskeletal protein on the inner membrane surface. Shown here is the fibronectin receptor ($\alpha_5\beta_1$), which has a binding site for fibronectin on the outer surface and a binding site for talin on the cytoplasmic side of the membrane. In this and several other integrins, the α subunit is split into two segments held together by a disulfide bond. Both the α and β subunits are glycosylated on the exterior side, although the sugar side chains are not shown here.

Structure of Integrins. An integrin consists of two large transmembrane polypeptides, the α and β subunits, that associate with each other noncovalently (Figure 17-22). Integrins differ from one another in their binding specificities and in the sizes of their subunits (molecular weight ranges: 110,000–140,000 for the α subunit, 85,000–91,000 for the β subunit). For a specific integrin, the extracellular portions of the α and β subunits interact to form the binding site for a particular ECM protein, with most of the binding specificity apparently depending on the α subunit. On the cytoplasmic side of the membrane, integrins have binding sites for specific molecules of the cytoskeleton, thereby mechanically linking the cytoskeleton and the ECM across the plasma membrane.

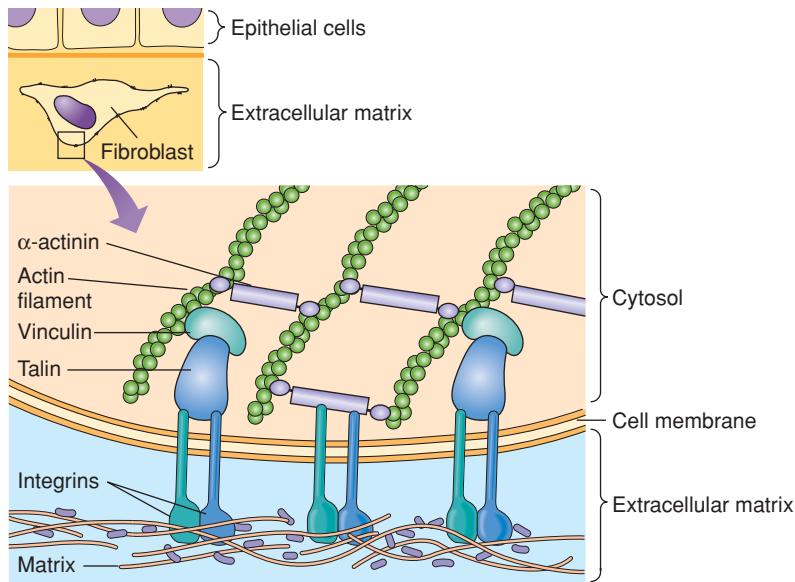

The presence of multiple types of both α and β subunits results in a large number of different integrin heterodimers, which vary in their binding specificities. For example, integrins containing a β_1 subunit are found on the surfaces of most vertebrate cells and mediate mainly cell-ECM interactions, whereas those containing a β_2 subunit are restricted to the surface of white blood cells and are involved primarily in cell-cell interactions. The most common integrin that binds fibronectin is $\alpha_5\beta_1$,

whereas $\alpha_6\beta_1$ binds laminin. Many integrins recognize the RGD sequence in the specific ECM glycoproteins that they bind. However, the binding site must recognize other parts of the glycoprotein molecule as well because integrins display a greater specificity of glycoprotein binding than can be accounted for by the RGD sequence alone.

Integrins and the Cytoskeleton. Although integrins link the extracellular matrix and the cytoskeleton, they do not do so directly. Instead, the tails of integrins interact with proteins in the cytosol that link integrins to cytoskeletal proteins. Integrins make two main types of connections to the cytoskeleton (Figure 17-23). Migratory and non-epithelial cells, such as fibroblasts, attach to extracellular matrix molecules via **focal adhesions**. Focal adhesions contain clustered integrins that interact with bundles of actin microfilaments via several linker proteins (Figure 17-23a, b). These include *talin*, which can bind to the actin-binding protein *vinculin*, and α -*actinin*, which can bind directly to actin microfilaments.

The other major type of integrin-mediated attachment is found in epithelial cells. Epithelial cells attach to laminin in the basal lamina via **hemidesmosomes** (so called because they resemble “half desmosomes”; desmosomes were discussed earlier in this chapter). The integrin found in hemidesmosomes is $\alpha_6\beta_4$ integrin. In this case, the integrins are not attached to actin but to intermediate filaments, typically *keratin* (Figure 17-23c and d). The linker proteins in hemidesmosomes form a dense **plaque** that connects clustered integrins to the cytoskeleton. Among the linker proteins, members of the **plakin** family of proteins are prominent. A plakin known as *plectin* attaches keratin filaments to the integrins. Another transmembrane protein, called *BPAG2*, and its associated plakin, *BPAG1*, can serve as a bridge between keratin and laminin. These proteins were first identified using antibodies derived from human patients who developed an autoimmune reaction against antigens in their own hemidesmosomes. The resulting disease, called *bullous pemphigoid*, affects predominantly elderly people and involves blistering of the skin. This disease also gives rise to the names of these proteins. (*BPAG* stands for “*bullous pemphigoid antigen*.”)

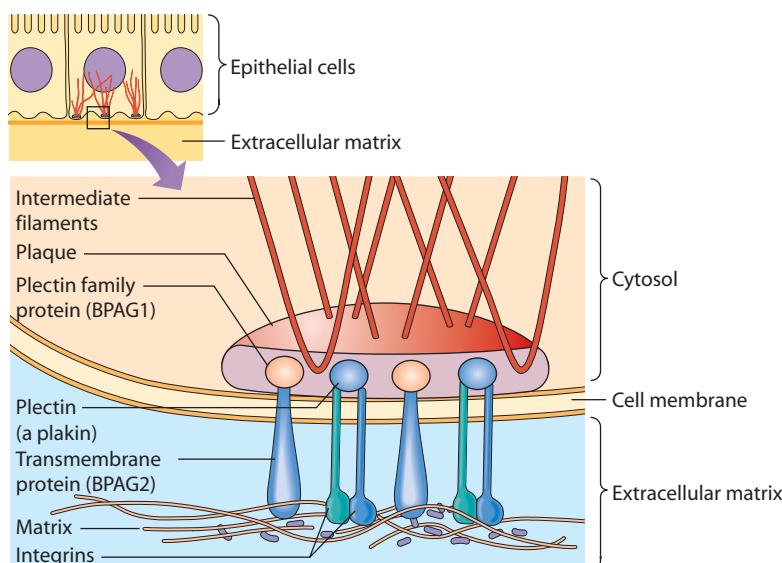

Integrin Function. Because they bind to components of the ECM on the outside of the cell and to actin microfilaments on the inside, integrins play important roles in regulating cell movement and cell attachment. For example, mice lacking a particular integrin subunit (α_7) required for attachment to laminin develop a distinctive form of progressive muscular dystrophy. Humans that carry the same mutation develop progressive muscle degeneration. Recall that hemidesmosomes use $\alpha_6\beta_4$ integrins to attach to laminin. Humans who carry mutations in the β_4 subunit develop *junctional epidermolysis bullosa*, a severe blistering disease of the skin.

FIGURE 17-23 Integrins, Focal Adhesions, and Hemidesmosomes. (a) Migrating cells attach to the extracellular matrix via focal adhesions. Focal adhesions contain integrins, such as $\alpha_5\beta_1$ integrin, and integrin-associated linker proteins, such as talin, vinculin, and α -actinin, that attach integrins to the actin cytoskeleton. (b) A cultured frog glial cell stained to visualize actin (green) and stained with antibodies that recognize β_1 integrin (purple) and vinculin. White streaks represent regions where the three proteins are found together. Note how the actin microfilaments terminate at focal adhesions. (c) Epithelial cells attach to the extracellular matrix via hemidesmosomes, which contain $\alpha_6\beta_4$ integrins, and connect to intermediate filaments via linker proteins such as plectin. (d) The external surface of a hemidesmosome directly abuts the basal lamina (TEM).

Integrins and Signaling. Although a key role of integrins is their ability to link the cytoskeleton and the extracellular matrix, they also interact with intracellular signaling pathways. For example, signals such as binding of growth factors that lead to MAP kinase activation (see Chapter 14) can result in integrin clustering. (Such effects are often called “inside out” signaling because internal changes in the cell result in effects on integrins at the surface.)

Inside-out signaling appears to result from conformational changes in the cytoplasmic regions of the α and β subunits. Integrins can also act as receptors that activate intracellular signaling themselves (sometimes called “outside in” signaling). The original observations that suggested involvement of integrins in signaling came from studies of cancer cells. For most normal cells to grow in culture, they must be attached to a substratum. Even in the presence of

growth factors that normally stimulate their proliferation, if such cells are prevented from attaching to an extracellular matrix layer, they will cease dividing and undergo apoptosis, a kind of programmed cell death (we will discuss apoptosis in detail in Chapter 19). Such behavior is referred to as **anchorage-dependent growth**. In contrast, cancer cells will continue to grow even when they are not firmly attached to an extracellular matrix layer, apparently because they no longer need to transduce signals that result from attachment to the extracellular matrix.

Anchorage-dependent growth involves the activation of intracellular pathways following integrin clustering. Several kinases are activated at focal adhesions following integrin clustering. They are recruited to focal adhesions by adapter proteins such as *paxillin*. These include *focal adhesion kinase (FAK)*, *kindlins*, and *integrin-linked kinase (ILK)*. ILK probably functions as a scaffolding protein during integrin-based signaling, since “kinase dead” versions of the protein still function. Although they are involved in integrin activation, the precise function of kindlins is unknown. Mutations in one kindlin result in Kindler syndrome. Infants and young children with Kindler syndrome tend to develop minor skin defects, and they are susceptible to sunburns. FAK appears to be important in regulating anchorage-dependent growth. Cancer cells contain activated FAK even when they are not attached, and cells can be transformed into cancerlike cells by the expression of a mutant, activated form of FAK. These experiments underscore the importance of cell adhesion for understanding cancer.

The Dystrophin/Dystroglycan Complex Stabilizes Attachments of Muscle Cells to the Extracellular Matrix

In addition to focal adhesions and hemidesmosomes, a third type of ECM attachment is important in human disease. The *costamere* is an attachment structure at the surface of striated muscle. Costameres are aligned in register with Z-discs around the surface of muscle cells. They physically attach myofibrils at the surface of the muscle cells to the plasma membrane (sarcolemma). Costameres contain many of the same proteins found at focal contacts, including β_1 -integrin, vinculin, talin, and α -actinin. They also contain the intermediate filament protein, desmin. In addition, costameres contain a specialized protein complex that includes the large protein **dystrophin** (Figure 17-24). Mutations in the dystrophin locus cause the most common type of muscular dystrophy, *Duchenne muscular dystrophy (DMD)*. DMD is a severe, recessive X-linked type of muscular dystrophy that afflicts 1 in 3500 human males. DMD patients undergo progressive muscle degeneration, eventually leading to loss of the ability to walk and death.

Dystrophin interacts with a multiprotein complex that includes the integral membrane protein *dystroglycan* and the *sarcoglycan-sarcospan* complexes, as well as

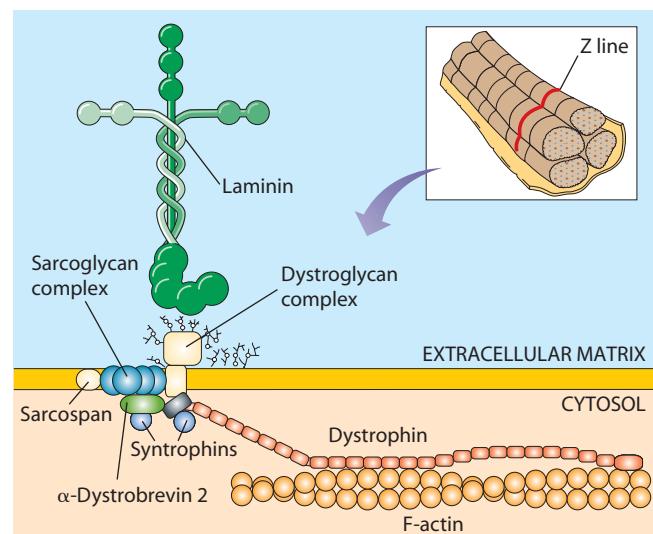

FIGURE 17-24 The Dystrophin/Dystroglycan Complex of Muscle Cells. Dystrophin, an enormous cytosolic protein, interacts with actin in the cytosol. Dystrophin is linked, via a series of proteins, to the dystroglycan complex at the cell surface. The dystroglycan complex in turn interacts with extracellular matrix proteins, such as laminin.

cytosolic proteins, the *dystrobrevins* and *syntrophins*. Dystroglycan is known to bind to laminin via three regions in the laminin G domain, linking the complex to the extracellular matrix (Figure 17-24). Loss of many of the other components of the dystrophin complex also results in muscular dystrophy in humans and mice.

The Glycocalyx Is a Carbohydrate-Rich Zone at the Periphery of Animal Cells

Although animal cells do not have a rigid enclosure like a cell wall, a carbohydrate-rich zone called the **glycocalyx** often surrounds the plasma membrane (see Figure 7-27). Roles of the glycocalyx include cell recognition and adhesion, protection of the cell surface, and the creation of permeability barriers. Specialized structures, such as the outer coat of amoebas and the jelly coats that surround most animal eggs, are each an example of a glycocalyx.

The Plant Cell Surface

Our discussion so far has focused on animal cell surfaces. The surfaces of plant, algal, fungal, and bacterial cells exhibit some of the same properties, but they also have several unique features of their own. In the rest of this chapter, we consider some distinctive features of the plant cell surface.

Cell Walls Provide a Structural Framework and Serve as a Permeability Barrier

One of the most remarkable features of plants is that they have no bones or related skeletal structures and yet exhibit remarkable strength. This strength is provided by the rigid

cell walls that surround all plant cells except sperm and some eggs. The rigidity of the cell wall makes cell movements virtually impossible. At the same time, sturdy cell walls enable plant cells to withstand the considerable *turgor pressure* that is exerted by the uptake of water. Turgor pressure is vital to plants because it accounts for much of the turgidity, or firmness, of plant tissues and provides the driving force behind cell expansion.

The wall that surrounds a plant cell is also a permeability barrier for large molecules. For water, gases, ions, and small water-soluble molecules such as sugars or amino acids, the cell wall is not a significant obstacle. These substances diffuse through the wall readily.

The Plant Cell Wall Is a Network of Cellulose Microfibrils, Polysaccharides, and Glycoproteins

Like the extracellular matrix of animal cells, plant cell walls consist predominantly of long fibers embedded in a network of branched molecules. Instead of collagen and proteoglycans, however, plant cell walls contain *cellulose microfibrils* enmeshed in a complex network of branched polysaccharides and glycoproteins called *extensins* (see Table 17-2). The two main types of polysaccharides are *hemicelluloses* and *pectins*. On a dry-weight basis, cellulose typically makes up about 40% of the cell wall, hemicelluloses account for another 20%, pectins represent about 30%, and glycoproteins make up about 10%. **Figure 17-25a** illustrates the relationships among these cell wall components. Cellulose, hemicelluloses, and glycoproteins are linked together to form a rigid interconnected network that is embedded in a pectin matrix. Not shown are lignins, which in woody tissues are localized between the cellulose fibrils and make the wall especially strong and rigid. We will consider each of these components in turn.

Cellulose and Hemicellulose. The predominant polysaccharide of the plant cell wall is **cellulose**, which is the single most abundant organic macromolecule on Earth. As we saw in Chapter 3, cellulose is an unbranched polymer consisting of thousands of β -D-glucose units linked together by β (1 \rightarrow 4) bonds (see Figure 3-25). Cellulose molecules are long, ribbonlike structures that are stabilized by intramolecular hydrogen bonds. Many such molecules (50–60, typically) associate laterally to form the **microfibrils** found in cell walls. Cellulose microfibrils are often twisted together in a ropelike fashion to generate even larger structures, called *macrofibrils* (Figure 17-25a). Cellulose macrofibrils are as strong as an equivalently sized piece of steel!

Despite the name, **hemicelluloses** are chemically and structurally distinct from cellulose. The hemicelluloses are a heterogeneous group of polysaccharides, each consisting of a long, linear chain of a single kind of sugar (glucose or xylose) with short side chains bonded into a rigid network (Figure 17-25a). The side chains usually contain several

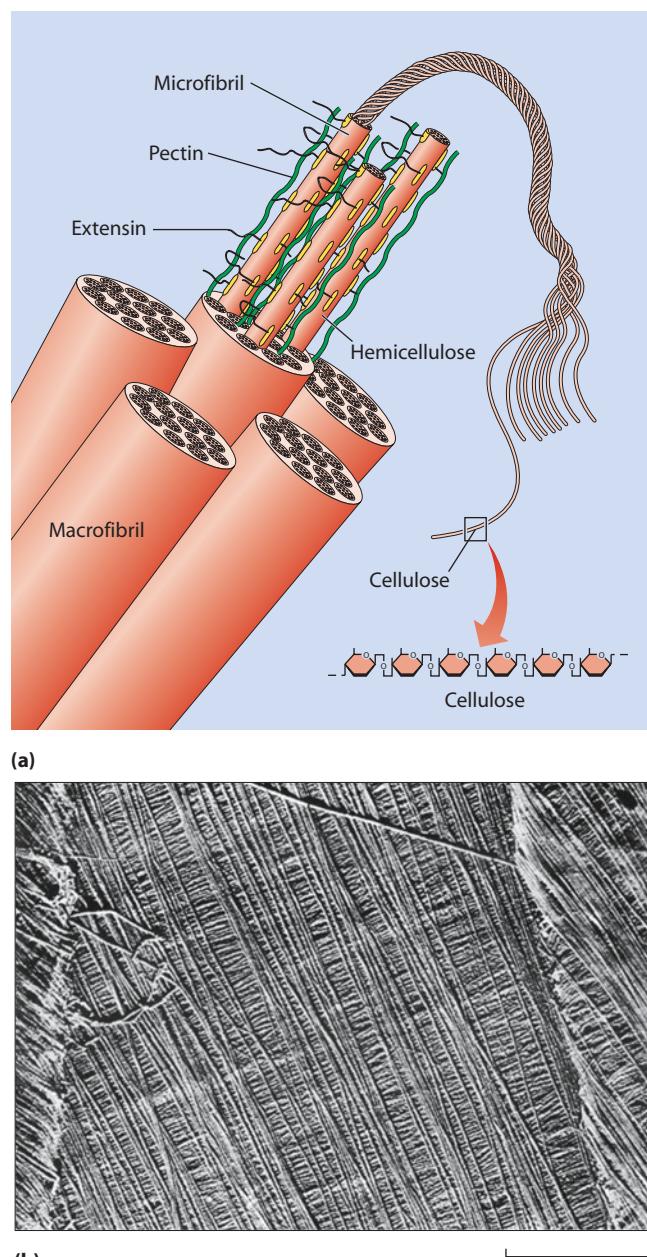

FIGURE 17-25 Structural Components of Plant Cell Walls. (a) Cellulose microfibrils are linked by hemicelluloses and glycoproteins called extensins to form a rigid interconnected network embedded in a matrix of pectins. Cellulose microfibrils are often twisted together to form larger structures called macrofibrils. (Not shown are the lignins that are localized between the cellulose microfibrils in woody tissues.) (b) This electron micrograph shows individual cellulose microfibrils in the cell wall of a green alga. Each microfibril consists of many cellulose molecules aligned laterally (TEM).

kinds of sugars, including the hexoses glucose, galactose, and mannose and the pentoses xylose and arabinose.

Other Cell Wall Components. In addition to cellulose and hemicellulose, cell walls have several other major components. **Pectins** are also branched polysaccharides but with backbones called *rhamnogalacturonans* that

consist mainly of negatively charged galacturonic acid and rhamnose. The side chains attached to the backbone contain some of the same monosaccharides found in hemicelluloses. Pectin molecules form the matrix in which cellulose microfibrils are embedded (Figure 17-25a). They also bind adjacent cell walls together. Because of their highly branched structure and their negative charge, pectins trap and bind water molecules. As a result, pectins have a gel-like consistency. (It is because of their gel-forming capacity that pectins are added to fruit juice in the process of making fruit jams and jellies.)

In addition to hemicelluloses and pectins, cell walls contain a group of related glycoproteins called **extensins**. Despite the name, extensins are actually rigid, rodlike molecules that are tightly woven into the complex polysaccharide network of the cell wall (Figure 17-25a). In fact, extensins are so integral to the cell wall matrix that attempts to extract them chemically usually result in the loss of cell wall structure. Extensins are initially deposited in the cell wall in a soluble form. Once deposited, however, extensin molecules become covalently crosslinked to one another and to cellulose, generating a reinforced protein-polysaccharide complex. Extensins are least abundant in the cell walls of actively growing tissues and most abundant in the cell walls of tissues that provide mechanical support to the plant.

Lignins are very insoluble polymers of aromatic alcohols that occur mainly in woody tissues. (The Latin word for “wood” is *lignum*.) Lignin molecules are localized mainly between the cellulose fibrils, where they function to resist compression forces. Lignin accounts for as much as 25% of the dry weight of woody plants, making it second only to cellulose as the most abundant organic compound on Earth.

Cell Walls Are Synthesized in Several Discrete Stages

The plant cell wall components are secreted from the cell stepwise, creating a series of layers in which the first layer to be synthesized ends up farthest away from the plasma membrane. The first structure to be laid down is called the **middle lamella**. It is shared by neighboring cell walls and holds adjacent cells together (Figure 17-26). The next structure to be formed is called the **primary cell wall**, which forms when the cells are still growing. Primary walls are about 100–200 nm thick, only several times the thickness of the basal lamina of animal cells. The primary cell wall consists of a loosely organized network of cellulose microfibrils associated with hemicelluloses, pectins, and glycoproteins (Figure 17-27a). The cellulose microfibrils are generated by cellulose-synthesizing enzyme complexes called *rosettes* that are localized within the plasma membrane. Because the microfibrils are anchored to other wall components, the rosettes must move in the plane of the membrane as they lengthen the growing cellulose microfibrils.

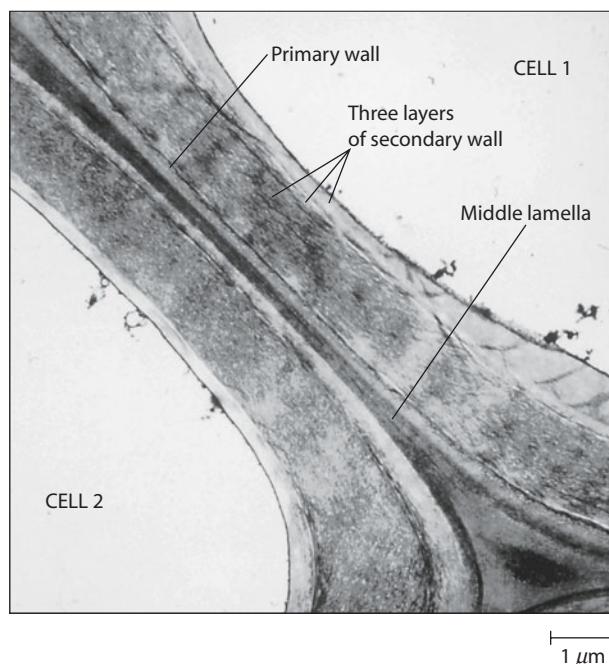

FIGURE 17-26 The Middle Lamella. The middle lamella is a layer of cell wall material that is shared by two adjacent plant cells. Consisting mainly of sticky pectins, the middle lamella binds the cells together tightly.

When the shoots or roots of a plant are growing, cell walls must be remodeled. A family of proteins called *expansins* helps cell walls retain their pliability. One way in which expansins may act is by disrupting the normal hydrogen bonding of glycans within the microfibrils of the cell wall to allow for rearrangement of the microfibrils.

The loosely textured organization of the primary cell wall creates a relatively thin, flexible structure. In some plant cells, development of the cell wall does not proceed beyond this point. However, many cells that have stopped growing add a thicker, more rigid set of layers that are referred to collectively as the **secondary cell wall** (Figure 17-27b). The components of the multilayered secondary wall are added to the inner surface of the primary wall after cell growth has ceased. Cellulose and lignins are the primary constituents of the secondary wall, making this structure significantly stronger, harder, and more rigid than the primary wall. Each layer of the secondary wall consists of densely packed bundles of cellulose microfibrils, arranged in parallel and oriented to lie at an angle to the microfibrils of adjacent layers. This organization imparts great mechanical strength and rigidity to the secondary cell wall.

As the secondary walls form, microtubules located beneath the plasma membrane are oriented in the same direction as the newly formed cellulose microfibrils, and the cellulose-synthesizing rosettes are aggregated into large arrays containing dozens of rosettes. The underlying microtubules are thought to guide the movement of these rosette aggregates, which synthesize large parallel bundles of cellulose microfibrils as they move.

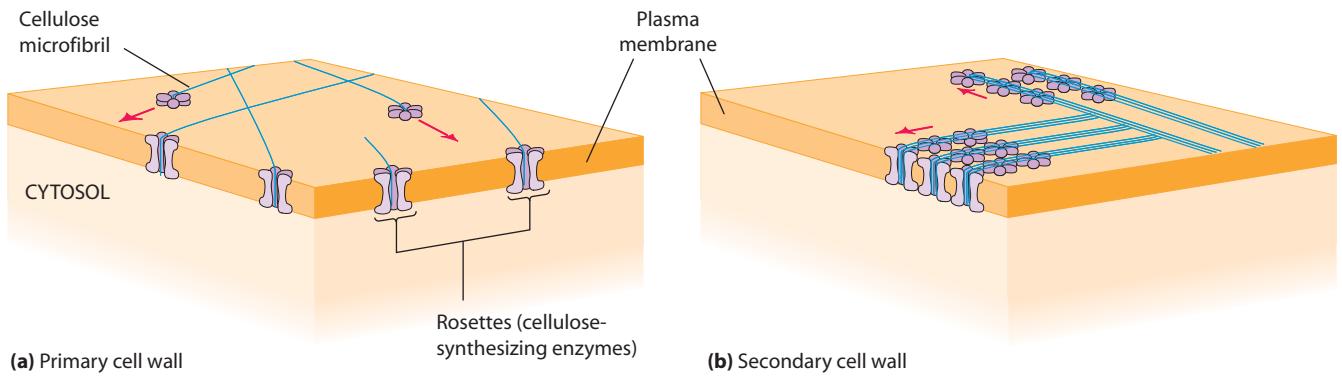

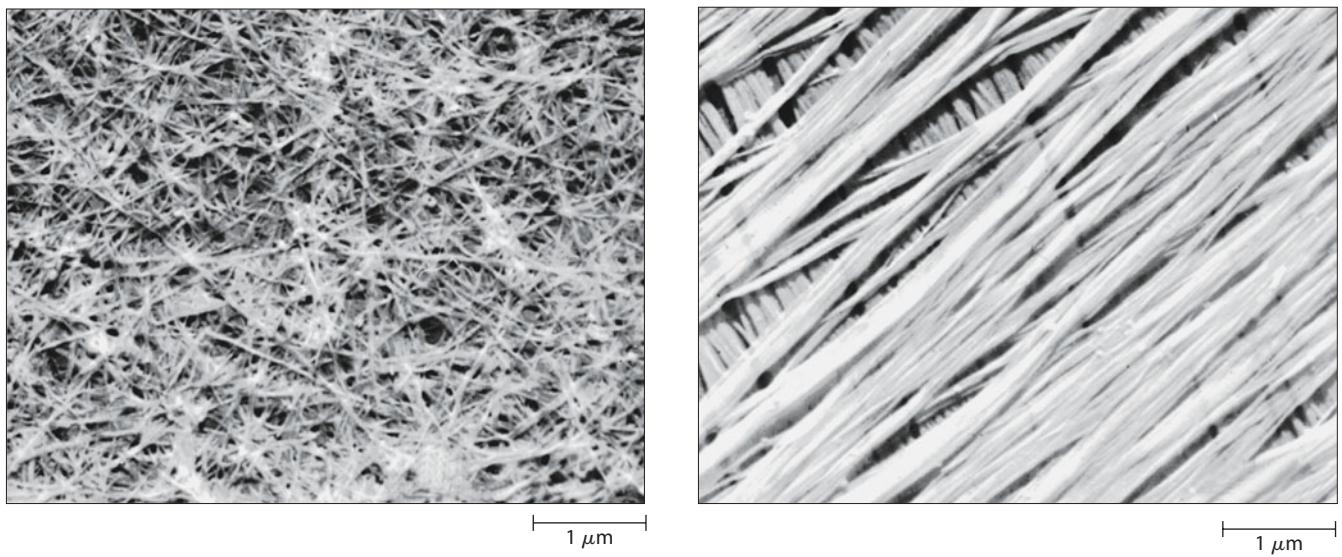

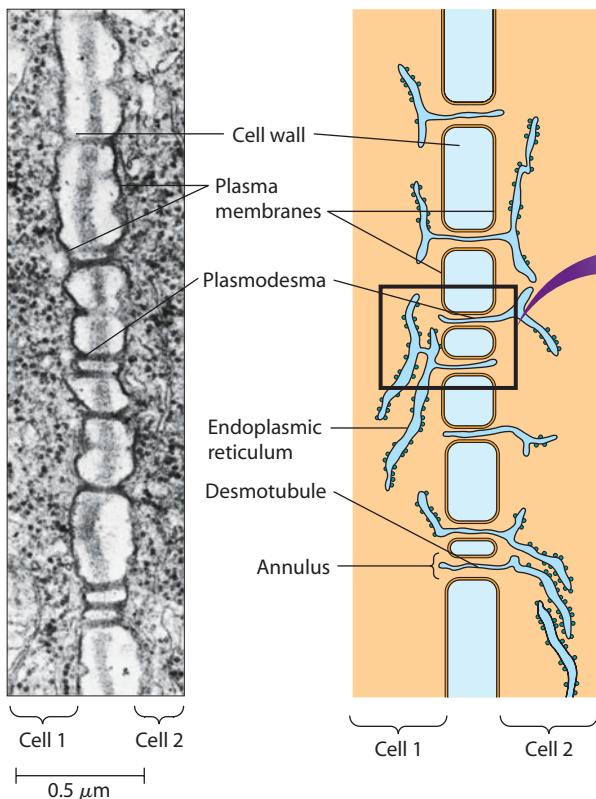

FIGURE 17-27 Cellulose Microfibrils of Primary and Secondary Plant Cell Walls. (a) *Primary cell wall:* The electron micrograph shows the loosely organized cellular microfibrils of a primary cell wall, and the diagram depicts how cellular microfibrils are synthesized by rosettes, each of which is a cluster of cellulose-synthesizing enzymes embedded in the plasma membrane. As a rosette synthesizes a bundle of cellulose molecules, it moves through the plasma membrane in the direction indicated by the arrows. (b) *Secondary cell wall:* The electron micrograph shows densely packed cellulose macrofibrils oriented in parallel, and the diagram depicts how rosettes form dense aggregates that synthesize large numbers of microfibrils in parallel, generating cellular macrofibrils. (TEMs.)

Plasmodesmata Permit Direct Cell-Cell Communication Through the Cell Wall

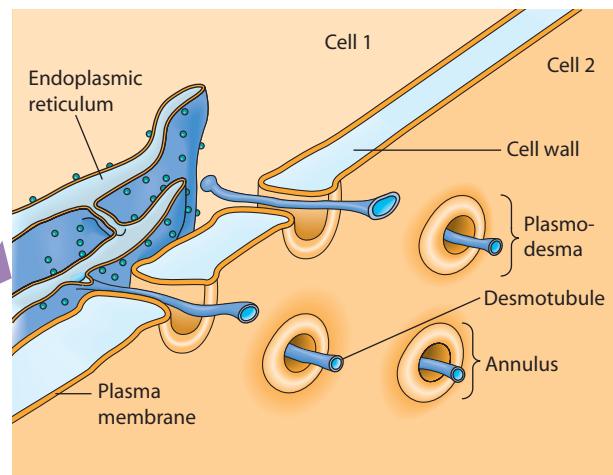

Since every plant cell is surrounded by a plasma membrane and a cell wall, you may wonder whether plant cells are capable of intercellular communication such as that afforded by the gap junctions of animal cells. In fact, plant cells do possess such structures. As shown in **Figure 17-28**, **plasmodesmata** (singular: **plasmodesma**) are cytoplasmic channels through relatively large openings in the cell wall, allowing continuity of the plasma membranes from two adjacent cells. Each plasmodesma is therefore lined with plasma membrane common to the two connected cells. A plasmodesma is cylindrical in shape, with the cylinder narrower in diameter at both ends. The channel diameter varies from about 20 to about 200 nm. A single tubular

structure, the *desmotubule*, usually lies in the central channel of the plasmodesma. Endoplasmic reticulum (ER) cisternae are often seen near the plasmodesmata on either side of the cell wall. ER membranes from adjoining cells are continuous with the desmotubule and with the ER of the other cells, as depicted in Figure 17-28b.

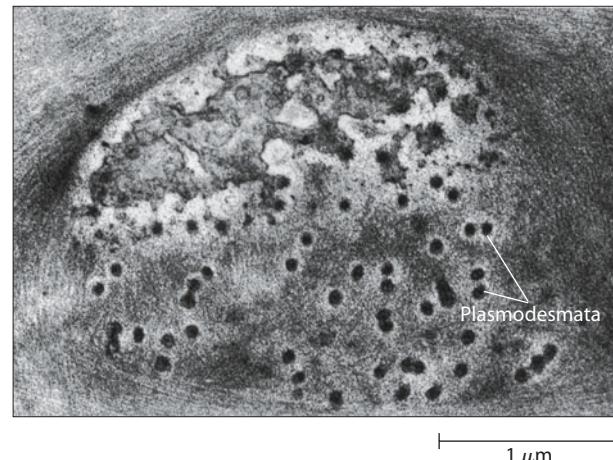

The ring of cytoplasm between the desmotubule and the membrane that lines the plasmodesma is called the *annulus*. The annulus is thought to provide cytoplasmic continuity between adjacent cells, thereby allowing molecules to pass freely from one cell to the next. Even after cell division and deposition of new cell walls between the two daughter cells, cytoplasmic continuities are maintained between the daughter cells by plasmodesmata that pass through the newly formed walls. In fact,

(a) Electron micrograph and diagram of plasmodesmata in longitudinal section

(b) Diagram of plasmodesmata

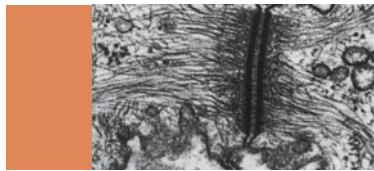

(c) Electron micrograph of plasmodesmata in cross section

FIGURE 17-28 Plasmodesmata. A plasmodesma is a channel through the cell wall between two adjacent plant cells, allowing cytoplasmic exchange between the cells. The plasma membrane of one cell is continuous with that of the other cell at each plasmodesma. Most plasmodesmata have a narrow cylindrical desmotubule at the center that is derived from the ER and appears to be continuous with the ER of both cells. Between the desmotubule and the plasma membrane that lines the plasmodesma is a narrow ring of cytoplasm called the annulus. (a) This electron micrograph and diagram show the cell wall between two adjacent root cells of timothy grass, with numerous plasmodesmata (TEM). (b) A diagrammatic view of a cell wall with numerous plasmodesmata, illustrating the continuity of the ER and cytoplasm between adjacent cells. (c) This electron micrograph shows many plasmodesmata in cross section (TEM).

most plasmodesmata are formed at the time of cell division, when the new cell wall is being formed. Minor changes may occur later, but the number and location of plasmodesmata are largely fixed at the time of division.

In many respects, plasmodesmata appear to function somewhat like gap junctions. They reduce electrical resistance between adjacent cells by about 50-fold compared

with cells that are completely separated by plasma membranes. In fact, the movement of ions between adjacent cells (measured as current flow) is proportional to the number of plasmodesmata that connect the cells. However, plasmodesmata allow the passage of much larger molecules, including signaling molecules, RNAs, transcription factors, and even viruses.

SUMMARY OF KEY POINTS

Cell-Cell Recognition and Adhesion

- Cell-cell recognition and adhesion are mediated by plasma membrane glycoproteins such as IgSF proteins, selectins, and cadherins.
- Carbohydrate groups on cell surfaces are also important in cell-cell recognition and adhesion.

Cell-Cell Junctions

- Junctions link many animal cells together. There are three general types: adhesive junctions, tight junctions, and gap junctions.
- Adhesive junctions, such as adherens junctions and desmosomes, use cadherins to hold cells together.
- Adhesive junctions are anchored to the cytoskeleton by linker proteins that attach to actin microfilaments (adherens junctions) or intermediate filaments (desmosomes).
- Desmosomes are particularly prominent in tissues that must withstand considerable mechanical stress.
- Tight junctions form a permeability barrier between epithelial cells, and they prevent the lateral movement of membrane proteins, thereby partitioning the membrane into discrete functional domains. They also mediate paracellular transport across epithelia.
- Gap junctions form open channels between cells, allowing direct chemical and electrical communication between cells. Gap junction permeability is limited to ions and small molecules.

The Extracellular Matrix of Animal Cells

- Plant as well as animal cells have extracellular structures consisting of long, rigid fibers embedded in an amorphous, hydrated matrix of branched molecules. In animals, the extracellular matrix (ECM) consists of collagen and/or elastin fibers embedded in a network of glycosaminoglycans and proteoglycans.
- Collagen is responsible for the strength of the ECM, and elastin imparts elasticity.
- The ECM is held in place by adhesive glycoproteins such as fibronectins, which link cells to the ECM, and laminins, which attach cells to the basal lamina.
- Cells use cell surface receptor glycoproteins called integrins to connect to the ECM. Integrins, like cadherins, attach to the cytoskeleton via linker proteins. Focal adhesions connect to actin, and hemidesmosomes connect to intermediate filaments.

The Plant Cell Surface

- The primary cell wall of a plant cell consists mainly of cellulose fibers embedded in a complex network of hemicelluloses, pectins, and extensins.
- The secondary cell wall is reinforced with lignins, a major component of wood.
- Plasmodesmata are membrane-lined cytoplasmic channels that allow chemical and electrical communication between adjacent plant cells.

MAKING CONNECTIONS

In this chapter we have seen that cells in multicellular organisms are organized into tissues. This organization requires that cells make specialized connections with one another and to the extracellular matrix. The adhesion of animal cells to one another and the ECM depends on connections to the cytoskeleton, which you learned about in Chapters 15 and 16. Since many cell adhesion receptors are transmembrane proteins, they are produced and transported like other transmembrane proteins to the cell sur-

face, as you learned about in Chapter 12 and you will learn more about in Chapter 22. Similarly, you learned about cell surface carbohydrates in Chapter 7. Cell adhesion both regulates cell signaling and in turn is regulated by cell signaling processes, which you learned about in Chapter 14. Alterations in cell adhesion are important for regulating cell growth and apoptosis (as you will see in Chapter 19), as well as metastasis of cancer cells (as you will see in Chapter 24).

PROBLEM SET

More challenging problems are marked with a •.

17-1 Beyond the Membrane: ECM and Cell Walls. Compare and contrast the extracellular matrix (ECM) of animal cells with the walls around plant cells.

- (a) What basic organizational principle underlies both ECM and cell walls?
- (b) What are the chemical constituents in each case?
- (c) What functional roles do the ECM and cell wall have in common?
- (d) What functional roles are unique to the ECM? To the cell wall?

• **17-2 Anchoring Cells to the ECM.** Animal cells attach to several different kinds of proteins within the ECM.

- (a) Briefly explain how the various domains of the fibronectin molecule (see Figure 17-18) or the laminin molecule (see Figure 17-21) are important for their function.
- (b) Historically, an important strategy for disrupting the adhesion of integrins to their ligands is by using a synthetic peptide that mimics the binding site on the ECM molecule to which the integrin attaches. In the case of fibronectin, the amino acid sequence is arginine-glycine-aspartate (when written using the single letter designation for each amino acid, this sequence becomes RGD). Explain why addition of such synthetic peptides would disrupt binding of cells to their normal substratum.

17-3 Compare and Contrast. For each of the terms in list A, choose a related term in list B, and explain the relationship between the two terms by comparing or contrasting them structurally or functionally.

List A	List B
(a) Collagen	Basolateral surface
(b) Fibronectin	Focal adhesion
(c) Integrin	Elastin
(d) IgSF	Laminin
(e) ECM	Cadherin
(f) Hemidesmosome	Glycocalyx
(g) Apical surface	Selectin

17-4 Compaction. In mammalian embryos such as the mouse, the fertilized egg divides three times to form eight loosely packed cells, which become tightly adherent in a process known as *compaction*. In the late 1970s, several laboratories made antibodies against mouse cell surface proteins. The antibodies prevented compaction, as did removal of Ca^{2+} from the medium. What sort of protein do the antibodies probably recognize, and why?

17-5 Cellular Junctions and Plasmodesmata. Indicate whether each of the following statements is true of adhesive junctions (A), tight junctions (T), gap junctions (G), and/or

plasmodesmata (P). A given statement may be true of any, all, or none (N) of these structures.

- (a) Associated with filaments that confer either contractile or tensile properties.
- (b) Sites of membrane fusion are limited to abutting ridges of adjacent membranes.
- (c) Require the alignment of connexons in the plasma membranes of two adjacent cells.
- (d) Seal membranes of two adjacent cells tightly together.
- (e) Allow the exchange of metabolites between the cytoplasms of two adjacent cells.

17-6 Junction Proteins. Indicate whether each of the following proteins or structures is a component of adherens junctions (A), desmosomes (D), tight junctions (T), gap junctions (G), or plasmodesmata (P), and describe briefly the role the protein plays in the junction.

- (a) Connexin
- (b) E-cadherin
- (c) Desmocollins
- (d) Desmotubule
- (e) Desmoplakin
- (f) Annulus
- (g) α -Catenin
- (h) Claudins

• **17-7 Mind the Gap.** Gap junctional communication can be examined using a variety of experimental tools. One of these is known as *dye coupling*, the ability of small fluorescent molecules to pass from one cell to another through gap junctions, a technique pioneered by Werner Loewenstein and his colleagues. What can you conclude about gap junctions from each of the following experiments?

- (a) Loewenstein and colleagues injected cells with fluorescent molecules of different molecular weights, and a fluorescence microscope was then used to observe the movement of the molecules into adjacent cells. When molecules with molecular weight of 1926 were injected, they did not pass from cell to cell, but molecules with molecular weight of 1158 did.
- (b) Microglia (support cells in the brain) are connected by gap junctions. When the fluorescent dye Lucifer yellow is injected into individual microglia that are part of a large group of cells, little dye passes to other cells. When microglia are treated with the calcium ionophore, 4Br-A23187, there is a dramatic increase in dye passage between cells.

• **17-8 Claudin Selectivity.** Claudin-4 normally prohibits movement of Na^+ ions across epithelial cells that express it. However, when positively charged amino acids near the tip of the large extracellular loop of claudin-4 are changed to negatively charged amino acids, Na^+ can pass through the epithelium. How do you account for this change in permeability to Na^+ ?

17-9 Plant Cell Walls. Distinguish between the terms in each of the following pairs with respect to the structure of the plant cell wall, and indicate the significance of each.

- (a) Primary wall; secondary wall
- (b) Cellulose; hemicellulose
- (c) Xylan; xyloglucan
- (d) Extensin; lignin
- (e) Desmotubule; annulus
- (f) Plasmodesma; gap junction

• **17-10 Scurvy and Collagen.** Scurvy is a disease that until the nineteenth century was common among sailors and others whose diets were deficient in vitamin C (ascorbic acid). Individ-

uals with scurvy suffer from various disorders, including extensive bruising, hemorrhages, and breakdown of supporting tissues. Ascorbic acid serves as a reducing agent responsible for maintaining the activity of prolyl hydroxylase, the enzyme that catalyzes hydroxylation of proline residues within the collagen triple helix, which is required for helix stability.

- (a) Based on this information, postulate a role for hydroxyproline in collagen triple helices, and explain the sequence of events leading from a dietary vitamin C deficiency to symptoms such as bruising and breakdown of supporting tissues.
- (b) Can you guess why sailors are no longer susceptible to scurvy? And why do you think British sailors are called “limeys” to this day?

The Structural Basis of Cellular Information: DNA, Chromosomes, and the Nucleus

Implicit in our earlier discussions of cellular structure and function has been a sense of predictability, order, and control. We have come to expect that organelles and other cellular structures will have a predictable appearance and function, that metabolic pathways will proceed in an orderly fashion in specific intracellular locations, and that all of a cell's activities will be carried out in a carefully controlled, highly efficient, and heritable manner.

Such expectations express our confidence that cells possess a set of "instructions" that specify their structure, dictate their functions, and regulate their activities and that these instructions can be passed on faithfully to daughter cells. More than a hundred years ago, the Augustinian monk Gregor Mendel worked out rules accounting for the inheritance patterns he observed in pea plants, although he had little inkling of the cellular or molecular basis for these rules. These studies led Mendel to conclude that hereditary information is transmitted in the form of distinct units that we now call **genes**. We also now know that genes consist of DNA sequences that code for functional products that are usually protein chains but may in some cases be RNA molecules that do not code for proteins.

Figure 18-1 presents a preview of how DNA carries out its instructional role in cells and, at the same time, provides a framework for describing how this set of chapters on information flow is organized. The figure highlights the fact that the information carried by DNA flows both between generations of cells and within each individual cell. During the first of these two processes (Figure 18-1a), the information stored in a cell's DNA molecules undergoes replication, generating two DNA copies that are distributed to the daughter cells when the cell divides. The initial three chapters in this section focus on the structures and events associated with this aspect of information flow. The present chapter covers the structural organization of DNA and the chromosomes in which it is packaged; it also discusses the nucleus, which is the organelle that houses the chromosomes

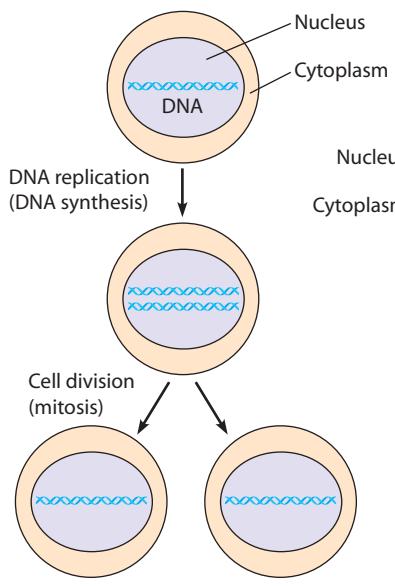

of eukaryotic cells. Chapter 19 then discusses DNA replication and cell division, while Chapter 20 considers the cellular and molecular events associated with information flow between generations of sexually reproducing organisms (including Mendel's work and its chromosomal basis).

Figure 18-1b summarizes how information residing in DNA is used within a cell. Instructions stored in DNA are transmitted in a two-stage process called transcription and translation. During transcription, RNA is synthesized in an enzymatic reaction that copies information from DNA. During translation, the base sequences of the resulting messenger RNA molecules are used to determine the amino acid sequences of proteins. Thus, the information initially stored in DNA base sequences is ultimately used to code for the synthesis of specific protein molecules. It is the particular proteins synthesized by a cell that ultimately determine most of a cell's structural features as well as the functions it performs. Transcription and translation, which together constitute the expression of genetic information, are the subjects of Chapters 21–23.

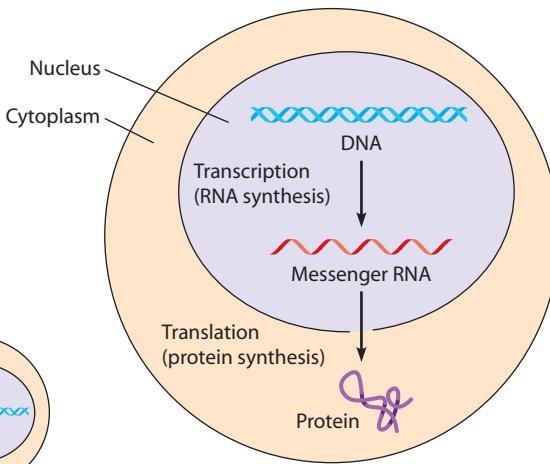

We open this chapter by describing the discovery of DNA, the molecule whose informational role lies at the heart of this group of six chapters.

Chemical Nature of the Genetic Material

When Mendel first postulated the existence of genes, he did not know the identity of the molecule that allows them to store and transmit inherited information. But a few years later, this molecule was unwittingly discovered by Johann Friedrich Miescher, a Swiss physician. Miescher reported the discovery of the substance now known as DNA in 1869, just a few years before the cell biologist Walther Flemming first observed chromosomes as he studied dividing cells under the microscope.

(a) The flow of genetic information between generations of cells

(b) The flow of genetic information within a cell: the expression of genetic information

FIGURE 18-1 The Flow of Information in Cells.

The diagrams here feature eukaryotic cells, but DNA replication, cell division, transcription, and translation are processes that occur in prokaryotic cells as well. (a) Genetic information encoded in DNA molecules is passed on to successive generations of cells by DNA replication and cell division (in eukaryotic cells, by means of mitosis). The DNA is first duplicated and then divided equally between the two daughter cells. In this way, each daughter cell is assured of having the same genetic information as the cell from which it arose. (b) Within each cell, genetic information encoded in the DNA is expressed through the processes of transcription (RNA synthesis) and translation (protein synthesis). Transcription involves the use of selected segments of DNA as templates for the synthesis of messenger RNA and other RNA molecules. Translation is the process whereby amino acids are joined together in a sequence dictated by the sequence of nucleotides in messenger RNA.

Miescher's Discovery of DNA Led to Conflicting Proposals Concerning the Chemical Nature of Genes

Miescher was interested in studying the chemistry of the nucleus, which most scientists guessed was the site of the cell's genetic material. In his initial experiments, Miescher isolated nuclei from white blood cells obtained from pus found on surgical bandages. Extracting these nuclei with alkali led to the discovery of a novel substance that he called "nuclein," though we now know it to have been largely DNA. Miescher then went on to study DNA from a more pleasant source, salmon sperm. Fish sperm may seem a somewhat unusual source material until we realize that the nucleus accounts for more than 90% of the mass of a typical sperm cell and therefore that DNA accounts for most of the mass of sperm cells. For this reason, Miescher initially believed that DNA is involved in the transmission of hereditary information. He soon rejected this idea, however, because his crude measuring techniques incorrectly suggested that egg cells contain much more DNA than sperm cells do. Reasoning that the sperm and egg must contribute roughly equal amounts of hereditary information to the offspring, it seemed to him that DNA could not be carrying hereditary information.

Although Miescher was led astray concerning the role of DNA, in the early 1880s a botanist named Eduard Zacharias reported that extracting DNA from cells causes the staining of the chromosomes to disappear. Since evidence was already beginning to suggest a role for chromosomes in transmitting hereditary information, Zacharias and others inferred that DNA is the genetic material. This view prevailed until the early 1900s, when incorrectly interpreted staining experiments led to the false conclusion that the amount of

DNA changes dramatically within cells. Because cells would be expected to maintain a constant amount of the substance that stores their hereditary instructions, these mistaken observations led to a repudiation of the idea that DNA carries genetic information.

As a result, from around 1910 to the 1940s, most scientists believed that genes were made of protein rather than DNA. The chemical building blocks of both proteins and nucleic acids had been identified by the early 1900s, and proteins were perceived to be more complex and hence more likely to store genetic information. It was argued that proteins are constructed from 20 different amino acids that can be assembled in a vast number of combinations, thereby generating the sequence diversity and complexity expected of a molecule that stores and transmits genetic information. In contrast, DNA was widely perceived to be a simple polymer consisting of the same sequence of four bases (e.g., the tetranucleotide–ATCG–) repeated over and over, thereby lacking the variability expected of a genetic molecule. Such a simple polymer was thought to serve merely as a structural support for the genes, which were in turn made of protein. This view prevailed until two lines of evidence resolved the matter in favor of DNA as the genetic material, as we describe next.

Avery Showed That DNA Is the Genetic Material of Bacteria

A great surprise was in store for biologists who were studying protein molecules to determine how genetic information is stored and transmitted. The background was provided in 1928 by the British physician Frederick Griffith, who was studying a pathogenic strain of a bacterium, then called "pneumococcus," that causes a fatal

pneumonia in animals. Griffith discovered that this bacterium (now called *Streptococcus pneumoniae*) exists in two forms called the *S strain* and the *R strain*. When grown on a solid agar medium, the *S* strain produces colonies that are smooth and shiny because of the mucous, polysaccharide coat each cell secretes, whereas the *R* strain lacks the ability to manufacture a mucous coat and therefore produces colonies exhibiting a rough boundary.

When injected into mice, *S*-strain (but not *R*-strain) bacteria trigger a fatal pneumonia. The *S* strain's ability to cause disease is directly related to the presence of its polysaccharide coat, which protects the bacterial cell from attack by the mouse's immune system. One of Griffith's most intriguing discoveries, however, was that pneumonia can also be induced by injecting animals with a mixture of live *R*-strain bacteria and dead *S*-strain bacteria (**Figure 18-2**). This finding was surprising because neither live *R*-strain nor dead *S*-strain organisms cause pneumonia if injected alone. When Griffith autopsied the animals that had been injected with the mixture of live *R*-strain and dead *S*-strain bacteria, he found them teeming with live *S*-strain bacteria. Since the animals had not been injected with any live *S*-strain cells, he concluded that the nonpathogenic *R* bacteria were somehow converted into pathogenic *S* bacteria by a substance present in the heat-killed *S* bacteria that had been co-injected. He called this phenomenon **genetic transformation** and referred to the active (though still unknown) substance in the *S* cells as the "transforming principle."

Griffith's discoveries set the stage for 14 years of work by Oswald Avery and his colleagues at the Rockefeller Institute in New York. These researchers pursued the investigation of bacterial transformation to its logical

conclusion by asking which component of the heat-killed *S* bacteria was actually responsible for the transforming activity. They fractionated cell-free extracts of *S*-strain bacteria and found that only the nucleic acid fraction was capable of causing transformation. Moreover, the activity was specifically eliminated by treatment with deoxyribonuclease, an enzyme that degrades DNA. This and other evidence convinced them that the transforming substance of pneumococcus was DNA—a conclusion published by Avery, Colin MacLeod, and Maclyn McCarty in 1944.

It was the first rigorously documented assertion that DNA can carry genetic information. But despite the rigor of the experiments, the assignment of a genetic role to DNA was not immediately accepted. Skepticism was due partly to the persistent, widespread conviction that DNA was not complex enough for such a role. In addition, many scientists questioned whether genetic information in bacteria had anything to do with heredity in other organisms. However, most remaining doubts were alleviated eight years later when DNA was also shown to be the genetic material of a virus, the bacteriophage T2.

Hershey and Chase Showed That DNA Is the Genetic Material of Viruses

Bacteriophages—or **phages**, for short—are viruses that infect bacteria. They have been objects of scientific study since the 1930s, and much of our early understanding of molecular genetics came from experiments involving these viruses. **Box 18A** describes the anatomy and replication cycle of some phages and highlights their advantages for genetic studies.

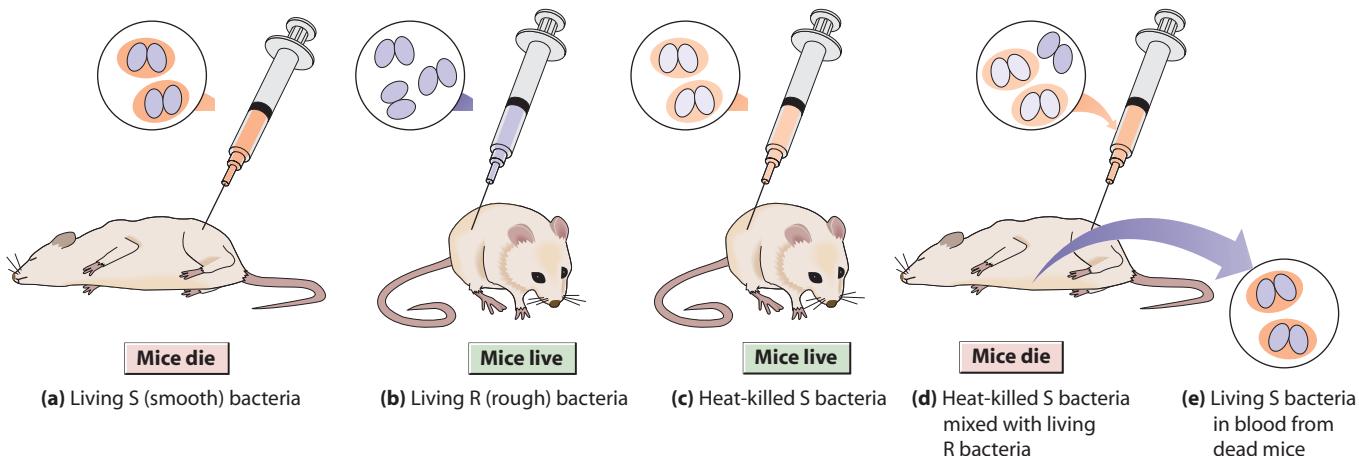

FIGURE 18-2 **Griffith's Experiment on Genetic Transformation in Pneumococcus.** *S* (smooth) cells of the pneumococcus bacterium (*Streptococcus pneumoniae*) are pathogenic in mice; *R* (rough) cells are not. (a) Injection of living *S* bacteria into mice causes pneumonia and death. (b) Injection of living *R* bacteria leaves mice healthy. (c) Heat-killed *S* bacteria have no effect when injected alone. (d) When a mixture of living *R* bacteria and heat-killed *S* bacteria is injected, the result is pneumonia and death. (e) The discovery of living *S*-strain bacteria in the blood of the mice in part d suggested to Griffith that a substance in the heat-killed *S* cells caused a heritable change (transformation) of nonpathogenic *R* bacteria into pathogenic *S* bacteria. The chemical substance was later identified as DNA.

Phages: Model Systems for Studying Genes

From its inception in the mid-nineteenth century, genetics has drawn upon a wide variety of organisms for its experimental materials. Initially, attention focused on plants and animals, such as Mendel's peas and the fruit flies popularized by later investigators. Around 1940, however, bacteria and viruses came into their own, providing biologists with experimental systems that literally revolutionized the science of genetics by bringing it to the molecular level.

Bacteriophages have been especially important. Bacteriophages, or phages for short, are viruses that infect bacterial cells. It is easy to grow huge numbers of phage particles in a short time; this greatly facilitates screening for mutants—phages with heritable variations—and thereby enables geneticists to identify particular genes. Some of the most thoroughly studied phages are the T2, T4, and T6 (the so-called T-even) bacteriophages, which infect the bacterium *Escherichia coli*. The three T-even phages have similar structures, which are quite elaborate. T4 is shown in **Figure 18A-1**. The head of the phage is a protein capsule shaped like a hollow icosahedron (a 20-sided object) and filled with DNA. The head is attached to a protein tail, which consists of a hollow tail core surrounded by a contractile tail sheath and terminating in a hexagonal baseplate, to which six tail fibers are attached.

Figure 18A-2 depicts the main events in the replication cycle of the T4 phage. The drawings are not to scale; the bacterium is proportionately larger, as the electron micrograph indicates. The process begins with the adsorption of a phage particle to the wall of a bacterial cell. When the phage collides with the cell, it "squats" so that its baseplate attaches to a specific receptor protein in the wall (Figure 18A-2a, ①). Next, the tail sheath contracts, driving the hollow tail core through the cell wall. The core forms a needle

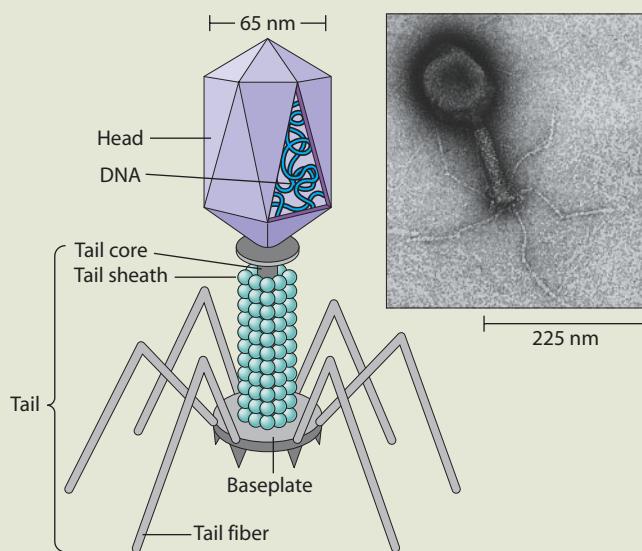

FIGURE 18A-1 The Structure of Bacteriophage T4. The drawing identifies the main structural components of this phage; not all of them are visible in the micrograph (TEM).

through which the bacteriophage DNA is injected into the bacterium (②). Once this DNA has gained entry to the bacterial cell, the genetic information of the phage is transcribed and translated (③). This gives rise to a few key proteins that subvert the metabolic machinery of the host cell for the phage's benefit, which is usually its own rapid multiplication. Since the phage consists simply

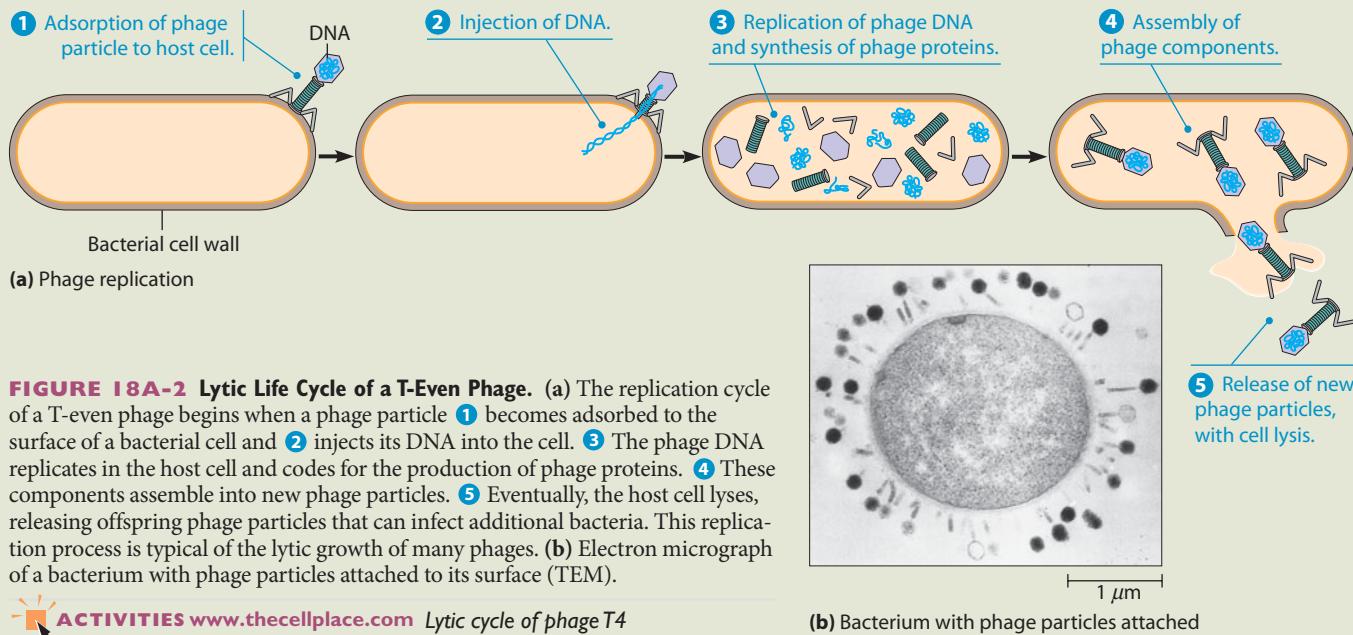

FIGURE 18A-2 Lytic Life Cycle of a T-Even Phage. (a) The replication cycle of a T-even phage begins when a phage particle ① becomes adsorbed to the surface of a bacterial cell and ② injects its DNA into the cell. ③ The phage DNA replicates in the host cell and codes for the production of phage proteins. ④ These components assemble into new phage particles. ⑤ Eventually, the host cell lyses, releasing offspring phage particles that can infect additional bacteria. This replication process is typical of the lytic growth of many phages. (b) Electron micrograph of a bacterium with phage particles attached to its surface (TEM).

ACTIVITIES www.thecellplace.com Lytic cycle of phage T4

of a DNA molecule surrounded by a protein coat (its *capsid*), most of the metabolic activity in the infected cell is channeled toward the replication of phage DNA and the synthesis of capsid proteins. The phage DNA and capsid proteins then self-assemble into hundreds of new phage particles (4). Within about half an hour, the infected cell lyses (breaks open), releasing the new phage particles into the medium (5). Each new phage can now infect another bacterial cell, making it possible to obtain enormous populations of phage—as many as 10^{11} phage particles per milliliter in infected bacterial cultures.

To determine the number of phage particles in a sample, a measured volume is mixed with bacterial cells growing in liquid medium to allow adsorption of the phages to the bacteria. The mixture is then spread onto agar growth medium in a Petri dish. Upon incubation, the bacteria multiply to produce a dense “lawn” of cells on the surface of the nutrient medium. But wherever a virus particle has infected a bacterial cell, a clear spot appears in the lawn because the bacterial cells there have been killed by the multiplying phage population. Such clear spots are called *plaques*. The number of plaques reflects the number of phage particles present in the original phage-bacterium mixture, provided only that the initial number of phages was small enough to ensure that each gives rise to a separate plaque. **Figure 18A-3** shows plaques formed by T4 bacteriophage on a lawn of *E. coli* cells.

The course of events shown in Figure 18A-2a is called *lytic growth* and is characteristic of a *virulent phage*. Lytic growth results in lysis of the host cell and the production of many progeny phage particles. In contrast, a *temperate phage* can either produce lytic growth, as a virulent phage does, or integrate its DNA into the bacterial chromosome without causing any immediate harm to the host cell. An especially well-studied example of a temperate phage is bacteriophage λ (*lambda*), which, like the T-even phages, infects

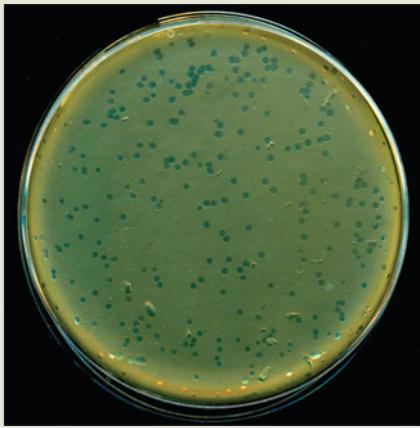

FIGURE 18A-3 Phage Plaques on a Lawn of Bacteria. Phage plaques have formed on a lawn of *E. coli* infected with phage T4. Each plaque arises from the reproduction of a single phage particle in the original mixture.

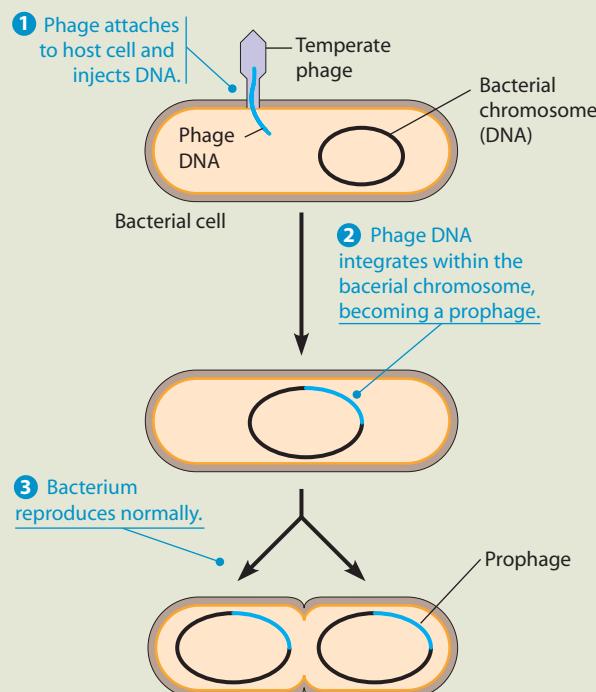

FIGURE 18A-4 Lysogenic State of a Prophage Within a Bacterial Chromosome. The DNA injected by a temperate phage can become integrated into the DNA of the bacterial chromosome. The integrated phage DNA, called a prophage, is replicated along with the bacterial DNA each time the bacterium reproduces.

E. coli cells. In the integrated or *lysogenic state*, the DNA of the temperate phage is called a *prophage*. The prophage is replicated along with the bacterial DNA, often through many generations of host cells (Figure 18A-4). During this time, the phage genes, though potentially lethal to the host, are inactive, or *repressed*. Under certain conditions, however, the prophage DNA is excised from the bacterial chromosome and again enters a lytic cycle, producing progeny phage particles and lysing the host cell.

One reason bacteriophages are so attractive to geneticists is that the small size of their genomes makes it relatively easy to identify and study their genes. The genome of bacteriophage λ , for example, is a single DNA molecule containing fewer than 60 genes, compared with several thousand genes in a bacterium such as *E. coli*. Other phages are still smaller; in some instances, they contain less than a dozen genes. Because of their simple genomes, their rapidity of multiplication, and the enormous numbers of progeny that can be produced in a small volume of culture medium, bacteriophages are among the best understood of all “organisms.” They may have some practical benefits as well. Since phages are capable of destroying bacteria, some biotechnology companies are exploring the development of modified phages that might be useful in treating human bacterial infections, especially in cases where the bacteria have become resistant to antibiotics.

One of the most thoroughly studied of the phages that infect the bacterium *Escherichia coli* is bacteriophage T2. During infection, this virus attaches to the bacterial cell surface and injects material into the cell. Shortly thereafter, the bacterial cell begins to produce thousands of new copies of the virus. This scenario suggests that material injected into the bacterial cell carries the genetic information that guides the production of the virus. What is the chemical nature of the injected material? In 1952, Alfred Hershey and Martha Chase designed an experiment to address this question. There are only two possibilities because the T2 virus is constructed from only two kinds of molecules: DNA and protein. To distinguish between these two alternatives, Hershey and Chase took advantage of the fact that the proteins of the T2 virus, like most proteins, contain the element sulfur (in the amino acids methionine and cysteine) but not phosphorus, while the viral DNA contains phosphorus (in its sugar-phosphate backbone) but not sulfur. Hershey and Chase therefore prepared two batches of T2 phage particles (as intact phages are called) with different kinds of radioactive labeling. In one batch, they labeled the phage proteins with the radioactive isotope ^{35}S ; in the other batch, they labeled the phage DNA with the isotope ^{32}P .

By using radioactive isotopes in this way, Hershey and Chase were able to trace the fates of both protein and DNA during the infection process (Figure 18-3a). They began the experiment by mixing radioactive phage with intact bacterial cells and allowing the phage particles to attach to the bacterial cell surface and inject their genetic material into the cells. At this point, Hershey and Chase found that the empty protein coats (or phage “ghosts”) could be effectively removed from the surface of the bacterial cells by agitating the suspension in an ordinary kitchen blender and recovering the bacterial cells by centrifugation. They then measured the radioactivity in the supernatant liquid and in the pellet of bacteria at the bottom of the tube.

The data revealed that most (65%) of the ^{32}P remained with the bacterial cells, while the bulk (80%) of the ^{35}S was released into the surrounding medium (Figure 18-3b). Since the ^{32}P labeled the viral DNA and the ^{35}S labeled the viral protein, Hershey and Chase concluded that DNA, not protein, had been injected into the bacterial cells; hence, DNA must function as the genetic material of phage T2. This conclusion received further support from the following observation: When the infected, radioactive bacteria were resuspended in fresh liquid and incubated longer, the ^{32}P was transferred to some of the offspring phage particles, but the ^{35}S was not.

As a result of the experiments we have described, by the early 1950s most biologists came to accept the view that genes are made of DNA, not protein. Unfortunately, Oswald Avery, the visionary most responsible for the complete turnaround in views concerning the function of DNA, never received the credit he so richly deserved. The

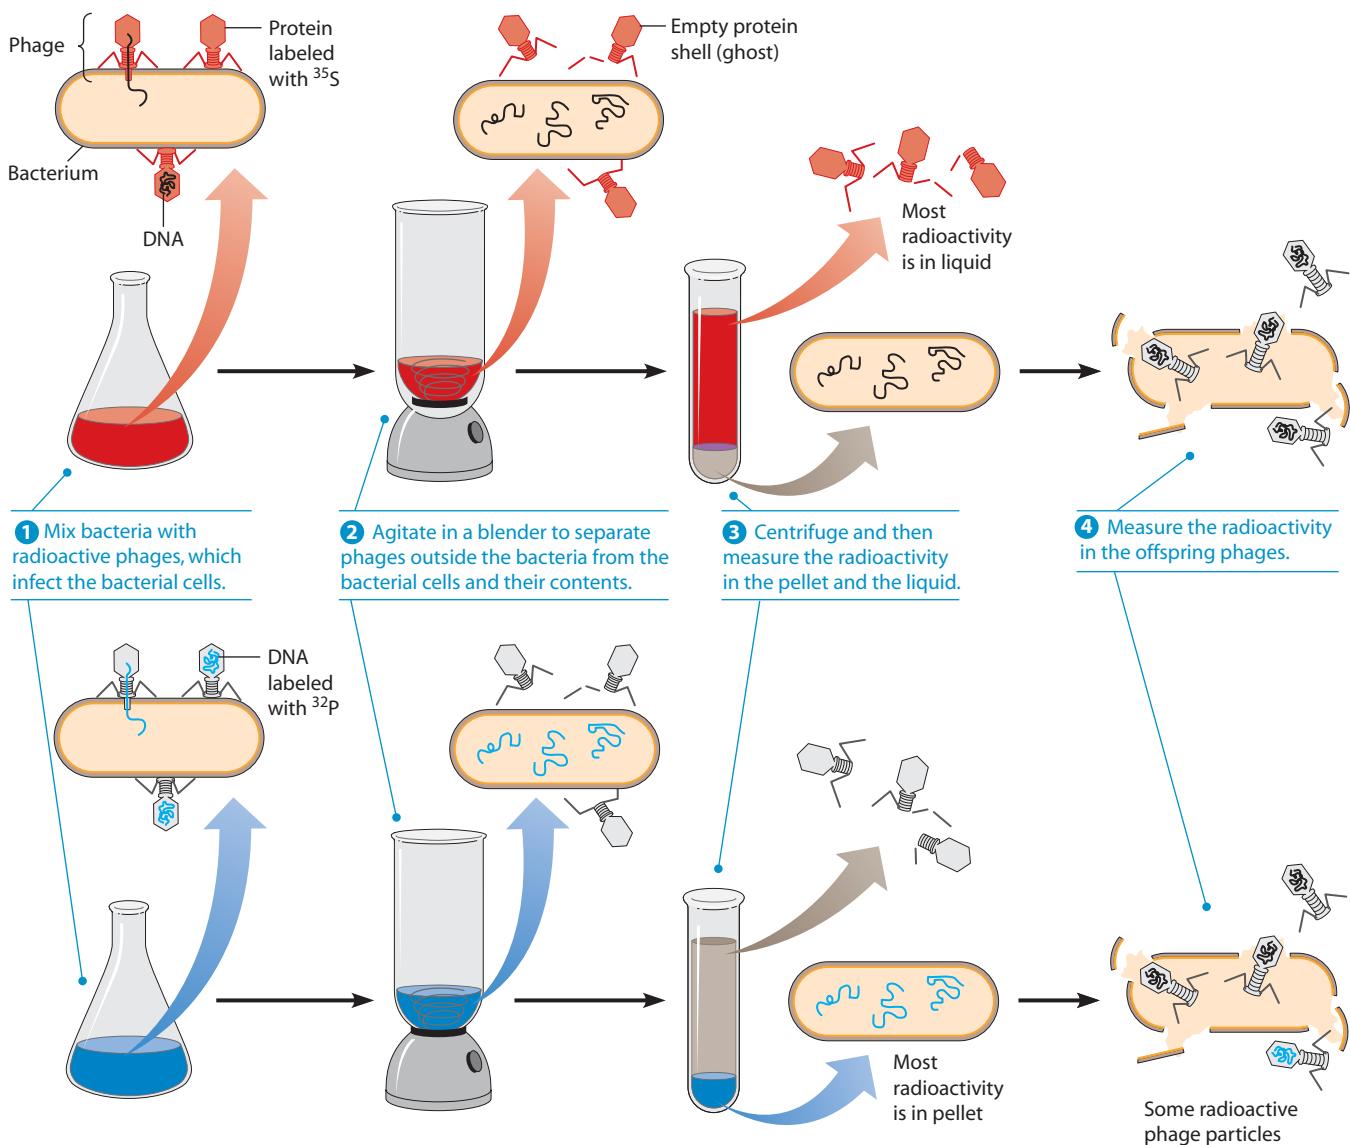

Nobel Prize Committee discussed Avery’s work but decided he had not done enough. Perhaps Avery’s modest and unassuming nature was responsible for this lack of recognition. After Avery died in 1955, the biochemist Erwin Chargaff wrote in tribute: “He was a quiet man; and it would have honored the world more, had it honored him more.”

Why did the Hershey–Chase experiments receive a warmer welcome than Avery’s earlier work on bacterial transformation, even though both led to the same conclusion? The main reason seems to have been simply the passage of time and the accumulation of additional, circumstantial evidence after Avery’s 1944 publication. Perhaps most important was evidence that DNA is indeed variable enough in structure to serve as the genetic material. This evidence came from studies of DNA base composition, as we will see next.

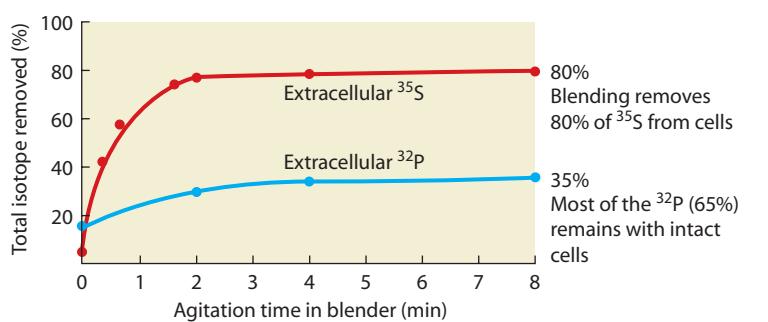

Chargaff’s Rules Reveal That $\text{A} = \text{T}$ and $\text{G} = \text{C}$

Despite the initial lukewarm reaction to Avery’s work, it had an important influence on several other scientists. Among them was Erwin Chargaff, who was interested in the base composition of DNA. Between 1944 and 1952, Chargaff used chromatographic methods to separate and quantify the relative amounts of the four bases—adenine (A), guanine (G), cytosine (C), and thymine (T)—found in DNA. Several important discoveries came from his analyses. First, he showed that DNA isolated from different cells of a given species has the same percentage of each of the four bases (Table 18-1, rows 1–4) and that this percentage does not vary with individual, tissue, age, nutritional state, or environment. This is exactly what would be expected of the chemical substance that stores genetic information because the cells of a given species would be expected to have similar genetic information. However, Chargaff did find that DNA base composition varies from species to species. This can be seen by examining the last column of Table 18-1, which shows the relative amounts of the bases A and T versus G and C in the DNAs of various organisms. The data also reveal that DNA preparations from closely related species have similar base compositions, whereas those from very different species tend to exhibit quite different base compositions. Again, this is what would be expected of a molecule that stores genetic information.

But Chargaff’s most striking observation was his discovery that, for all DNA samples examined, the number of adenines is equal to the number of thymines ($\text{A} = \text{T}$), and the number of guanines is equal to the number of cytosines ($\text{G} = \text{C}$). This meant that the number of purines is equal to the number of pyrimidines ($\text{A} + \text{G} = \text{C} + \text{T}$). The significance of these equivalencies, known as **Chargaff’s rules**, was an enigma and remained so until Watson and Crick proposed the double-helical model of DNA in 1953.

FIGURE 18-3 The Hershey-Chase Experiment: DNA as the Genetic Material of Phage T2. (a) ① T2 labeled with either ^{35}S (to label protein) or ^{32}P (to label DNA) is used to infect bacteria. The phages adsorb to the cell surface and inject their DNA. ② Agitation of the infected cells in a blender dislodges most of the ^{35}S from the cells, whereas most of the ^{32}P remains. ③ Centrifugation causes the cells to form a pellet; any free phage particles, including ghosts, remain in the supernatant liquid. ④ When the cells in each pellet are incubated further, the phage DNA within them dictates the synthesis and eventual release of new phage particles. Some of these phages contain ^{32}P in their DNA (because the old, labeled phage DNA is packaged into some of the new particles), but none contain ^{35}S in their coat proteins. (b) The graph shows the extent to which ^{35}S and ^{32}P are removed from the intact cells at step ③, as a function of time in the blender. A few minutes of blending is enough to remove most (80%) of the ^{35}S , while leaving most (65%) of the ^{32}P with the cells.

<i>Saccharomyces cerevisiae</i> (yeast)	31.3	32.9	18.7	17.1	0.95	1.09	1.79
<i>Clostridium</i> (bacterium)	36.9	36.3	14.0	12.8	1.02	1.09	2.73

*The values in these four columns are the average number of each type of nucleotide found per 100 nucleotides in DNA.

**The A/T and G/C ratios are not all exactly 1.00 because of experimental error.

DNA Structure

As the scientific community gradually came to accept the conclusion that DNA stores genetic information, a new set of questions began to emerge concerning how DNA performs its genetic function. One of the first questions to be addressed was how do cells accurately replicate their DNA so that duplicate copies of the genetic information can be passed on from cell to cell during cell division and from parent to offspring during reproduction? Answering this question required an understanding of the three-dimensional structure of DNA, which was provided in 1953 when Watson and Crick formulated their double-helical model of DNA. We described the structure of the double helix in Chapter 3 and its discovery in Box 3A (page 60), but we return to it now for review and some further details.

Watson and Crick Discovered That DNA Is a Double Helix

In 1952, James Watson and Francis Crick were among a handful of scientists who were convinced that DNA is the genetic material and that knowing its three-dimensional structure would provide valuable clues to how it functions. Working at Cambridge University in England, Watson and Crick approached the puzzle by building wire models of possible structures. DNA had been known for years to be a long polymer having a backbone of repeating sugar (deoxyribose) and phosphate units, with a nitrogenous base attached to each sugar. These scientists were aided in their model building by knowing that the particular forms in which the bases A, G, C, and T exist at physiological pH permit specific hydrogen bonds to form between pairs of them. The crucial experimental evidence, however, came

from an X-ray diffraction picture of DNA produced by Rosalind Franklin, who was working at King's College in London. Franklin's painstaking analysis of the diffraction pattern revealed that DNA was a long, thin, helical molecule with one type of structural feature being repeated every 0.34 nm and another being repeated every 3.4 nm. Based on the information provided by this picture, Watson and Crick eventually produced a DNA model consisting of two intertwined strands—a **double helix**.

In the Watson–Crick double helix, illustrated in **Figure 18-4**, the sugar-phosphate backbones of the two strands are on the outside of the helix, and the bases face inward toward the center of the helix, forming the “steps” of the “circular staircase” that the structure resembles. The helix is right-handed, meaning that it curves “upward” to the right (notice that this is true even if you turn the diagram upside down). It contains ten nucleotide pairs per turn and advances 0.34 nm per nucleotide pair. Consequently, each complete turn of the helix adds 3.4 nm to the length of the molecule. The diameter of the helix is 2 nm. This distance turns out to be too small for two purines and too great for two pyrimidines; but it accommodates a purine and a pyrimidine well, consistent with Chargaff's rules. Pyrimidine-purine pairing, in other words, was necessitated by their physical sizes. The two strands are held together by hydrogen bonding between the bases in opposite strands. Moreover, the hydrogen bonds holding together the two strands of the double helix fit *only when they form between the base adenine (A) in one chain and thymine (T) in the other or between the base guanine (G) in one chain and cytosine (C) in the other*. This means that the base sequence of one chain determines the base sequence of the opposing chain; the two chains of the DNA double helix are therefore said to be **complementary** to each other. Such a model explains why Chargaff had

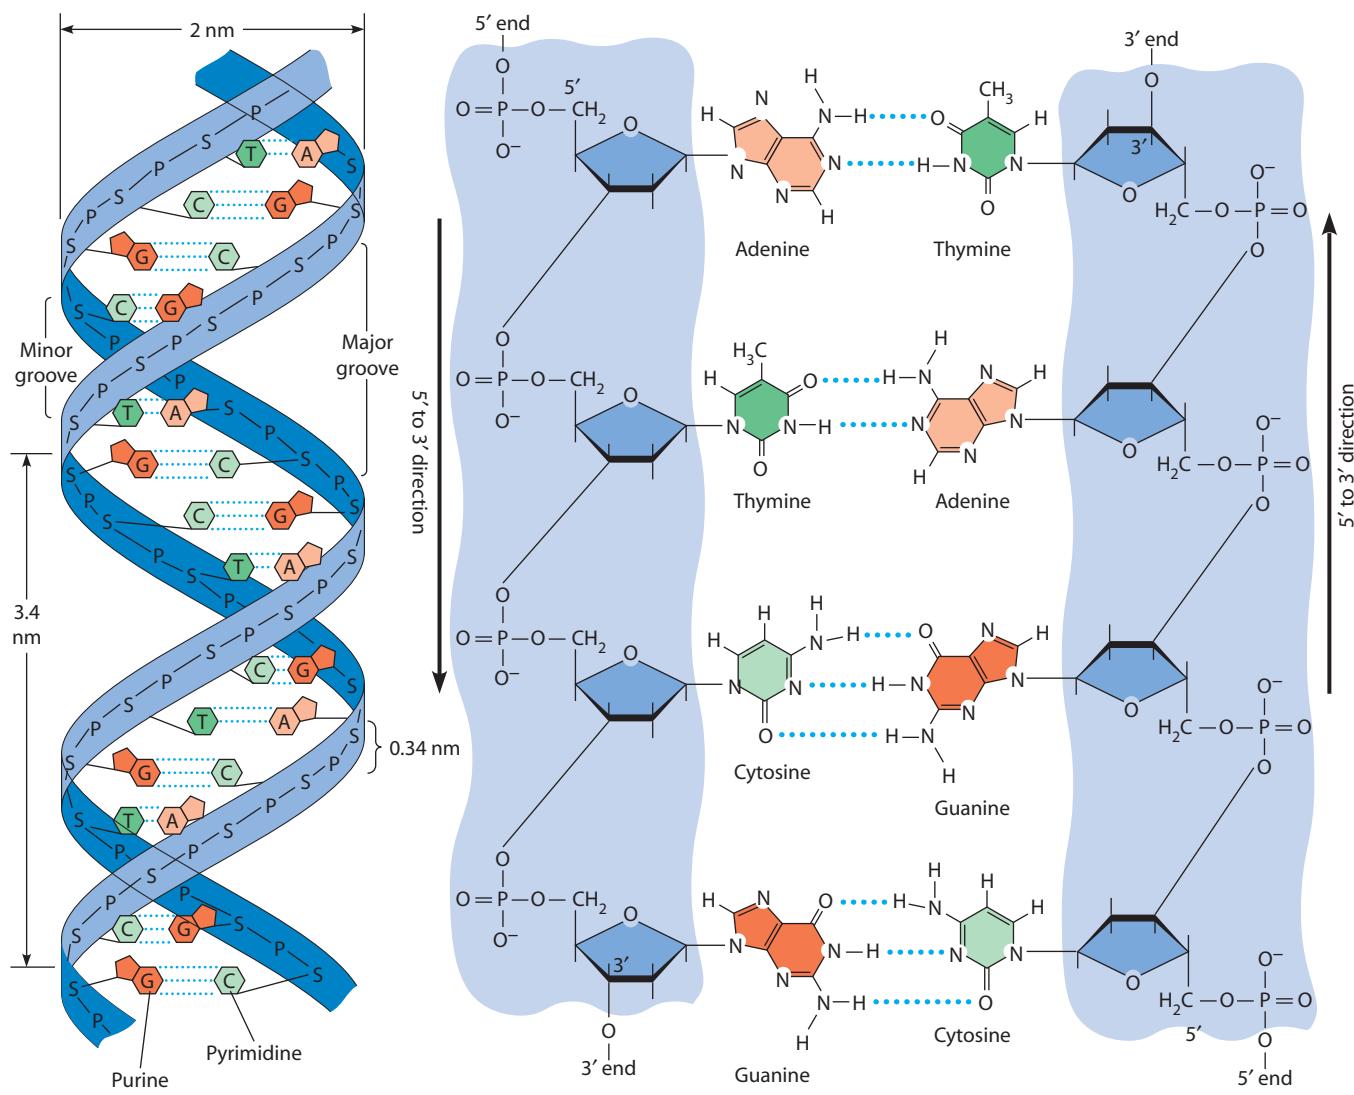

FIGURE 18-4 The DNA Double Helix. (a) This schematic illustration shows the sugar-phosphate chains of the DNA backbone, the complementary base pairs, the major and minor grooves, and several important dimensions. A = adenine, G = guanine, C = cytosine, T = thymine, P = phosphate, and S = sugar (deoxyribose). (b) One strand of a DNA molecule is oriented 5' → 3' in one direction, whereas its complement has a 5' → 3' orientation in the opposite direction. This diagram also shows the hydrogen bonds that connect the bases in AT and GC pairs.

observed that DNA molecules contain equal amounts of the bases A and T and equal amounts of the bases G and C.

The most profound implication of the Watson–Crick model was that it suggested a mechanism by which cells can replicate their genetic information: The two strands of the DNA double helix could simply separate from each other before cell division so that each strand could function as a *template*, dictating the synthesis of a new complementary DNA strand using the base-pairing rules. In other words, the base A in the template strand would specify insertion of the base T in the newly forming strand, the base G would specify insertion of the base C, the base T would specify insertion of the base A, and the base C would specify insertion of the base G. In the next

chapter, we will discuss the experimental evidence for this proposed mechanism and describe the molecular basis of DNA replication in detail.

Several other important features of the DNA double helix are illustrated in Figure 18-4. For example, notice that the two strands are twisted around each other so that there is a *major groove* and a *minor groove*. Base pairs viewed from the major groove yield more information than when viewed from the minor groove because more hydrogen bond donors (H) and acceptors (O, N), as well as the methyl group of the base T, are exposed to the major groove. As a result, regulatory proteins can bind to the major groove and recognize specific base sequences without unfolding the DNA double helix (see Figure 23-24).

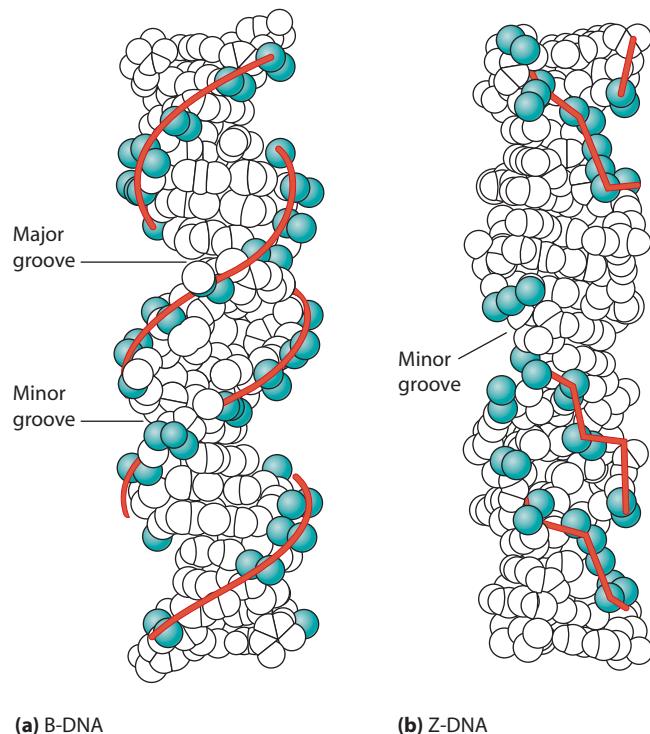

FIGURE 18-5 Alternative Forms of DNA. (a) In the normal B form of DNA, the sugar-phosphate backbone forms a smooth right-handed double helix. (b) In Z-DNA, the backbone forms a zigzag left-handed helix. Color is used to highlight the backbones.

Another important feature is the *antiparallel* orientation of the two DNA strands, illustrated in Figure 18-4b. This diagram shows that the phosphodiester bonds, which join the 5' carbon of one nucleotide to the 3' carbon of the adjacent nucleotide, are oriented in *opposite* directions in the two DNA strands. Starting at the top of the diagram, the strand on the left is said to exhibit a 5' → 3' *orientation* because its first nucleotide has a free 5' end and its final nucleotide has a free 3' end. Conversely, the strand on the right exhibits a 3' → 5' *orientation* starting from the top because its first nucleotide has a free 3' end and its final nucleotide has a free 5' end. The opposite orientation of the two strands has important implications for both DNA replication and DNA transcription, as we will see in Chapters 19 and 21.

The right-handed Watson–Crick helix is an idealized version of what is called *B-DNA* (Figure 18-5a). Naturally occurring B-DNA double helices are flexible molecules whose exact shapes and dimensions depend on the local nucleotide sequence. Although B-DNA is the main form of DNA in cells (and in test tube solutions of DNA), other forms may also exist, perhaps in short segments interspersed in molecules that are mostly B-DNA. The most important of these alternative forms are Z-DNA and A-DNA. As shown in Figure 18-5b, Z-DNA is a *left-handed* double helix. Its name derives from the zigzag pattern of its sugar-phosphate backbone,

and it is longer and thinner than B-DNA. The Z form arises most readily in DNA regions that contain either alternating purines and pyrimidines or have cytosines with extra methyl groups (which do occur in chromosomal DNA; see Chapter 23). Although the biological significance of Z-DNA is not well understood, some evidence suggests that short stretches of DNA transiently flip into the Z configuration as part of the process that activates the expression of certain genes.

A-DNA is a right-handed helix, shorter and thicker than B-DNA, and can be created artificially by dehydrating B-DNA. Although A-DNA does not exist in significant amounts under normal cellular condition, most RNA double helices are of the A type. A-type helices have a wider minor groove and a narrower major groove than B-type helices, so A-RNA is not well suited for base recognition by RNA-binding proteins from the major groove. To recognize specific base sequences in A-RNA, regulatory proteins generally need to unwind the duplex.

DNA Can Be Interconverted Between Relaxed and Supercoiled Forms

In many situations, the DNA double helix can be twisted upon itself to form **supercoiled DNA**. Although now known to be a widespread property of DNA, supercoiling was first identified in the DNA of certain small viruses containing circular DNA molecules that exist as closed loops. Circular DNA molecules are also found in bacteria, mitochondria, and chloroplasts. Although supercoiling is not restricted to circular DNA, it is easiest to study in such molecules.

A DNA molecule can go back and forth between the supercoiled state and the nonsupercoiled, or *relaxed*, state. To understand the basic idea, you might perform the following exercise. Start with a length of rope consisting of two strands twisted together into a right-handed coil; this is the equivalent of a relaxed, linear DNA molecule. Just joining the ends of the rope together changes nothing; the rope is now circular but still in a relaxed state. But before sealing the ends, if you first give the rope an extra twist in the direction in which the strands are already entwined around each other, the rope is thrown into a *positive supercoil*. Conversely, if before sealing, you give the rope an extra twist in the opposite direction, the rope is thrown into a *negative supercoil*. Like the rope in this example, a relaxed DNA molecule can be converted to a positive supercoil by twisting in the same direction as the double helix is wound and into a negative supercoil by twisting in the opposite direction (Figure 18-6). Circular DNA molecules found in nature, including those of bacteria, viruses, and eukaryotic organelles, are invariably negatively supercoiled.

Supercoiling also occurs in linear DNA molecules when regions of the molecule are anchored to some cell structure and so cannot freely rotate. At any given time,

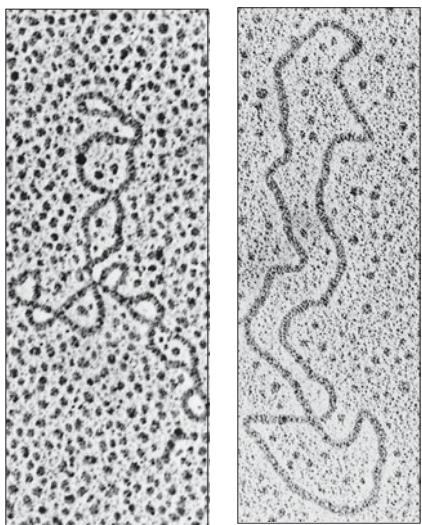

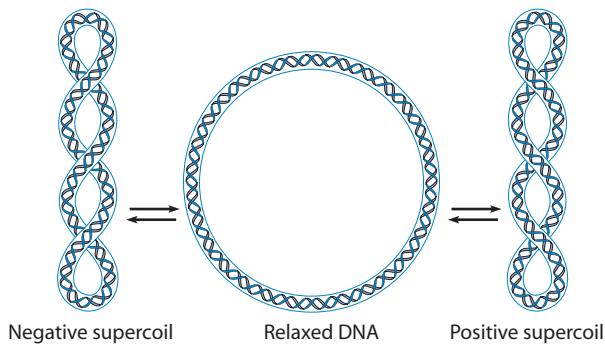

FIGURE 18-6 Interconversion of Relaxed and Supercoiled DNA. (Top) Conversion of a relaxed circular DNA molecule into a negatively supercoiled form (by twisting it in the opposite direction as the double helix is wound) and into a positively supercoiled form (by twisting it in the same direction as the double helix is wound). (Bottom) Electron micrographs of circular DNA molecules from a bacteriophage called PM2, showing a molecule with negative supercoils on the left and a relaxed molecule on the right (TEMs).

 [ACTIVITIES www.thecellplace.com](http://www.thecellplace.com) DNA supercoiling

significant portions of the linear DNA in the nucleus of eukaryotic cells may be supercoiled; and, when DNA is packaged into chromosomes at the time of cell division, extensive supercoiling helps to make the DNA more compact.

By influencing both the spatial organization and the energy state of DNA, supercoiling affects the ability of a DNA molecule to interact with other molecules. Positive supercoiling involves tighter winding of the double helix and therefore reduces opportunities for interaction. In contrast, negative supercoiling is associated with unwinding of the double helix, which gives its strands increased access to proteins involved in DNA replication or transcription.

The interconversion between relaxed and supercoiled forms of DNA is catalyzed by enzymes known as **topoisomerases**, which are classified as either *type I* or

type II. Both types catalyze the relaxation of supercoiled DNA; type I enzymes do so by introducing transient single-strand breaks in DNA, whereas type II enzymes introduce transient double-strand breaks. **Figure 18-7** shows how these temporary breaks affect DNA supercoiling. Type I topoisomerases induce DNA relaxation by cutting one strand of the double helix, thereby allowing the DNA to rotate and the uncut strand to be passed through the break before the broken strand is resealed. In contrast, type II topoisomerases induce relaxation by cutting both DNA strands and then passing a segment of uncut double helix through the break before resealing. Unlike the type I reaction, this action of type II topoisomerases requires energy derived from the hydrolysis of ATP.

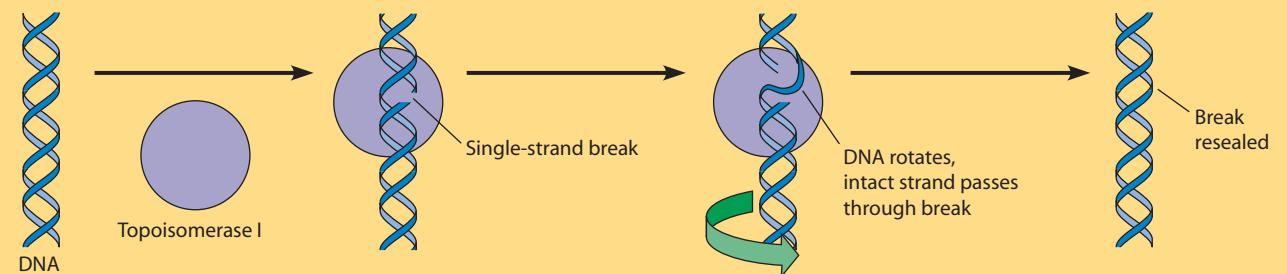

Type I and type II topoisomerases are able to remove both positive and negative supercoils from DNA. In addition, bacteria have a type II topoisomerase called **DNA gyrase**, which can induce as well as relax supercoiling. As you will learn in Chapter 19, DNA gyrase is one of several enzymes involved in DNA replication. It can relax the positive supercoiling that results from partial unwinding of a double helix, or it can actively introduce negative supercoils that promote strand separation, thereby facilitating access of other proteins involved in DNA replication. DNA gyrase requires ATP to generate supercoiling but not to relax an already supercoiled molecule.

The Two Strands of a DNA Double Helix Can Be Separated Experimentally by Denaturation and Rejoined by Renaturation

Because the two strands of the DNA double helix are bound together by relatively weak, noncovalent bonds, the two strands can be readily separated from each other under appropriate conditions. As we will see in coming chapters, strand separation is an integral part of both DNA replication and RNA synthesis. Strand separation can also be induced experimentally, resulting in **DNA denaturation**; the reverse process, which reestablishes a double helix from separated DNA strands, is called **DNA renaturation**.

DNA is commonly denatured in the laboratory by raising either the temperature or the pH. When denaturation is induced by slowly raising the temperature, the DNA retains its double-stranded, or native, state until a critical temperature is reached; at that point the duplex rapidly denatures, or “melts,” into its component strands. The melting process is easy to monitor because double-stranded and single-stranded DNA differ in their light-absorbing properties. All DNA absorbs ultraviolet light, with an absorption maximum around 260 nm. When the temperature of a DNA solution is slowly raised, the absorbance at 260 nm remains constant until the double helix begins to melt into its component strands. As the strands separate, the absorbance of the solution

(a) Topoisomerase I. Supercoils are removed by transiently cleaving one strand of the DNA double helix and passing the unbroken strand through the break.

(b) Topoisomerase II. Supercoils are removed by transiently cleaving both strands of the DNA double helix and passing an unbroken region of the DNA double helix through the break.

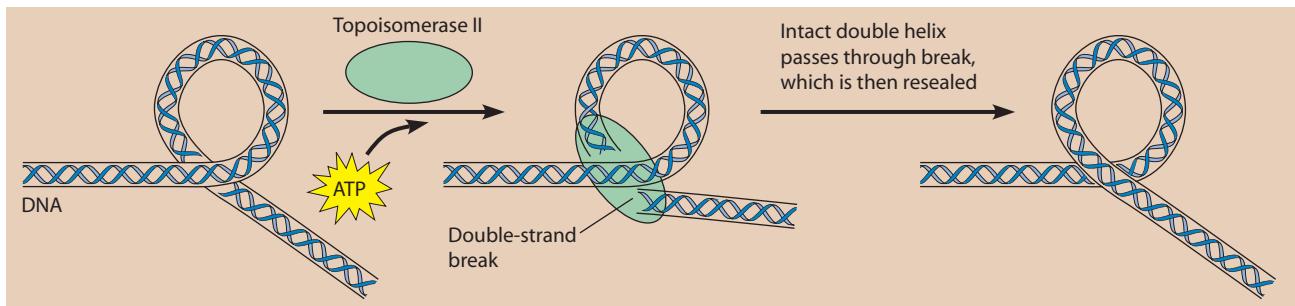

FIGURE 18-7 Reactions Catalyzed by Topoisomerases I and II. (a) Type I and (b) type II topoisomerases are used for removing both positive and negative supercoils from DNA.

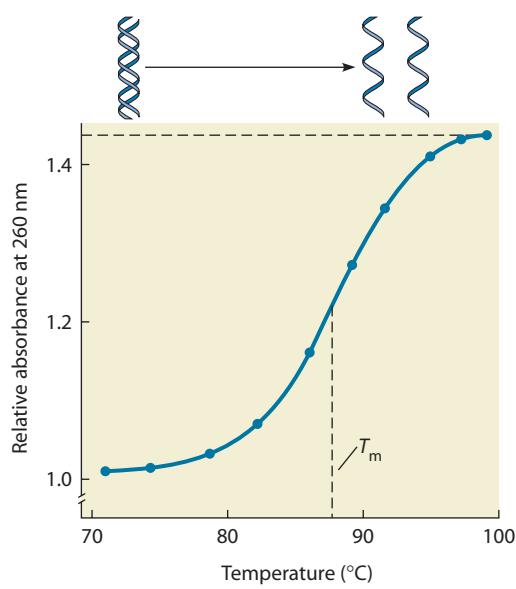

FIGURE 18-8 A Thermal Denaturation Profile for DNA.

When the temperature of a solution of double-stranded (native) DNA is raised, the heat causes the DNA to denature. The conversion to single strands is accompanied by an increase in the absorbance of light at 260 nm. The temperature at which the midpoint of this increase occurs is called the melting temperature, T_m . For the sample shown, the T_m is about 87°C.

increases rapidly due to the higher intrinsic absorption of single-stranded DNA (Figure 18-8).

The temperature at which one-half of the absorbance change has been achieved is called the **DNA melting temperature** (T_m). The value of the melting temperature reflects how tightly the DNA double helix is held together. For example, GC base pairs, held together by three hydrogen bonds, are more resistant to separation than are AT base pairs, which have only two (see Figure 18-4b). The melting temperature therefore increases in direct proportion to the relative number of GC base pairs in the DNA (Figure 18-9). Likewise, DNA molecules in which the two strands of the double helix are properly base-paired at each position will melt at higher temperatures than will DNA in which the two strands are not perfectly complementary.

Denatured DNA can be renatured by lowering the temperature to permit hydrogen bonds between the two strands to be reestablished (Figure 18-10). The ability to renature nucleic acids has a variety of important scientific applications. Most importantly, it forms the basis for **nucleic acid hybridization**, a family of procedures for identifying nucleic acids based on the ability of single-stranded chains with complementary base sequences to bind, or *hybridize*, to each other. Nucleic acid hybridization can be applied to DNA–DNA, DNA–RNA, and even RNA–RNA interactions. In DNA–DNA hybridization, for

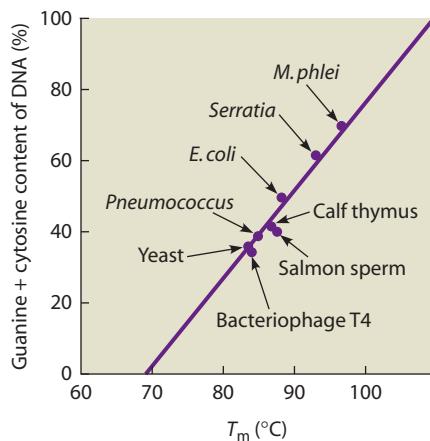

FIGURE 18-9 Dependence of DNA Melting Temperature on Base Composition. The melting temperature of DNA increases with its G + C content, as shown by the relationship between T_m and G + C content for DNA samples from a variety of sources.

example, the DNA being examined is denatured and then incubated with a purified, single-stranded radioactive DNA fragment, called a **probe**, whose sequence is complementary to the base sequence one is trying to detect. Box 18C provides an example of the use of a probe in DNA fingerprinting.

Nucleic acid sequences do not need to be perfectly complementary to be able to hybridize. Changing the temperature, salt concentration, and pH used during hybridization can permit pairing to take place between partially complementary sequences exhibiting numerous

mismatches. Under such conditions, hybridization will occur between DNAs that are related to one another but not identical. This approach is useful for identifying families of related genes, both within a given type of organism and among different kinds of organisms.

The Organization of DNA in Genomes

So far, we have considered several chemical and physical properties of DNA. But as cell biologists, we are primarily interested in its importance to the cell. We therefore want to know how much DNA cells have, how and where they store it, and how they utilize the genetic information it contains. We begin by inquiring about the amount of DNA present because that determines the maximum amount of information a cell can possibly possess.

The **genome** of an organism or virus consists of the DNA (or for some viruses, RNA) that contains one complete copy of all the genetic information of that organism or virus. For many viruses and prokaryotes, the genome resides in a single linear or circular DNA molecule or in a small number of them. Eukaryotic cells have a nuclear genome, a mitochondrial genome, and, in the case of plants and algae, a chloroplast genome as well. Mitochondrial and chloroplast genomes are single, usually circular DNA molecules resembling those of bacteria. The nuclear genome generally consists of multiple DNA molecules dispersed among a haploid set of chromosomes. (As we will explore in more detail in Chapter 20, a *haploid* set of chromosomes consists of one representative of each type of chromosome, whereas a *diploid* set consists of two copies of each type of chromosome, one copy from the mother and one from the father. Sperm and egg cells each have a haploid set of chromosomes, whereas most other types of eukaryotic cells are diploid.)

Genome Size Generally Increases with an Organism's Complexity

Genome size is usually expressed as the total number of base-paired nucleotides, or **base pairs (bp)**. For example, the circular DNA molecule that constitutes the genome of an *E. coli* cell has 4,639,221 bp. Since such numbers tend to be rather large, the abbreviations **Kb** (kilobases), **Mb** (megabases), and **Gb** (gigabases) are used to refer to a thousand, or million, or billion base pairs, respectively. Thus, the size of the *E. coli* genome can be expressed simply as 4.6 Mb. The range of genome sizes observed for various groups of organisms is summarized in **Figure 18-11**. These data reveal a spread of almost eight orders of magnitude in genome size, from a few thousand base pairs for the simplest viruses to more than 100 billion base pairs for certain plants, amphibians, and protists. Expressed in terms of total DNA length, this corresponds to a range of less than 2 μm of DNA for a small virus, such as SV40, to

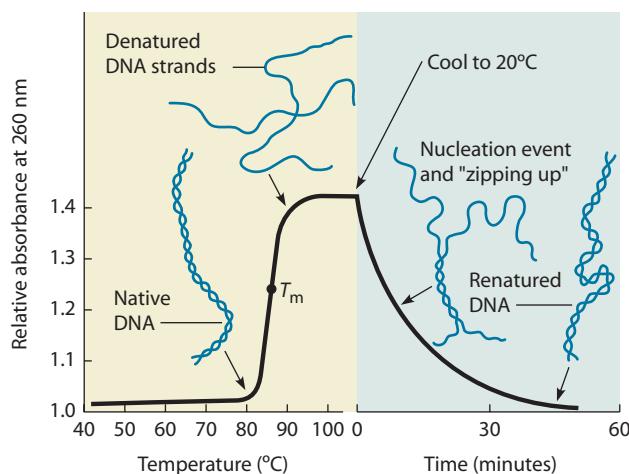

FIGURE 18-10 DNA Denaturation and Renaturation. If a solution of native (double-stranded) DNA is heated slowly under carefully controlled conditions, the DNA “melts” over a narrow temperature range, with an increase in absorbance at 260 nm. When the solution is allowed to cool, the separated DNA strands reassociate by random collisions, followed by a rapid “zipping up” of complementary base pairs in the two strands. The reassociation requires varying amounts of time, depending on both the DNA concentration in the solution and the length of the DNA strands.

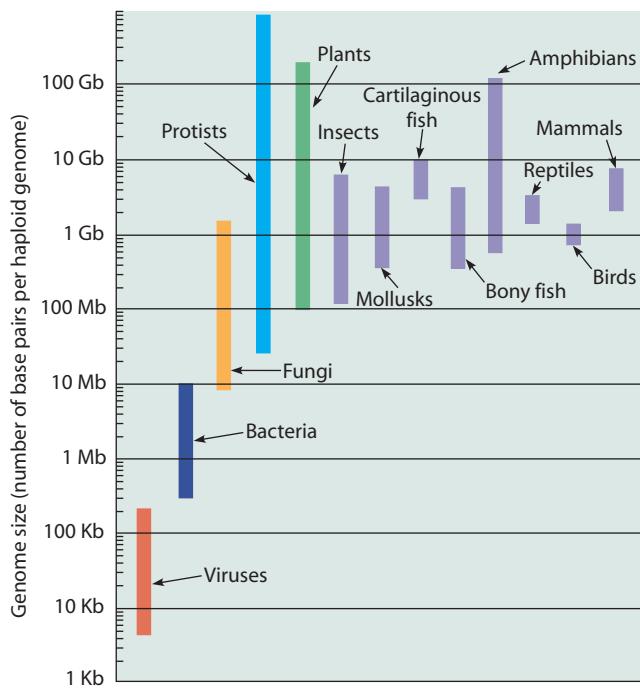

FIGURE 18-11 Relationship Between Genome Size and Type of Organism. For each group of organisms shown, the bar represents the approximate range in genome size measured as the number of base pairs per haploid genome. The same color (purple) is used for groups that involve members of the animal kingdom.

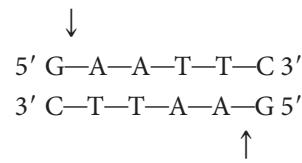

roughly 34 meters of DNA (more than 100 feet!) for certain plants, such as the wildflower *Trillium*.

Broadly speaking, genome size increases with the complexity of the organism. Viruses contain enough nucleic acid to code for only a few or a few dozen proteins, bacteria can specify a few thousand proteins, and eukaryotic cells have enough DNA (at least in theory) to encode hundreds of thousands of proteins. But closer examination of such data reveals some puzzling features. Most notably, the genome sizes of eukaryotes exhibit great variations that do not clearly correlate with any known differences in organismal complexity. Some amphibians and plants, for example, have gigantic genomes that are tens or even hundreds of times larger than those of other amphibians or plants or of mammalian species. *Trillium*, for example, is a member of the lily family that has no obvious need for exceptional amounts of genetic information. Yet its genome size is more than 20 times that of pea plants and 30 times that of humans. Moreover, a single-celled amoeba has a genome that is 200 times the size of the human genome. We have no idea why lily plants and amoebae possess so much DNA. Its presence highlights the fact that most eukaryotic genomes carry large amounts of DNA of no currently known function, a phenomenon we will discuss shortly. In the final analysis, genome size is less important than the number and identity of functional genes and the DNA sequences that control their expression.

Restriction Endonucleases Cleave DNA Molecules at Specific Sites

Since the hereditary similarities and differences observed among organisms derive from their DNA, we can expect the study of DNA molecules to yield important biological insights. Clues to a myriad of mysteries—from the control of gene expression within a cell to the evolution of new species—are to be found in the nucleotide sequences of genomic DNA. Most DNA molecules, however, are far too large to be studied intact. In fact, until the early 1970s, DNA was the most difficult biological molecule to analyze biochemically. Eukaryotic DNA seemed especially intimidating, given the size of most eukaryotic genomes, and no method was known for cutting DNA at specific sites to yield reproducible fragments. The prospect of ever being able to identify, isolate, sequence, or manipulate specific eukaryotic genes seemed unlikely. Yet in less than a decade, DNA became one of the easiest biological molecules to work with.

This breakthrough was made possible by the discovery of **restriction endonucleases** (also called *restriction enzymes*), which are proteins isolated from bacteria that cut foreign DNA molecules at specific internal sites. (Box 18B describes the biological role of restriction endonucleases and provides some details about the sites they cut; here we focus on their use as analytical tools.) The cutting action of a restriction enzyme generates a specific set of DNA pieces called *restriction fragments*. Each restriction enzyme cleaves double-stranded DNA only in places where it encounters a specific recognition sequence, called a **restriction site**, that is usually four or six (but may be eight or more) nucleotides long. For example, here is the restriction site recognized by the widely used *E. coli* restriction enzyme called EcoRI:

The arrows indicate where EcoRI cuts the DNA. This restriction enzyme, like many others, makes a *staggered cut* in the double-stranded DNA molecule, as you can see in Figure 18B-1b (Box 18B).

Restriction sites occur frequently enough in DNA to permit typical restriction enzymes to cleave DNA into fragments ranging from a few hundred to a few thousand base pairs in length. Fragments of these sizes are far more amenable to further manipulation than are the enormously long DNA molecules from which they are generated.

Separation of Restriction Fragments by Gel Electrophoresis. Incubating a DNA sample with a specific restriction enzyme yields a collection of restriction fragments of different sizes. To determine the number

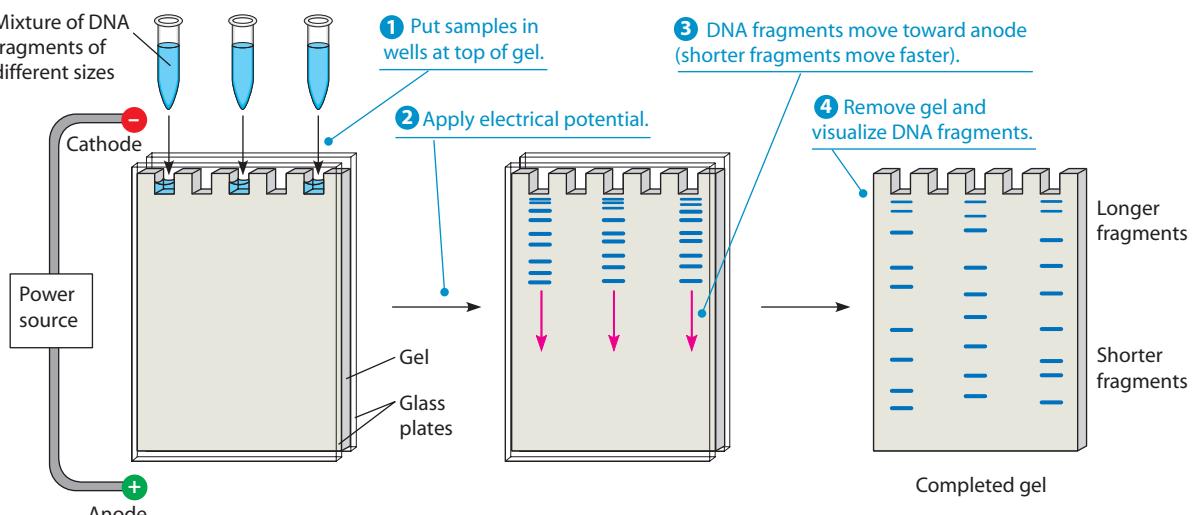

FIGURE 18-12 Gel Electrophoresis of DNA. The three test tubes contain mixtures of DNA fragments produced by incubating DNA with different restriction enzymes. A small sample of each is applied to the top of a gel, and an electrical potential of several hundred volts is applied. This causes the DNA fragments to migrate toward the anode, with shorter fragments migrating faster than larger ones. After allowing time for the fragments to separate from one another, the gel is removed and stained with a dye such as ethidium bromide, which binds to the DNA fragments and causes them to fluoresce under ultraviolet light. Alternatively, autoradiography can be used to locate the DNA bands in the gel, provided that the DNA is radioactively labeled.

and lengths of such fragments and to isolate individual fragments for further study, a researcher must be able to separate the fragments from one another. The technique of choice for this purpose is **gel electrophoresis**, essentially the same method used to separate proteins and polypeptides (see Figure 7-22). In fact, the procedure for DNA is even simpler than for proteins because DNA molecules have an inherent negative charge (due to their phosphate groups) and therefore do not need to be treated with a negatively charged detergent to make them move toward the anode. Small DNA fragments are usually separated in *polyacrylamide* gels, whereas larger DNA fragments are separated in more porous gels made of *agarose*, a polysaccharide.

Figure 18-12 illustrates the separation of restriction fragments of different sizes by gel electrophoresis. DNA samples are first incubated with the desired restriction enzyme; in the figure, three different restriction enzymes are used. The samples are then placed in separate compartments ("wells") at one end of the gel. Next, an electrical potential is applied across the gel, with the anode situated at the opposite end of the gel from the samples. Because their phosphate groups have a negative charge, DNA fragments migrate toward the anode. Smaller fragments (i.e., those with lower molecular weight) move through the gel with relative ease and therefore migrate rapidly, while larger fragments move more slowly. The current is left on until the fragments are well spaced out on the gel. The final result is a series of DNA fragments that have been separated based on differences in size.

DNA fragments in the gel can be visualized either by staining or by using radioactively labeled DNA. A

common staining technique involves soaking the gel in the dye *ethidium bromide*, which binds to DNA and fluoresces orange when exposed to ultraviolet light. If the DNA fragments are radioactive, their locations can be determined by **autoradiography**, a technique for detecting radioactive molecules by overlaying a sample with X-ray film. When the film is developed, it yields an *autoradiogram* that is darkened wherever radioactivity has interacted with the film. After individual DNA fragments are located in this way, they can be removed from the gel for further study.

Restriction Mapping. How does a researcher determine the order in which a set of restriction fragments is arranged in a DNA molecule? One approach involves treating the DNA with two or more restriction enzymes, alone and in combination, followed by gel electrophoresis to determine the size of the resulting DNA fragments. **Figure 18-13** shows how it would work for a simple DNA molecule cleaved with the restriction enzymes *Eco*RI and *Hae*III. In this example, each individual restriction enzyme cleaves the DNA into two fragments, indicating that the DNA contains one restriction site for each enzyme. Based on such information alone, two possible restriction maps can be proposed (see maps A and B in Figure 18-13). To determine which of the two maps is correct, an experiment must be done in which the starting DNA molecule is cleaved *simultaneously* with *Eco*RI and *Hae*III. The size of the fragments produced by simultaneous digestion with both enzymes reveals that map A must be the correct one.

In practice, restriction mapping usually involves data that are considerably more complex than in our simple

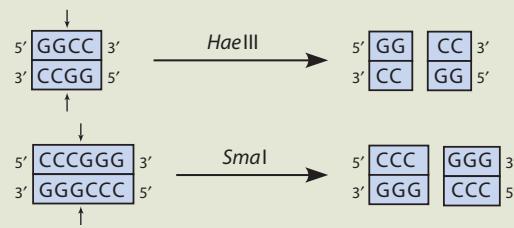

A Closer Look at Restriction Endonucleases

Restriction enzymes are a type of endonuclease (an enzyme that cuts DNA internally) found in most bacteria. These enzymes help bacteria protect themselves against invasion by foreign DNA molecules, particularly the DNA of bacteriophages. In fact, the name “restriction” endonuclease came from the discovery that these enzymes restrict the ability of foreign DNA to take over the transcription and translation machinery of the bacterial cell.

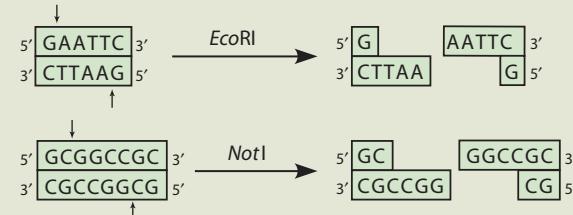

To protect its own DNA from being degraded, the bacterial cell has enzymes that add methyl groups ($-\text{CH}_3$) to specific nucleotides that its own restriction enzymes would otherwise recognize. Once they have been methylated, the nucleotides are no longer recognized by the restriction enzymes, and so the bacterial DNA is not attacked by the cell’s own restriction enzymes. Restriction enzymes are therefore said to be part of the cell’s **restriction/methylation system**: Foreign DNA is cleaved by the restriction enzymes, while the bacterial genome is protected by prior methylation.

Restriction enzymes are named after the bacteria from which they are obtained. Each enzyme name is derived by combining the first letter of the bacterial genus with the first two letters of the species. The strain of the bacterium may also be indicated, and if two or more enzymes have been isolated from the same species, the enzymes are numbered (using Roman numerals) in order of discovery. Thus, the first restriction enzyme isolated from *E. coli* strain R is designated EcoRI, whereas the third enzyme isolated from *Hemophilus aegyptius* is called *HaeIII*.

Restriction enzymes are specific for double-stranded DNA and cleave both strands. Each restriction enzyme recognizes a specific DNA sequence that is usually four or six (but may be eight or more) nucleotide pairs long. For example, the enzyme *HaeIII* recognizes the tetranucleotide sequence GGCC and cleaves the DNA double helix as shown in **Figure 18B-1a**. The restriction sites for several other restriction enzymes are summarized in **Table 18B-1**. Some restriction enzymes, such as *HaeIII*, cut both strands at the same point, generating restriction fragments with

(a) Cleavage by enzymes producing blunt ends

(b) Cleavage by enzymes producing sticky ends

FIGURE 18B-1 Cleavage of DNA by Restriction Enzymes.

(a) *HaeIII* and *SmaI* are examples of restriction enzymes that cut both DNA strands in the same location, generating fragments with blunt ends. (b) *EcoRI* and *NotI* are examples of enzymes that cut DNA in a staggered fashion, generating fragments with sticky ends. A genetic “engineer” can use such sticky ends for joining DNA fragments from different sources, as we will explain in Chapter 20.

blunt ends. Many other restriction enzymes cleave the two strands in a staggered manner, generating short, single-stranded tails or overhangs on both fragments. *EcoRI* is an example of such an enzyme; it recognizes the sequence GAATTC and cuts the DNA molecule in an offset manner, leaving an AATT tail on both

example. In such situations, the DNA fragments produced by each restriction enzyme can be physically isolated—for example, by cutting the gel into slices and extracting the DNA from each slice. The isolated fragments are then individually cleaved with the second restriction enzyme, allowing the cleavage sites in each fragment to be analyzed separately. Problem 18-4 provides an example of how this approach can be used to construct a **restriction map** depicting the location of all the restriction sites in the original DNA.

Rapid Procedures Exist for DNA Sequencing

At about the same time that techniques for preparing restriction fragments were developed, two methods were devised for rapid **DNA sequencing**—that is, determining the linear order of bases in DNA. One method was devised

by Allan Maxam and Walter Gilbert, the other by Frederick Sanger and his colleagues. The Maxam–Gilbert method, called the *chemical method*, is based on the use of (nonprotein) chemicals that cleave DNA preferentially at specific bases; the Sanger procedure, called the *chain termination method*, utilizes *dideoxynucleotides* (nucleotides lacking a 3’ hydroxyl group) to interfere with the normal enzymatic synthesis of DNA. We will focus on Sanger’s method because it has been adapted for use in automated machines that are now employed for most DNA sequencing tasks.

In this procedure, a single-stranded DNA fragment is employed as a template to guide the synthesis of new complementary DNA strands. DNA synthesis is carried out in the presence of the *deoxynucleotides* dATP, dCTP, dTTP, and dGTP, which are the normal substrates that provide the bases A, C, T, and G to growing DNA chains. Also included, at lower concentrations, are four dye-labeled

fragments (Figure 18B-1b). The restriction fragments generated by enzymes with this staggered cleavage pattern always have **sticky ends** (also called *cohesive ends*). These terms derive from the fact that the single-stranded tail at the end of each such fragment can base-pair with the tail at either end of any other fragment generated by the same enzyme, causing the fragments to stick to one another by hydrogen bonding. Enzymes that generate such fragments are particularly useful because they can be employed experimentally to create recombinant DNA molecules, as we will see in Chapter 20.

The restriction sites for most restriction enzymes are **palindromes**, which means that the sequence reads the same in either direction. (The English word *radar* is a palindrome, for example.) The palindromic nature of a restriction site is due to its twofold rotational symmetry, which means that rotating the double-stranded sequence 180° in the plane of the paper yields a sequence that reads the same as it did before rotation. Palindromic restriction sites have the same base sequence on both strands when each strand is read in the 5'→3' direction.

The frequency with which any particular restriction site is likely to occur within a DNA molecule can be predicted statistically. For example, in a DNA molecule containing equal amounts of the four bases (A, T, C, and G), we can predict that, on average, a recognition site with four nucleotide pairs will occur once every 256 (i.e., 4⁴) nucleotide pairs, whereas the likely frequency of a six-nucleotide sequence is once every 4096 (i.e., 4⁶) nucleotide pairs. Restriction enzymes therefore tend to cleave DNA into fragments that typically vary in length from several hundred to a few thousand nucleotide pairs—gene-sized pieces, essentially. Such pieces are called **restriction fragments**. Because each restriction enzyme cleaves only a single, specific nucleotide sequence, it will always cut a given DNA molecule in the same predictable manner, generating a reproducible set of restriction fragments. This property makes restriction enzymes powerful tools for generating manageable-sized pieces of DNA for further study.

dideoxynucleotides (ddATP, ddCTP, ddTTP, and ddGTP), which lack the hydroxyl group attached to the 3' carbon of normal deoxynucleotides. When a dideoxynucleotide is incorporated into a growing DNA chain in place of the normal deoxynucleotide, *DNA synthesis is prematurely halted* because the absence of the 3' hydroxyl group makes it impossible to form a bond with the next nucleotide. Hence, a series of incomplete DNA fragments are produced whose sizes provide information concerning the linear sequence of bases in the DNA.

Figure 18-14 illustrates how this procedure works. In step ①, a reaction mixture is assembled that includes the dideoxynucleotides ddATP, ddCTP, ddTTP, and ddGTP, each labeled with a fluorescent dye of a different color (e.g., ddATP = red, ddCTP = blue, ddTTP = orange, and ddGTP = green). These colored dideoxynucleotides are mixed with the normal deoxynucleotide substrates for

Table 18B-1 Some Common Restriction Enzymes and Their Recognition Sequences

Enzyme	Source Organism	Recognition Sequence*
BamHI	<i>Bacillus amyloliquefaciens</i>	5' G↓G—A—T—C—C 3' 3' C↑C—T—A—G—G 5'

*The arrows within the recognition sequence indicate the points at which each restriction enzyme cuts the two strands of the DNA molecule.

DNA synthesis, along with a single-stranded DNA molecule to be sequenced and a short, single-stranded DNA *primer* that is complementary to the 3' end of the DNA strand being sequenced. When DNA polymerase is added, it catalyzes the attachment of nucleotides, one by one, to the 3' end of the primer, producing a growing DNA strand that is complementary to the template whose sequence is being determined. Most of the nucleotides inserted are the normal deoxynucleotides because they are the preferred substrates for DNA polymerase. But every so often, at random, a colored dideoxynucleotide is inserted instead of its normal equivalent. Each time a dideoxynucleotide is incorporated, it halts further DNA synthesis for that particular strand. Consequently, a mixture of strands of varying lengths is generated, each containing a colored base at the end where DNA synthesis was prematurely terminated by incorporation of a dideoxynucleotide (step ②).

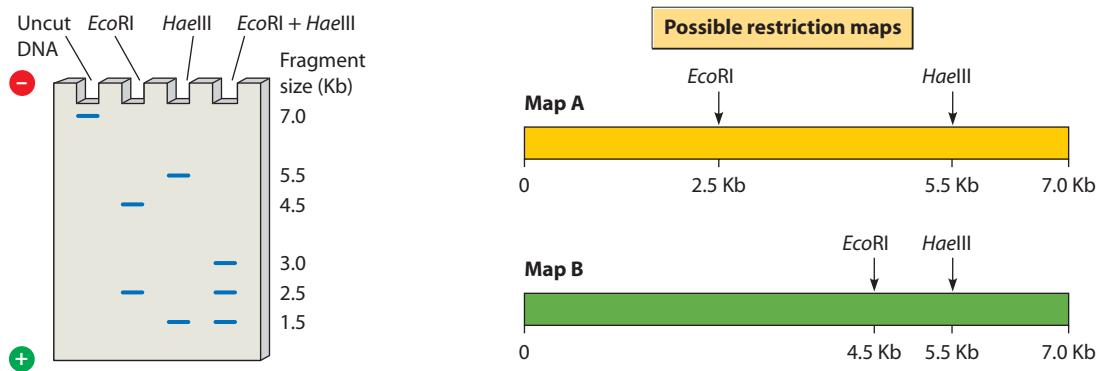

FIGURE 18-13 Restriction Mapping. In this hypothetical example, the location of restriction sites for *Eco*RI and *Hae*III is determined in a DNA fragment 7.0 Kb long. The gel on the left shows that *Eco*RI cleaves the DNA into two fragments measuring 2.5 Kb and 4.5 Kb, indicating that DNA has been cleaved at a single point located 2.5 Kb from one end. Treatment with *Hae*III cleaves the DNA into two fragments measuring 1.5 Kb and 5.5 Kb, indicating that DNA has been cleaved at a single point located 1.5 Kb from one end. Based on this information alone, two possible restriction maps can be proposed. If map A were correct, simultaneous digestion of the DNA with *Eco*RI and *Hae*III should yield three fragments measuring 3.0 Kb, 2.5 Kb, and 1.5 Kb. If map B were correct, simultaneous digestion of the DNA with *Eco*RI and *Hae*III should yield three fragments measuring 4.5 Kb, 1.5 Kb, and 1.0 Kb. The experimental data reveal that map A must be correct.

ACTIVITIES www.thecellplace.com *Restriction mapping*

Next, the sample is subjected to electrophoresis in a polyacrylamide gel, which allows the newly synthesized DNA fragments to be separated from one another because the shorter fragments migrate through the gel more quickly than the longer fragments (step ③). As the fragments move through the gel, a special camera detects the color of each fragment as it passes by. Step ④ shows how such information allows the DNA base sequence to be determined. In this particular example, the shortest DNA fragment is blue, and the next shortest fragment is green. Since blue and green are the colors of ddCTP and ddGTP, respectively, the first two bases added to the primer must have been C followed by G. In automatic sequencing machines, such information is collected for hundreds of bases in a row and fed into a computer, allowing the complete sequence of the initial DNA fragment to be quickly determined.

The Genomes of Many Organisms Have Been Sequenced

The significance of the technique we have just described can scarcely be overestimated. DNA sequencing is now so commonplace and automated that it is routinely applied not just to individual genes, but to entire genomes. Although DNA sequencing machines determine the sequence of only short pieces of DNA, usually 500–800 bases long, one at a time, computer programs search for overlapping sequences between such fragments and thereby allow data from hundreds or thousands of DNA pieces to be assembled into longer stretches that can reach millions of bases in length.

Many of the initial successes in genome sequencing involved bacteria because they have relatively small

genomes, typically a few million bases. Complete DNA sequences are now available for over 2000 different bacteria, including those that cause a variety of human diseases. In fact, sequencing machines are so efficient that one research institute reported the sequences of 15 different bacterial genomes in a single month! But DNA sequencing has also been successfully applied to much larger genomes, including those from several dozen organisms that are most important in biological research (**Table 18-2**). For example, scientists have completed the genome sequences of the yeast *Saccharomyces cerevisiae* (12.1 million bases), the roundworm *Caenorhabditis elegans* (97 million bases), the mustard plant *Arabidopsis thaliana* (125 million bases), and the fruit fly *Drosophila melanogaster* (180 million bases).

To us as human beings, of course, the ultimate challenge of DNA sequencing is the human genome. How awesome a challenge was that? To answer this question, we need to realize that the human nuclear genome contains about 3.2 billion bases, which is roughly a thousandfold more DNA than is present in an *E. coli* cell. One way to comprehend the magnitude of such a challenge is to note that in the early 1990s, when genome sequencing efforts began in earnest, it required almost 6 years for the laboratory of Frederick Blattner to determine the complete base sequence of the *E. coli* genome. At this rate, it would have taken a single lab almost 6000 years to sequence the entire human genome! Consequently, scientists came together in 1990 to establish the *Human Genome Project*, a cooperative international effort involving hundreds of scientists who shared their data in an attempt to determine the entire sequence of the human genome. In the late 1990s a commercial company, Celera Genomics, tackled the job as well. Through these efforts,

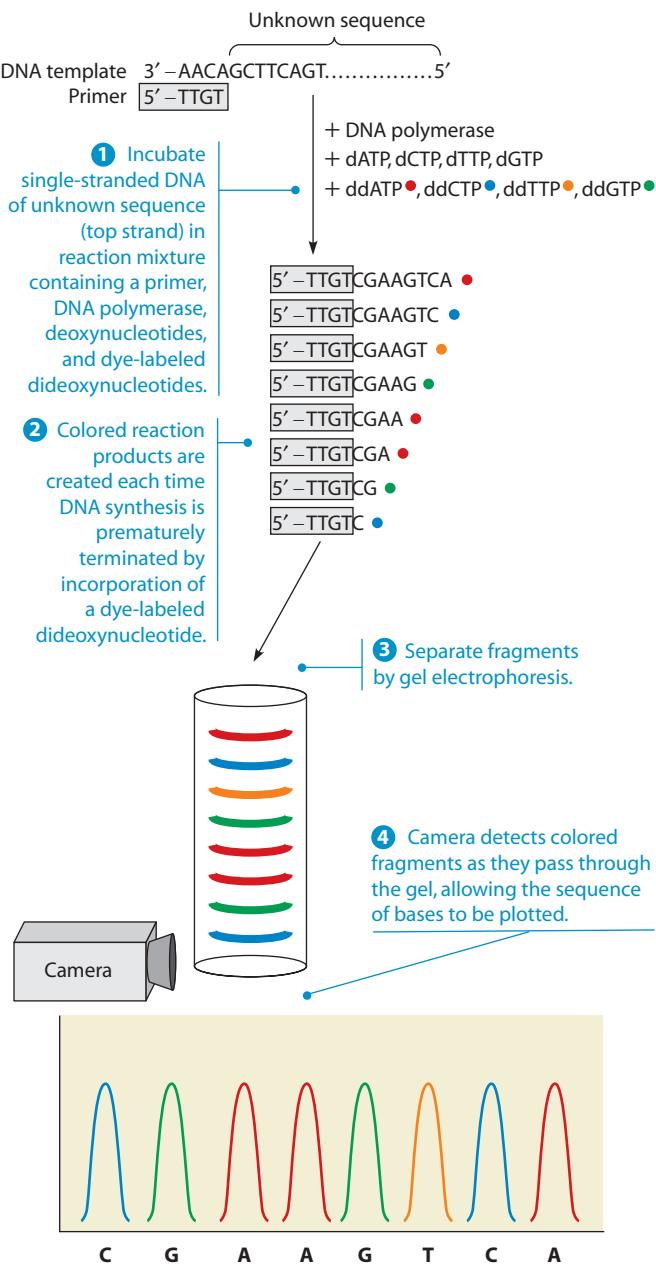

FIGURE 18-14 DNA Sequencing. The chain termination technique illustrated here, which employs dye-labeled dideoxynucleotides, has been adapted for use in high-speed, automated sequencing machines. Although this example summarizes the results obtained for only the first eight bases of a DNA sequence, experiments of this type typically determine the sequence of DNA fragments that are 500–800 bases long. The four main steps involved in the procedure are described in more detail in the text.

 [ACTIVITIES www.thecellplace.com](http://www.thecellplace.com) Dideoxy DNA sequencing

the complete sequence of the human genome was determined by 2003, roughly two years ahead of schedule.

This monumental achievement took more than a decade to complete and cost nearly \$3 billion. Today, continued improvements to the Sanger sequencing method have made it possible to sequence a comparable-sized genome for \$20 million in less than a year, and rapid progress continues to be made. For example, a newly

developed sequencing approach permits a million DNA fragments to be sequenced simultaneously in microscopic reaction chambers, thereby making it possible to sequence a human genome for less than \$100,000 in a month or less. And efforts are not stopping there. A prize has been established to spur the development of a technology that can sequence a human genome for \$1000—a cost so affordable that doctors may one day be able to order a copy of a patient's own genome sequence to facilitate treatment decisions best suited to the genes found in that person.

The Field of Bioinformatics Has Emerged to Decipher Genomes, Transcriptomes, and Proteomes

Because of its sheer scale as well as its potential impact on our understanding of human evolution, physiology, and disease, sequencing the human genome is one of the crowning achievements of modern biology. And yet, unraveling the sequence of bases was the “easy” part. Next comes the hard part: figuring out the meaning of this sequence of 3 billion A’s, G’s, C’s, and T’s. For example, which stretches of DNA correspond to genes, when and in what tissues are these genes expressed, what kinds of proteins do they code for, and how do all these proteins interact with each other and function?

The prospect of analyzing such a vast amount of data has led to the emergence of a new discipline, called **bioinformatics**, which merges computer science and biology in an attempt to make sense of it all. For example, computer programs that analyze DNA for stretches that could code for amino acid sequences are used to estimate the number of protein-coding genes. Such analyses suggest the presence of about 25,000 protein-coding genes in the human genome, roughly half of which were not known to exist prior to genome sequencing. The fascinating

Table 18-2 Examples of Sequenced Genomes*

Organism	Genome Size	Estimated Gene Number
Bacteria		
<i>Mycoplasma genitalium</i>	0.6 Mb	470
<i>Haemophilus influenza</i>	1.8 Mb	1,740
<i>Streptococcus pneumoniae</i>	2.2 Mb	2,240
<i>Escherichia coli</i>	4.6 Mb	4,400
Yeast (<i>S. cerevisiae</i>)	12.1 Mb	6,200
Roundworm (<i>C. elegans</i>)	97 Mb	19,700
Mustard plant (<i>A. thaliana</i>)	125 Mb	25,500
Fruit fly (<i>D. melanogaster</i>)	180 Mb	13,600
Rice (<i>O. sativa</i>)	389 Mb	37,500
Mouse (<i>Mus musculus</i>)	2500 Mb	25,000
Human (<i>H. sapiens</i>)	3200 Mb	25,000

*As of November 2009, complete genome sequences had been published for 2351 organisms (2060 bacteria, 80 archaea, and 211 eukaryotes).

thing about this estimate is that it means humans have only about twice the number of genes as a fruit fly, barely more genes than a worm, and 12,000 fewer genes than a rice plant! Computer analysis has also revealed that less than 2% of the human genome actually codes for proteins. While the remaining 98% contains some important regulatory elements and some genes that code for RNA products instead of proteins, much of it has no obvious function. (For examples, see the discussions of repeated DNA in the following section and introns in Chapter 21). While the significance of this extra DNA is not clear, some evidence suggests that its presence may enhance the ability of the genome to evolve over time.

Determining the DNA sequence of an organism's genome can provide only a partial understanding of the functions a genome performs. Scientists must look beyond the genome to examine the molecules it produces. Because the first step in gene expression involves transcription of genome sequences into RNA, techniques have been developed for identifying **transcriptomes**—that is, the entire set of RNA molecules produced by a genome. In Chapter 23, you will see how the development of *DNA microarray* technology for identifying thousands of RNA molecules simultaneously has facilitated the study of transcriptomes.

Most RNAs, in turn, are used to guide the production of proteins, so scientists are also studying **proteomes**—the structure and properties of every protein produced by a genome. An organism's proteome is considerably more complex than its genome. For example, the roughly 25,000 genes in human cells produce hundreds of thousands of different proteins. In Chapters 21 and 23, we explain how cells can produce so many proteins from a smaller number of genes. You will see that this ability to produce so many proteins is made possible by a mechanism called *alternative splicing*, which allows each individual gene to be “read” in multiple ways to produce multiple versions of its protein product. Moreover, the resulting proteins are subject to subsequent biochemical modifications that produce either new proteins or multiple versions of the same protein.

Identifying the vast number of proteins produced by a genome has been facilitated by **mass spectrometry**, a high-speed, extremely sensitive technique that utilizes magnetic and electric fields to separate proteins or protein fragments based on differences in mass and charge. One application of mass spectrometry involves using it to identify peptides derived from proteins that have been separated by gel electrophoresis and then digested with specific proteases, such as trypsin. Comparing the resulting data to the predicted masses of peptides that would be produced by DNA sequences present in genomic databases permits the proteins produced by newly discovered genes to be identified. Other techniques make it feasible to study the interactions and functional properties of the vast number of proteins found in a proteome. For example, it is possible to immobilize thousands of different proteins (or other molecules

that bind to specific proteins) as tiny spots on a piece of glass smaller than a microscope slide. The resulting *protein microarrays* (or protein “chips”) can then be used to study a variety of protein properties, such as the ability of each individual spot to bind to other molecules added to the surrounding solution.

The enormous amount of data being collected on DNA and protein sequences presents a daunting challenge to scientists who wish to locate information about a particular gene or protein. To cope with this problem, the most recent DNA and protein sequences from hundreds of organisms are stored in several online databases, and software has been developed to help researchers find the information they need. Among the more widely used tools is **BLAST (Basic Local Alignment Search Tool)**, a software program that searches databases to locate DNA or protein sequences that resemble any known sequence of interest. For example, if you identify a new gene in an organism that has not been previously studied and determine its base sequence, a BLAST search could then determine whether humans (or any other organism in the database) possess a similar gene. Or if you are interested in the properties of a particular protein and know part of its amino acid sequence, you could do a BLAST search to identify related proteins. BLAST searching has therefore become a routine step when analyzing and characterizing genes and proteins.

Tiny Differences in Genome Sequence Distinguish People from One Another

The published sequence of the human genome is actually a mosaic obtained from the analysis of DNA isolated from ten different individuals. On average, about 99.7% of the bases in your genome will match perfectly with this published sequence, or with the DNA base sequence of your next-door neighbor. But the remaining 0.3% of the bases vary from person to person, creating features that make us unique individuals. Differences involving single base changes are called **single nucleotide polymorphisms**, or **SNPs** (pronounced “snips”). Although 0.3% might not sound like very much, 0.3% multiplied by the 3.2 billion bases in the human genome yields a total of roughly 10 million SNPs. Scientists have already created databases containing most of the common SNPs, which are thought to be important because some of these tiny genetic variations may influence your susceptibility to certain diseases or determine how well you respond to a particular treatment.

Most SNPs, however, are not located in the protein-coding regions of genes. So how do we find out which SNPs are related to important traits, such as susceptibility to a specific disease? Fortunately, it is not necessary to examine all 10 million SNPs separately because SNPs are not independent of one another. SNPs located near each other on the same chromosome tend to be inherited together in blocks called **haplotypes**. A database of these

haplotypes, called the *HapMap*, provides a shortcut for scientists interested in the relationship between genes and disease: Only a few hundred thousand SNPs (each located in a different haplotype) need to be examined rather than 10 million. Once a trait has been linked to a particular haplotype, only the SNPs within that haplotype are studied to determine which one is responsible.

SNPs are not the only sources of genetic variation that define a person's individuality. DNA rearrangements, deletions, and duplications also contribute to variability among genomes. Such mechanisms have produced DNA segments thousands of bases long that are present in variable numbers of copies among different individuals. Each person's genome is thought to contain hundreds of such **copy number variations (CNVs)** involving millions of bases of DNA overall.

The impact of our rapidly growing understanding of the human genome is already becoming apparent as discoveries regarding the genetic basis of many human diseases—from breast cancer and colon cancer to diabetes and Alzheimer's disease—are being reported at a rapidly increasing pace. Such discoveries promise to revolutionize the future practice of medicine because having the ability to identify disease genes and investigate their function makes it possible to devise medical interventions for alleviating and even preventing disease.

But being able to identify potentially harmful genes also raises ethical concerns because all of us are likely to carry a few dozen genes that place us at risk for something. Such information possibly could be misused—for example, in genetic discrimination against individuals or groups of people by insurance companies, employers, or even government agencies. Moreover, detailed knowledge of the human genome increases the potential for using recombinant DNA techniques (see Chapter 20) to alter people's genes, not only to correct diseases in malfunctioning body tissues but also to change genes in sperm and eggs, thereby altering the genetic makeup of future generations. What use to make of these abilities and how to regulate them are clearly questions that concern not only the scientific community but human society as a whole.

Repeated DNA Sequences Partially Explain the Large Size of Eukaryotic Genomes

Besides the difficulties it created for DNA sequencing studies, the enormous size of the human genome raises a more fundamental question: Does the large amount of DNA in human cells simply reflect the need for thousands of times more genes than are present in bacterial cells, or are other factors at play as well? The first breakthrough in answering this question occurred in the late 1960s, when DNA renaturation studies carried out by Roy Britten and David Kohne led to the discovery of repeated DNA sequences.

In these experiments, DNA was broken into small fragments and dissociated into single strands by heating.

The temperature was then lowered to permit the single-stranded fragments to renature. The renaturation rate depends on the concentration of each individual kind of DNA sequence; the higher the concentration of fragments exhibiting any given DNA sequence, the greater the probability that they will randomly collide with complementary strands and reassociate. As an example, let us consider DNA from a bacterial cell and from a typical mammalian cell containing a thousandfold more DNA. If this difference in DNA content reflects a thousandfold difference in the kinds of DNA sequences present, then bacterial DNA should renature 1000 times faster than mammalian DNA. The rationale for this prediction is that any particular DNA sequence should be present in a thousandfold lower concentration in the mammalian DNA sample because there are a thousand times more kinds of sequences present, and so each individual sequence represents a smaller fraction of the total population of sequences.

When Britten and Kohne compared the behavior of mammalian and bacterial DNAs, however, the results were not exactly as expected. In **Figure 18-15**, which summarizes their data obtained for calf and *E. coli* DNA, renaturation is plotted as a function of initial DNA concentration multiplied by the elapsed time because it facilitates comparison of data obtained from reactions run at different DNA concentrations. When graphed this way, the data reveal that calf DNA consists of two classes of sequences that renature at very different rates. One type of sequence, which accounts for about 40% of the calf DNA, renatures more rapidly than bacterial DNA does. The most straightforward explanation for this unexpected result is that calf DNA contains **repeated DNA** sequences that are present in multiple copies. The existence of multiple copies increases the concentration of such sequences, thereby generating more collisions and a faster rate of reassociation than would be expected if each sequence were present in only a single copy.

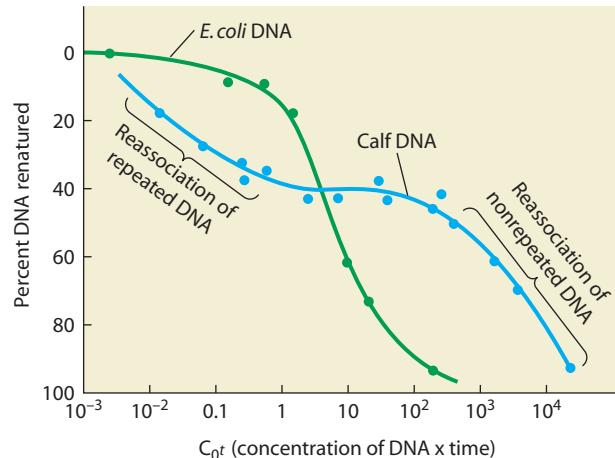

FIGURE 18-15 Renaturation of Calf and *E. coli* DNAs. The calf DNA that reassociates more rapidly than the bacterial DNA consists of repeated sequences.

The remaining 60% of the calf DNA renatures about a thousand times more slowly than *E. coli* DNA does, which is the behavior expected of sequences present as single copies. This fraction is therefore called **nonrepeated DNA** to distinguish it from the repeated sequences that renature more quickly. Nonrepeated DNA sequences are each present in one copy per genome. Most protein-coding genes consist of nonrepeated DNA, although this does not mean that all nonrepeated DNA codes for proteins.

In bacterial cells virtually all the DNA is nonrepeated, whereas eukaryotes exhibit large variations in their amounts of repeated versus nonrepeated DNA. This helps explain the mystery of the seemingly excess amount of DNA in species such as *Trillium*: This organism contains a relatively large amount of repeated DNA. Using the sequencing techniques described earlier, researchers have been able to determine the base sequences of various types of repeated DNAs and to classify them into two main categories: *tandemly repeated DNA* and *interspersed repeated DNA* (Table 18-3).

Tandemly Repeated DNA. One major category of repeated DNA is referred to as **tandemly repeated DNA** because the multiple copies are arranged next to each other in a row—that is, tandemly. Tandemly repeated DNA accounts for 10–15% of a typical mammalian genome and consists of many different types of DNA sequences that vary in both the length of the basic repeat unit and the number of times this unit is repeated in succession. The length of the repeated unit can measure anywhere from 1 to 2000 bp or so. Most of the time,

however, the repeated unit is shorter than 10 bp; consequently, this subcategory is called *simple-sequence repeated DNA*. Here is an example (showing one strand only) of a simple-sequence repeated DNA built from the five-base unit, GTTAC:

... GTTACGTTACGTTACGTTACGTTAC ...

The number of sequential repetitions of the GTTAC unit can be as high as several hundred thousand at selected sites in the genome.

Tandemly repeated DNA of the simple-sequence type was originally called *satellite DNA* because its distinctive base composition often causes it to appear in a “satellite” band that separates from the rest of the genomic DNA during centrifugation procedures designed to separate molecules by density. This difference in density arises because adenine and guanine differ slightly in molecular weight, as do cytosine and thymine; hence, the densities of DNAs with differing base compositions will differ. In the procedures that reveal satellite bands, the genomic DNA is cleaved to short lengths, thus allowing DNA segments of differing densities to migrate freely to different positions during centrifugation.

What is the function of simple-sequence repeated DNA (satellite DNA)? Because such sequences are not usually transcribed, it has been proposed that they may instead be responsible for imparting special physical properties to certain regions of the chromosome. In most eukaryotes, chromosomal regions called **centromeres**—which play an important role in chromosome distribution during cell division (see Chapter 19)—are particularly rich in simple-sequence repeats, and these sequences may impart specialized structural properties to the centromere. **Telomeres**, which are DNA sequences located at the ends of chromosomes, also have simple-sequence repeats. In the next chapter, we will learn how telomeres protect chromosomes from degradation at their vulnerable ends during each round of replication (see Figure 19-16). Human telomeres contain 250–1500 copies of the sequence TTAGGG, which has been highly conserved over hundreds of millions of years of evolution. All vertebrates studied so far have this same identical sequence, and even unicellular eukaryotes possess similar sequences. Apparently, such sequences are critical to the survival of these organisms.

The amount of satellite DNA present at any given site can vary enormously. Typical satellite DNAs usually range from 10^5 to 10^7 bp in overall length. The term *minisatellite DNA* refers to shorter regions, about 10^2 to 10^5 bp in total length, composed of a tandem repeat unit of roughly 10–100 bp. *Microsatellite DNAs*, in which the repeat unit is only 1–10 bp, are even shorter (about 10–100 bp in length), although numerous sites in the genome may exhibit the same sequence. The short repeated sequences found in microsatellite and minisatellite DNAs are extremely useful in the laboratory for **DNA fingerprinting**. This procedure,

Table 18-3 Categories of Repeated Sequences in Eukaryotic DNA

I. Tandemly repeated DNA, including simple-sequence repeated DNA (satellite DNA)

10–15% of most mammalian genomes is this type of DNA

Length of each repeated unit:	1–2000 bp; typically 5–10 bp for simple-sequence repeated DNA
Number of repetitions per genome:	10^2 – 10^5
Arrangement of repeated units:	Tandem
Total length of satellite DNA at each site:	
Regular satellite DNA:	10^5 – 10^7 bp
Minisatellite DNA:	10^2 – 10^5 bp
Microsatellite DNA:	10^1 – 10^2 bp

II. Interspersed repeated DNA

25–50% of most mammalian genomes is this type of DNA

Length of each repeated unit:	10^2 – 10^4 bp
Arrangement of repeated units:	Scattered throughout the genome
Number of repetitions per genome:	10^1 – 10^6 ; “copies” not identical

described more fully in **Box 18C**, uses gel electrophoresis to compare DNA fragments derived from various regions of the genomes of two or more individuals. It is a means of identifying individuals that is as accurate as conventional fingerprinting.

Medical researchers have made the surprising discovery that more than a dozen inherited diseases of the nervous system involve simple changes in microsatellite DNAs. More specifically, these diseases are traceable to excessive numbers of repeated trinucleotide sequences within an otherwise normal gene. An example of this phenomenon, called *triplet repeat amplification*, is found in *Huntington's disease*, a devastating neurological disease that strikes in middle age and is invariably fatal. The normal version of the Huntington's gene contains the tri-nucleotide CAG tandemly repeated 11–34 times. The genes of afflicted individuals, however, possess up to 100 copies of the repeated unit. Neurological diseases resulting from the amplification of other triplet repeat sequences include *fragile X syndrome*, which is a major cause of mental retardation, and *myotonic dystrophy*, which affects the muscles. For some of these diseases, the repeated sequence is in a region of the affected gene that is not translated; for others, it is translated into a polypeptide segment consisting of a long string of the same amino acid. In both cases, the severity of the disease appears to correlate with the number of triplet repeats.

Interspersed Repeated DNA. The other main type of repeated DNA is **interspersed repeated DNA**. Rather than being clustered in tandem arrangements, the repeated units of this type of DNA are scattered around the genome. A single repeat unit tends to be hundreds or even thousands of base pairs long, and its dispersed “copies,” which may number in the hundreds of thousands, are similar but usually not identical to one another. Interspersed repeated DNA typically accounts for 25–50% of mammalian genomes.

Most interspersed repeated DNA consists of families of **transposable elements (transposons)**, also known as “jumping genes” because they can move around the genome and leave copies of themselves wherever they stop. Remarkably, in humans, roughly half the genome consists of these mobile elements. The most abundant, called **LINEs (long interspersed nuclear elements)**, measure 6000–8000 bp in length and account for roughly 20% of the genome. LINEs possess genes coding for enzymes involved in copying LINE sequences (and other mobile elements) and inserting the copies elsewhere in the genome. Another class of mobile elements, called **SINEs (short interspersed nuclear elements)**, consist of short repeated sequences less than 500 bp in length that do not contain genes, relying instead on enzymes made by other mobile elements for their movement. The most common SINEs in humans measure about 300 bp in length and are called *Alu sequences*, because the first ones identified all contained a restriction site for the restriction enzyme

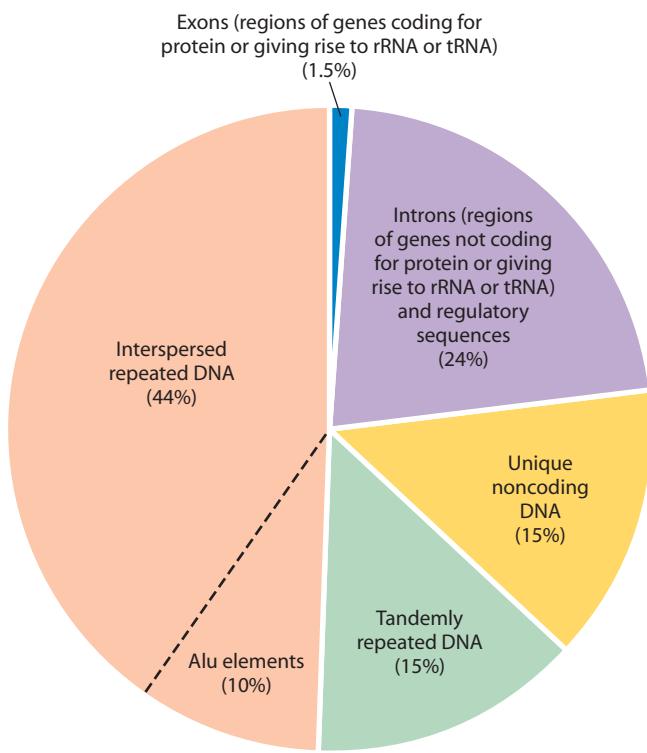

FIGURE 18-16 Types of DNA in the Human Genome. The DNA that encodes proteins or that is transcribed into ribosomal or transfer RNA accounts for only 1.5% of the DNA in the human genome. Interspersed repeat DNA accounts for 44% of the human genome; almost one quarter of this consists of *Alu* elements. Tandemly repeated DNA accounts for another 15% of the genome.

Alu. Close to a million copies of the *Alu* sequence are spread throughout the human genome, accounting for approximately 10% of the DNA. DNA that encodes proteins or gives rise to ribosomal or transfer RNAs (such DNA is found in *exons*, as we will see in Chapter 21) accounts for surprisingly little of the DNA in the human genome (**Figure 18-16**).

The mobility of LINEs, SINEs, and other types of transposable elements is thought to create genomic variability that contributes to the evolutionary adaptability of organisms. In addition, the movement of some LINEs can occur during normal development and alter the expression of adjacent genes, suggesting a possible role in gene regulation. The origins of transposable elements and the mechanisms by which they move will be discussed more fully in Chapter 21.

DNA Packaging

Cells must accommodate an awesome amount of DNA, even in species with modestly sized genomes. For example, the typical *E. coli* cell measures about 1 μm in diameter and 2 μm in length, yet it must accommodate a (circular) DNA molecule with a length of about 1600 μm —enough DNA to encircle the cell more than 400 times! Eukaryotic cells face an even greater challenge. A human cell of average size

DNA Fingerprinting

Analysis of the fragment patterns produced when DNA is digested with restriction enzymes has been exploited for a variety of purposes, ranging from research into genome organization to practical applications such as diagnosing genetic diseases and solving violent crimes. These practical applications are based on the fact that no two people (other than identical twins) have the same exact set of DNA base sequences. Although the differences in DNA sequence between any two people are quite small, they alter the lengths of some of the DNA

fragments produced by restriction enzymes. These differences in fragment length, called **restriction fragment length polymorphisms (RFLPs)**, can be analyzed by gel electrophoresis. The resulting pattern of fragments serves as a “fingerprint” that identifies the individual from whom the DNA was obtained.

In practical usage, DNA fingerprinting is performed in a way that examines only a small, selected subset of restriction fragments. To illustrate this point, **Figure 18C-1** summarizes

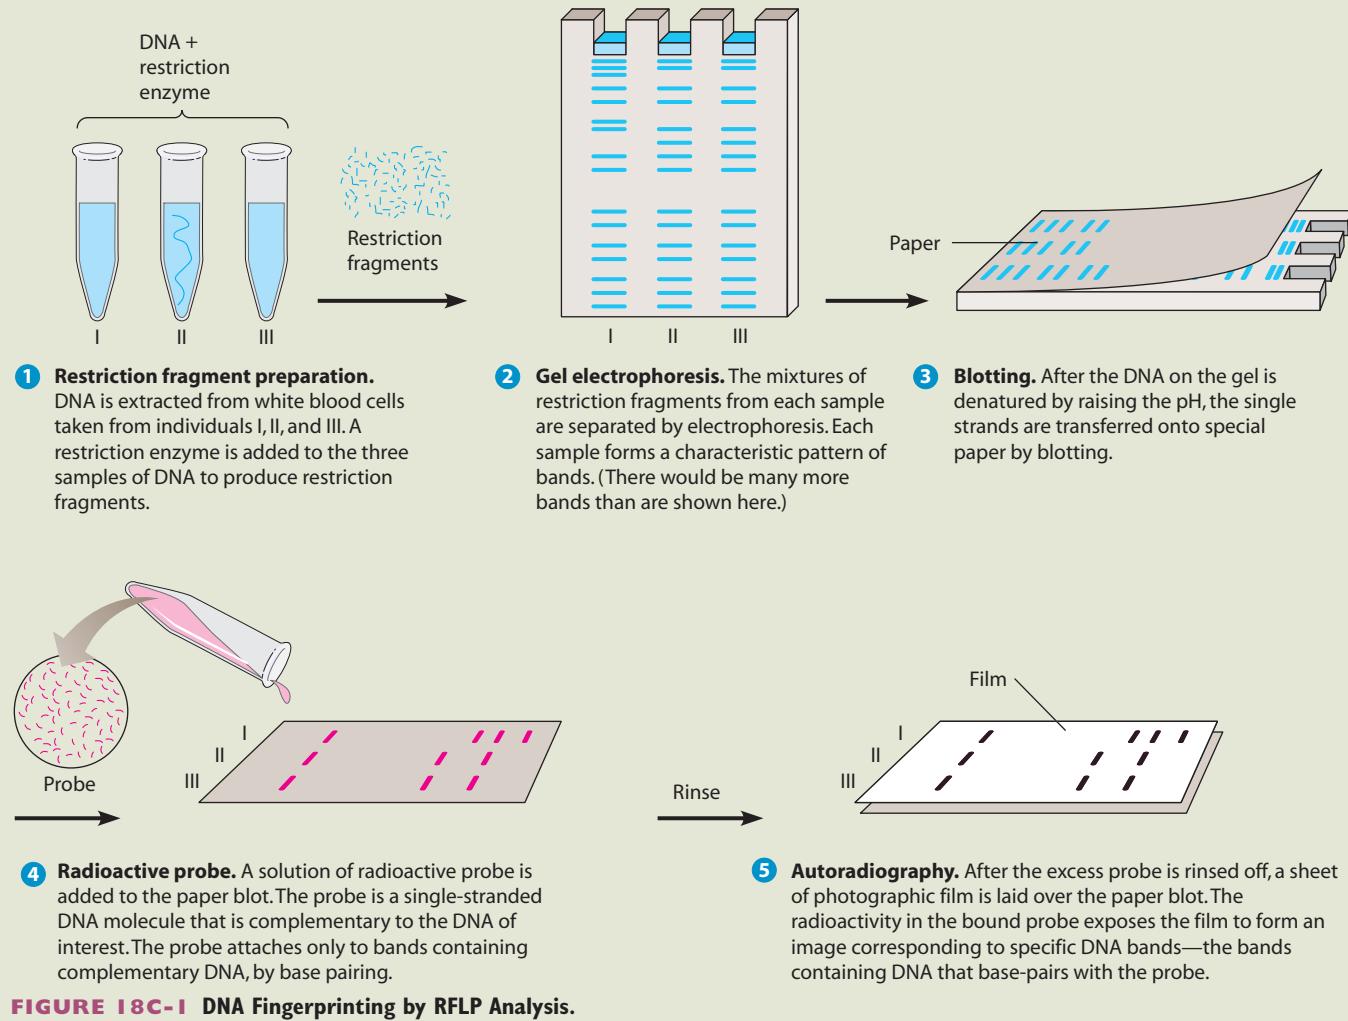

FIGURE 18C-1 DNA Fingerprinting by RFLP Analysis.

contains enough DNA to wrap around the cell more than 15,000 times. Somehow, all of this DNA must be efficiently packaged into cells and still be accessible to the cellular machinery for both DNA replication and the transcription of specific genes. Clearly, DNA packaging is a challenging problem for all forms of life. We will look first at how bacteria accomplish this task of organizing their DNA and then consider how eukaryotes address the same problem.

Bacteria Package DNA in Bacterial Chromosomes and Plasmids

The genome of a bacterium such as *E. coli* was once thought to be a “naked” DNA molecule lacking any elaborate organization and having only trivial amounts of protein associated with it. We now know that the organization of the bacterial genome is more like the

how DNA fingerprinting might be used to determine whether individuals carry a particular disease-causing gene even though they may not yet exhibit symptoms of the disease. In this example, imagine that individuals I, II, and III are members of a family in which the disease-causing gene is common. It is known that individual I carries the defective gene but individual II does not, and we want to determine the genetic status of their child, individual III.

The key step in DNA fingerprinting is called **Southern blotting** (after E. M. Southern, who developed it in 1975), but the fingerprinting procedure actually involves several distinct steps. In ① of Figure 18C-1, DNA obtained from the three individuals is digested with a restriction enzyme. In ②, the resulting fragments are then separated from each other by gel electrophoresis. Because each person's DNA represents an entire genome, hundreds of thousands of bands would appear at this stage if all were made visible. Here is where Southern's stroke of brilliance comes in, with a technique that enables us to locate particular DNA sequences of interest within a complex mixture. In the Southern blotting process (③), a special kind of "blotter" paper (nitrocellulose or nylon) is pressed against the completed gel, allowing the separated DNA fragments to be transferred to the paper. In ④, a radioactive probe is added to the blot. The probe is simply a radioactive single-stranded DNA (or RNA) molecule whose base sequence is complementary to the DNA of interest—in this case, the DNA of the disease-causing gene. The probe binds to complementary DNA sequences by base pairing (the same process that occurs when denatured DNA renatures). In ⑤, the bands that bind the radioactive probe are made visible by autoradiography. The results indicate that the child's version of the gene matches that of the *healthy* parent, individual II.

The autoradiogram in Figure 18C-2 illustrates the use of DNA fingerprinting in a murder case. Here, RFLP analysis makes it clear that blood found on the defendant's clothes came from the victim, strongly implicating the defendant in the murder. Another practical application of DNA fingerprinting in the legal area is the determination of paternity or maternity.

For many DNA fingerprinting applications, scientists now analyze the length of short repeated sequences (microsatellite DNAs) called **short tandem repeats (STRs)**. The STR sites chosen for DNA fingerprinting vary in length from person to person because of differences in the number of times the basic repeat unit is sequentially repeated. As a result, STR patterns in a person's DNA can be used to identify that individual uniquely. For example, the DNA of three suspects in a murder case might all

FIGURE 18C-2 DNA Fingerprints from a Murder Case. DNA was isolated from bloodstains on the defendant's clothes and compared, by RFLP analysis, with DNA from the defendant and DNA from the victim. The band pattern for the bloodstain DNA matches that for the victim, showing that the blood on the defendant's clothes came from the victim. (Courtesy of Cellmark Diagnostics.)

have different numbers of copies of the repeat sequence CTG at a particular place in the genome; one might have 19 copies, another 21 copies, and the third 32 copies. In criminal cases, the numbers of repeat copies present at 13 different STR sites in the genome are routinely examined. The chance that any two unrelated individuals would exhibit the same exact profile at all 13 sites is roughly one in a million billion.

The usefulness of DNA fingerprinting is further enhanced by the *polymerase chain reaction (PCR)*, a technique for making multiple DNA copies that will be described in Chapter 19. Starting with DNA isolated from a single cell, the PCR reaction can be used to selectively synthesize millions of copies of any given DNA sequence within a few hours, easily producing enough DNA for fingerprinting analysis of the 13 STR sites. In this way, a few skin cells left on a pen or car keys touched by a person may yield enough DNA to uniquely identify that individual.

chromosomes of eukaryotes than we previously realized. Bacterial geneticists therefore refer to the structure that contains the main bacterial genome as the **bacterial chromosome**.

Bacterial Chromosomes. Bacteria can have single or multiple, circular or linear chromosomes; the most common arrangement, however, is a single circular DNA

molecule that is bound to small amounts of protein and localized to a special region of the bacterial cell called the **nucleoid** (Figure 18-17). Although the nucleoid is not surrounded by a membrane, the bacterial DNA residing in this region forms a threadlike mass of fibers packed together in a way that maintains a distinct boundary between the nucleoid and the rest of the cell. The DNA of the bacterial chromosome is negatively

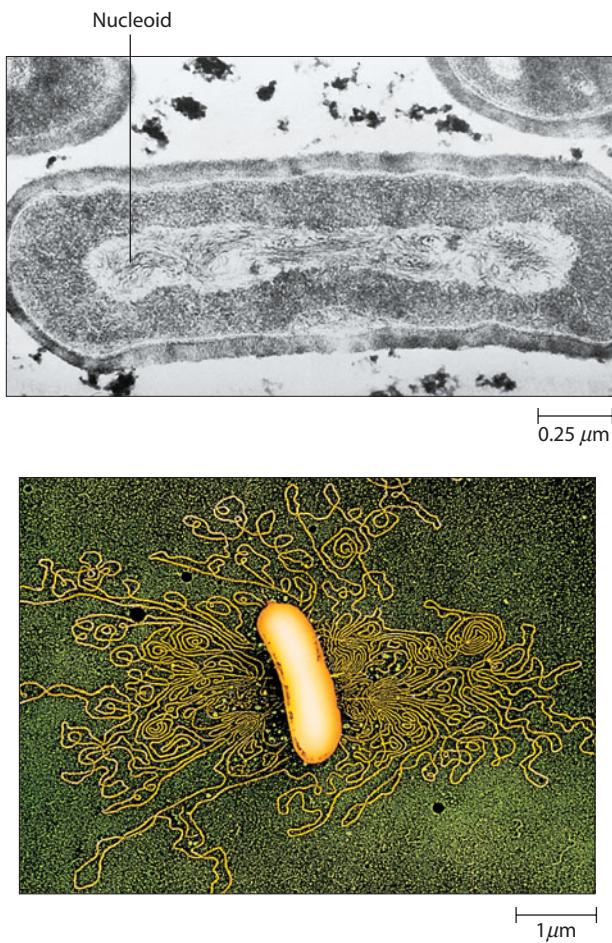

FIGURE 18-17 The Bacterial Nucleoid. The electron micrograph at the top shows a bacterial cell with a distinct nucleoid, in which the bacterial chromosome resides. When bacterial cells are ruptured, their chromosomal DNA is released from the cell. The bottom micrograph shows that the released DNA forms a series of loops that remain attached to a structural framework within the nucleoid (TEMs).

supercoiled and folded into an extensive series of loops averaging about 20,000 bp in length. Because the two ends of each loop are anchored to structural components that lie within the nucleoid, the supercoiling of any individual loop can be altered without influencing the supercoiling of adjacent loops.

The loops are thought to be held in place by RNA and protein molecules. Evidence for a structural role for RNA in the bacterial chromosome has come from studies showing that treatment with ribonuclease, an enzyme that degrades RNA, releases some of the loops, although it does not relax the supercoiling. Nicking the DNA with a topoisomerase, on the other hand, relaxes the supercoiling but does not disrupt the loops. The supercoiled DNA that forms each loop is organized into beadlike packets containing small, basic protein molecules, analogous to the histones of eukaryotic cells (discussed below). Current evidence suggests that the DNA molecule is wrapped around particles of the basic protein. Thus, from what we

know so far, the bacterial chromosome consists of supercoiled DNA that is bound to small, basic proteins and then folded into looped domains.

Bacterial Plasmids. In addition to its chromosome, a bacterial cell may contain one or more plasmids. **Plasmids** are relatively small, usually circular molecules of DNA that carry genes both for their own replication and, often, for one or more cellular functions (usually nonessential ones). Most plasmids are supercoiled, giving them a condensed, compact form. Although plasmids replicate autonomously, the replication is usually sufficiently synchronized with the replication of the bacterial chromosome to ensure a roughly comparable number of plasmids from one cell generation to the next. In *E. coli* cells, several classes of plasmids are recognized: *F* (*fertility*) factors are involved in the process of conjugation, a sexual process we will discuss in Chapter 20; *R* (*resistance*) factors carry genes that impart drug resistance to the bacterial cell; *col* (*colicinogenic*) factors allow the bacterium to secrete *colicins*, compounds that kill other bacteria lacking the col factor; *virulence* factors enhance the ability to cause disease by producing toxic proteins that cause tissue damage or enzymes that allow the bacteria to enter host cells; and *metabolic* plasmids produce enzymes required for certain metabolic reactions. Some strains of *E. coli* also possess *cryptic* plasmids, which have no known function and possess no genes other than those needed for the plasmid to replicate and spread to other cells.

Eukaryotes Package DNA in Chromatin and Chromosomes

When we turn from bacteria to eukaryotes, DNA packaging becomes more complicated. First, substantially larger amounts of DNA are involved. Each eukaryotic chromosome contains a single, linear DNA molecule of enormous size. In human cells, for example, just *one* of these DNA molecules may be 10 cm or more in length—roughly a hundred times the size of the DNA molecule found in a typical bacterial chromosome. Second, greater structural complexity is introduced by the association of eukaryotic DNA with greater amounts and numbers of proteins. When bound to these proteins, the DNA is converted into **chromatin** fibers 10–30 nm in diameter that are normally dispersed throughout the nucleus. At the time of cell division (and in a few other situations), these fibers condense and fold into much larger, compact structures that become recognizable as individual **chromosomes**.

The proteins with the most important role in chromatin structure are the **histones**, a group of relatively small proteins whose high content of the amino acids lysine and arginine gives them a strong positive charge. The binding of histones to DNA, which is negatively charged, is therefore stabilized by ionic bonds. In most cells, the mass of histones in chromatin is approximately

equal to the mass of DNA. Histones are divided into five main types, designated H1, H2A, H2B, H3, and H4. Chromatin contains roughly equal numbers of H2A, H2B, H3, and H4 molecules, and about half that number of H1 molecules. These proportions are remarkably constant among different kinds of eukaryotic cells, regardless of the type of cell or its physiological state. In addition to histones, chromatin contains a diverse group of *nonhistone proteins* that play a variety of enzymatic, structural, and regulatory roles.

Nucleosomes Are the Basic Unit of Chromatin Structure

The DNA contained within a typical nucleus would measure a meter or more in length if it were completely extended, whereas the nucleus itself is usually no more than 5–10 μm in diameter. The folding of such an enormous length of DNA into a nucleus that is almost a million times smaller presents a significant topological problem. One of the first insights into the folding process emerged in the late 1960s, when X-ray diffraction studies carried out by Maurice Wilkins revealed that purified chromatin fibers have a repeating structural subunit that is seen in neither DNA nor histones alone. Wilkins therefore concluded that histones impose a repeating structural organization upon DNA. A clue to the nature of this structure was provided in 1974, when Ada Ollins and Donald Ollins published electron micrographs of chromatin fibers isolated from cells in a way that avoided the harsh solvents used in earlier procedures for preparing chromatin for microscopic examination. Chromatin fibers viewed in this way appear as a series of tiny particles attached to one another by thin filaments. This “beads-on-a-string” appearance led to the suggestion that the beads consist of protein (presumably histones) and the thin filaments connecting the beads correspond to DNA. We now refer to each bead, along with its associated short stretch of DNA, as a **nucleosome** (Figure 18-18).

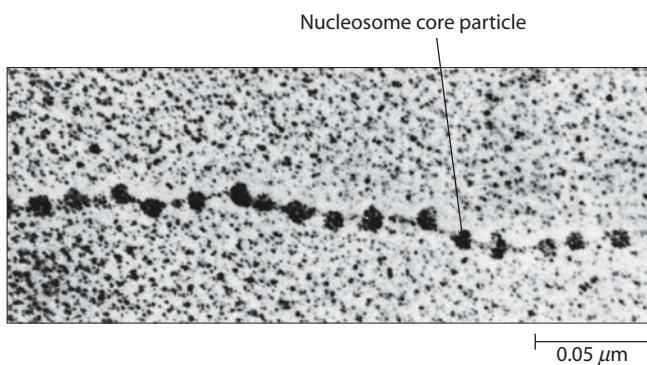

FIGURE 18-18 Nucleosomes. The core particles of nucleosomes appear as beadlike structures spaced at regular intervals along eukaryotic chromatin fibers. A nucleosome is defined to include both a core particle and the stretch of DNA that connects to the next core particle (TEM).

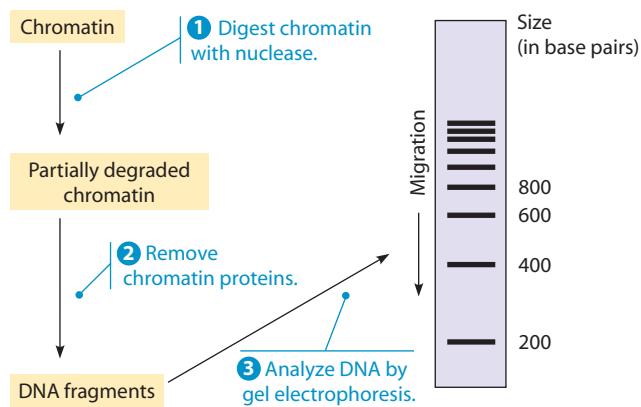

FIGURE 18-19 Evidence That Proteins Are Clustered at 200 Base-Pair Intervals Along the DNA Molecule in Chromatin Fibers. In these experiments, DNA fragments generated by nuclease digestion of rat liver chromatin were analyzed by gel electrophoresis. The discovery that the DNA fragments are multiples of 200 base pairs suggests that histones are clustered at 200 base-pair intervals along the DNA, thereby conferring a regular pattern of protection against nuclease digestion.

Based on electron microscopy alone, it would have been difficult to determine whether nucleosomes are a normal component of chromatin or an artifact generated during sample preparation. Fortunately, independent evidence for the existence of a repeating structure in chromatin was reported at about the same time by Dean Hewish and Leigh Burgoine, who discovered that rat liver nuclei contain a nuclease that is capable of cleaving the DNA in chromatin fibers. In one crucial set of experiments, these investigators exposed chromatin to this nuclease and then purified the partially degraded DNA to remove chromatin proteins. Upon examining the purified DNA by gel electrophoresis, they found a distinctive pattern of fragments in which the smallest piece of DNA measured about 200 bp in length, and the remaining fragments were exact multiples of 200 bp (Figure 18-19). Since nuclease digestion of protein-free DNA does not generate this fragment pattern, they concluded that (1) chromatin proteins are clustered along the DNA molecule in a regular pattern that repeats at intervals of roughly 200 bp, and (2) the DNA located between these protein clusters is susceptible to nuclease digestion, yielding fragments that are multiples of 200 bp in length.

These observations raised the question of whether the protein clusters postulated to occur at 200-bp intervals correspond to the spherical particles observed in electron micrographs of chromatin fibers. Answering this question required a combination of the nuclease digestion and electron microscopic approaches. In these studies, chromatin was briefly exposed to *micrococcal nuclease*—a bacterial enzyme that, like the rat liver nuclease, cleaves chromatin DNA at intervals of 200 bp. The fragmented chromatin was then separated into fractions of varying sizes by centrifugation and examined by electron microscopy. The smallest fraction was found to contain single spherical

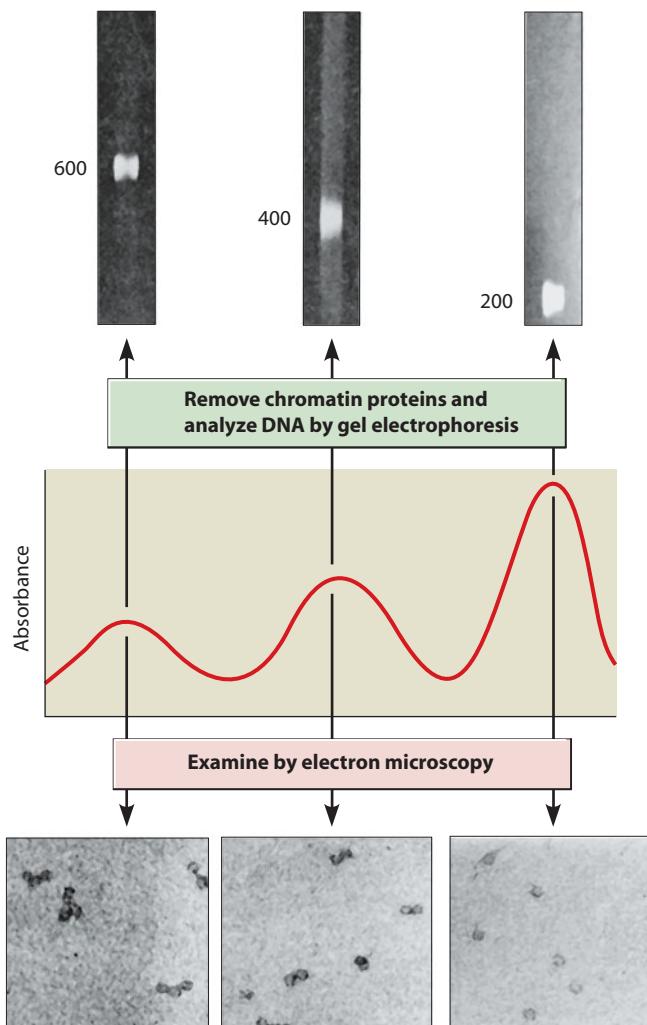

FIGURE 18-20 Evidence for the Existence of Nucleosomes.

Chromatin that had been partially degraded by treatment with micrococcal nuclease was fractionated by density gradient centrifugation (*center graph*). The individual peaks were then analyzed both by electron microscopy (*bottom*) and by gel electrophoresis after removal of chromatin proteins (*top*). The peak on the right consists of single protein particles associated with 200 base pairs of DNA, the middle peak consists of clusters of two particles associated with 400 base pairs of DNA, and the peak on the left consists of clusters of three particles associated with 600 base pairs of DNA. This indicates that the basic repeat unit in chromatin is a protein particle associated with 200 base pairs of DNA.

particles, the next fraction contained clusters of two particles, the succeeding fraction contained clusters of three particles, and so forth (**Figure 18-20**). When DNA was isolated from these fractions and analyzed by gel electrophoresis, the DNA from the fraction containing single particles measured 200 bp in length, the DNA from the fraction containing clusters of two particles measured 400 bp in length, and so on. It was therefore concluded that the spherical particles observed in electron micrographs are each associated with 200 bp of DNA. This basic repeat unit, containing an average of 200 bp of DNA associated with a protein particle, is the nucleosome.

A Histone Octamer Forms the Nucleosome Core

The first insights into the molecular architecture of the nucleosome emerged from the work of Roger Kornberg, who was awarded a Nobel Prize in 2006 for a series of fundamental discoveries concerning DNA packaging and transcription in eukaryotes. In their early studies, Kornberg and his colleagues showed that chromatin fibers composed of nucleosomes can be generated by combining purified DNA with a mixture of all five histones. However, when they attempted to use individually purified histones, they discovered that nucleosomes could be assembled only when histones were isolated using gentle techniques that left histone H2A bound to histone H2B, and histone H3 bound to histone H4. When these H3–H4 and H2A–H2B complexes were mixed with DNA, chromatin fibers exhibiting normal nucleosomal structure were reconstituted. Kornberg therefore concluded that histone H3–H4 and H2A–H2B complexes are an integral part of the nucleosome.

To investigate the nature of these histone interactions in more depth, Kornberg and his colleague, Jean Thomas, treated isolated chromatin with a chemical reagent that forms covalent crosslinks between protein molecules that are located next to each other. After being treated with this reagent, the chemically crosslinked proteins were isolated and analyzed by polyacrylamide gel electrophoresis. Protein complexes the size of eight histone molecules were prominent in such gels, suggesting that the nucleosomal particle contains an *octamer* of eight histones. Given the knowledge that histones H3–H4 and histones H2A–H2B each form tight complexes and that these four histones are present in roughly equivalent amounts in chromatin, Kornberg and Thomas proposed that histone octamers are created by joining together two H2A–H2B dimers and two H3–H4 dimers and that the DNA double helix is then wrapped around the resulting octamer (**Figure 18-21**).

One issue not addressed by the preceding model concerns the significance of histone H1, which is not part of the octamer. If individual nucleosomes are isolated by briefly digesting chromatin with micrococcal nuclease, histone H1 is still present (along with the four other histones and 200 bp of DNA). When digestion is carried out for longer periods, the DNA fragment is further degraded until it reaches a length of about 146 bp; during the final stages of the digestion process, histone H1 is released. The remaining particle, consisting of a histone octamer associated with 146 bp of DNA, is referred to as a *core particle*. The DNA that is degraded during digestion from 200 to 146 bp in length is referred to as *linker DNA* because it joins one nucleosome to the next (Figure 18-21). Since histone H1 is released upon degradation of the linker DNA, histone H1 molecules are thought to be associated with the linker region. The length of the linker DNA varies somewhat among organisms, but the DNA

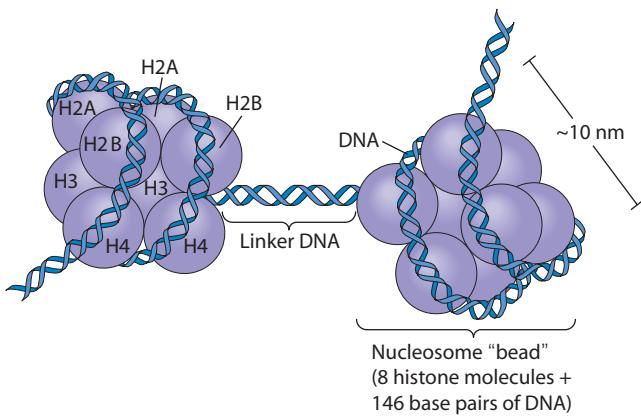

FIGURE 18-21 A Closer Look at Nucleosome Structure. Each nucleosome consists of eight histone molecules (two each of histones H2A, H2B, H3, and H4) associated with 146 base pairs of DNA and a stretch of linker DNA about 50 base pairs in length. The diameter of the nucleosome “bead,” or core particle, is about 10 nm. Histone H1 (not shown) is thought to bind to the linker DNA and facilitate the packing of nucleosomes into 30-nm fibers.

 [ACTIVITIES](http://www.thecellplace.com) www.thecellplace.com Nucleosome structure

associated with the core particle always measures close to 146 bp, which is enough to wrap around the core particle roughly 1.7 times.

Nucleosomes Are Packed Together to Form Chromatin Fibers and Chromosomes

The formation of nucleosomes is only the first step in the packaging of nuclear DNA (Figure 18-22). Isolated chromatin fibers exhibiting the beads-on-a-string appearance measure about 10 nm in diameter, but the chromatin of intact cells often forms a slightly thicker fiber, about 30 nm in diameter, called the **30-nm chromatin fiber**. In preparations of isolated chromatin, the 10-nm and 30-nm forms of the chromatin fiber can be interconverted by changing the salt concentration of the solution. However, the 30-nm fiber does not form in chromatin preparations whose histone H1 molecules have been removed, suggesting that histone H1 facilitates the packing of nucleosomes into the 30-nm fiber. Several models have been proposed to explain how individual nucleosomes are packed together to form a 30-nm fiber. Most early models postulated that the chain of nucleosomes is twisted upon itself to form some type of coiled structure. However, more recent studies suggest that the structure of the 30-nm fiber is much less uniform than a coiled model suggests. Instead, the nucleosomes of the 30-nm fiber seem to be packed together to form an irregular, three-dimensional zigzag structure that can interdigitate with its neighboring fibers.

The next level of chromatin packaging is the folding of the 30-nm fibers into **looped domains** averaging 50,000–100,000 bp in length. This looped arrangement is maintained by the periodic attachment of DNA to an insoluble network of nonhistone proteins that form a

chromosomal *scaffold* to which the long loops of DNA are attached. The looped domains can be most clearly seen in electron micrographs of chromosomes isolated from dividing cells and treated to remove all the histones and most of the nonhistone proteins (Figure 18-23). Loops can also be seen in specialized types of chromosomes that are not associated with the process of cell division (see the discussion of polytene chromosomes in Chapter 23). In these cases, the chromatin loops turn out to contain “active” regions of DNA—that is, DNA that is being transcribed. It makes sense that active DNA would be less tightly packed than inactive DNA because it would allow easier access by proteins involved in gene transcription.

Even in cells where genes are being actively transcribed, significant amounts of chromatin may be further compacted (Figure 18-22d). The degree of folding in such cells varies over a continuum. Segments of chromatin so highly compacted that they show up as dark spots in micrographs are called **heterochromatin**, whereas the more loosely packed, diffuse form of chromatin is called **euchromatin** (see Figure 18-27a). The tightly packed heterochromatin contains DNA that is transcriptionally inactive, while the more loosely packed euchromatin is associated with DNA that is being actively transcribed. Much of the chromatin in metabolically active cells is loosely packed as euchromatin; but as a cell prepares to divide, *all* of its chromatin becomes highly compacted, generating a group of microscopically distinguishable chromosomes. Because the chromosomal DNA has recently been duplicated, each chromosome is composed of two duplicate units called *chromatids* (Figure 18-22e).

The extent to which a DNA molecule has been folded in chromatin and chromosomes can be quantified using the **DNA packing ratio**, which is calculated by determining the total extended length of a DNA molecule and dividing it by the length of the chromatin fiber or chromosome into which it has been packaged. The initial coiling of the DNA around the histone cores of the nucleosomes reduces the length by a factor of about seven, and formation of the 30-nm fiber results in a further sixfold condensation. The packing ratio of the 30-nm fiber is therefore about $7 \times 6 = 42$. Further folding and coiling brings the overall packing ratio of typical euchromatin to about 750. For heterochromatin and the chromosomes of dividing cells, the packing ratio is still higher. At the time of cell division, for example, a typical human chromosome measures about 4–5 μm in length, yet contains a DNA molecule that would measure almost 75 mm if completely extended. The packing ratio for such a chromosome therefore falls in the range of 15,000–20,000.

Eukaryotes Package Some of Their DNA in Mitochondria and Chloroplasts

A eukaryotic cell’s DNA is not contained solely in the nucleus. Though nuclear DNA accounts for nearly all of a cell’s genetic information, mitochondria and chloroplasts

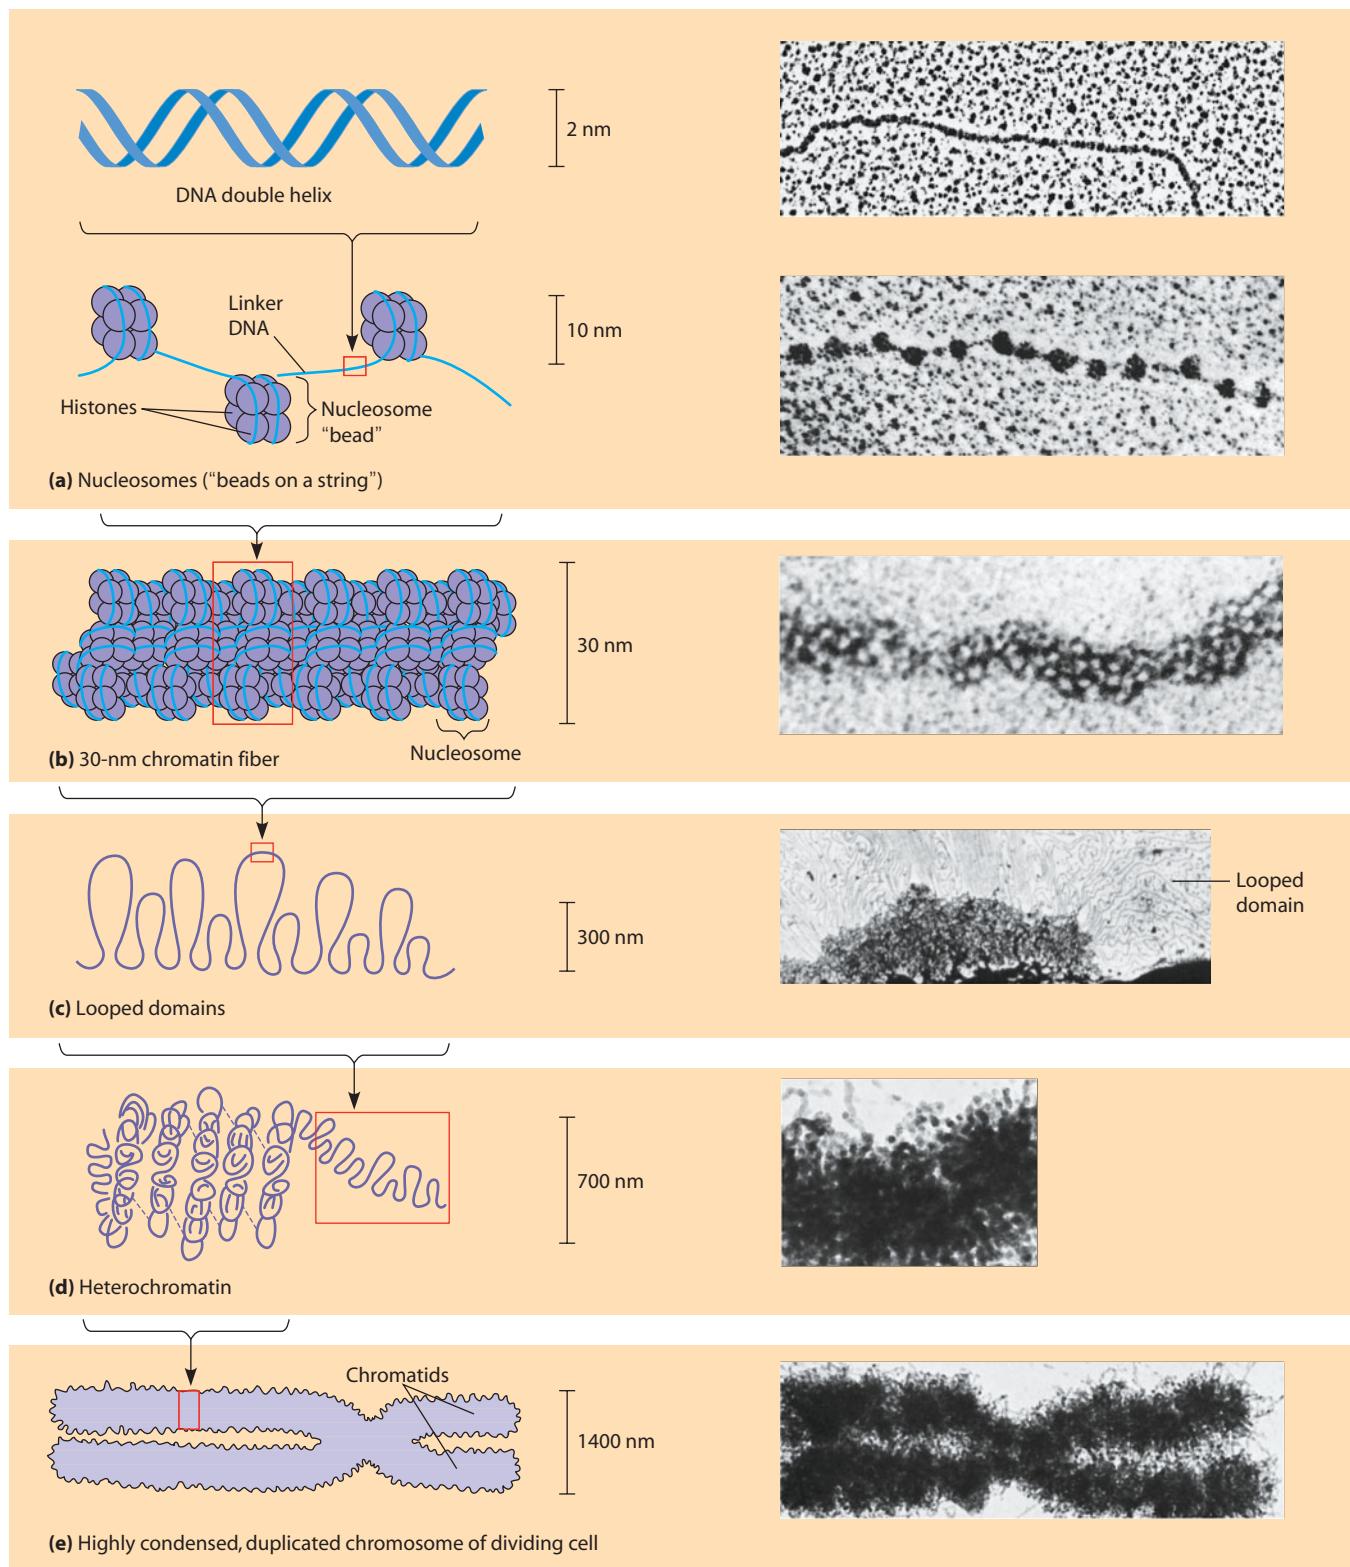

FIGURE 18-22 Levels of Chromatin Packing. These diagrams and TEMs show a current model for progressive stages of DNA coiling and folding, culminating in the highly compacted chromosome of a dividing cell. (a) “Beads on a string,” an extended configuration of nucleosomes formed by the association of DNA with four types of histones. (b) The 30-nm chromatin fiber, shown here as a tightly packed collection of nucleosomes. The fifth histone, H1, may be located in the interior of the fiber. (c) Looped domains of 30-nm fibers, visible in the TEM here because a mitotic chromosome has been experimentally unraveled. (d) Heterochromatin, highly folded chromatin that is visible as discrete spots even in interphase cells. (e) A replicated chromosome (two attached chromatids) from a dividing cell, with all the DNA of the chromosome in the form of very highly compacted heterochromatin.

FIGURE 18-23 Electron Micrograph Showing the Protein Scaffold That Remains After Removing Histones from Human Chromosomes. The chromosomal DNA remains attached to the scaffold as a series of long loops. The arrow points to a region where a loop of the DNA molecule can be clearly seen (TEM).

contain some DNA of their own—along with the machinery needed to replicate, transcribe, and translate the information encoded by this DNA. The DNA molecules residing in mitochondria and chloroplasts are devoid of histones and are usually circular (Figure 18-24). In other words, they resemble the genomes of bacteria, as we might expect from the likely endosymbiotic origin of these organelles (discussed in Box 11A). Mitochondrial and chloroplast genomes tend to be relatively small, comparable in size to a viral genome. Both organelles are therefore semiautonomous, able to code for some of their polypeptides but dependent on the nuclear genome to encode most of them.

The genome of the human mitochondrion, for example, consists of a circular DNA molecule containing 16,569 base pairs and measuring about 5 μm in length. It has been completely sequenced, and all of its 37 genes are known. The RNA and polypeptides encoded by this DNA are just a small fraction (about 5%) of the number of RNA molecules and proteins needed by the mitochondrion. This is nonetheless a vital genetic contribution, for these products include the RNA molecules present in mitochondrial ribosomes, all of the transfer RNA molecules

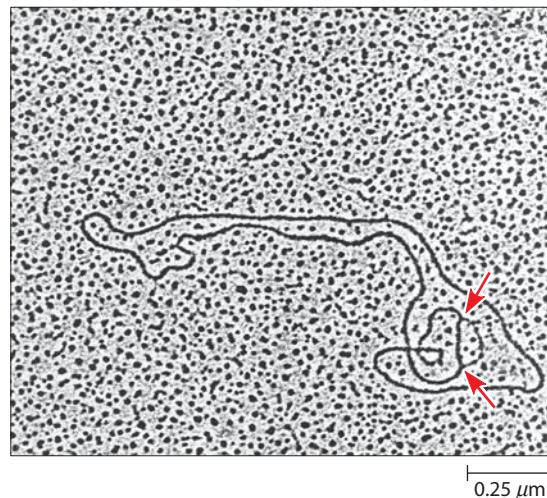

FIGURE 18-24 Mitochondrial DNA. Mitochondrial DNA from most organisms is circular, as seen in this electron micrograph. This molecule was caught in the act of replication; the arrows indicate the points at which replication was proceeding when the molecule was fixed for electron microscopy (TEM).

required for mitochondrial protein synthesis, and 13 of the polypeptide subunits of the electron transport system. These include subunits of NADH dehydrogenase, cytochrome *b*, cytochrome *c* oxidase, and ATP synthase (Figure 18-25).

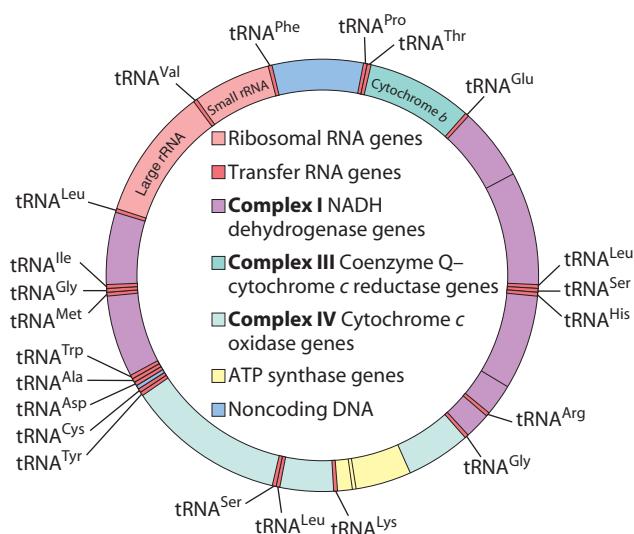

FIGURE 18-25 Genome of the Human Mitochondrion. The double-stranded DNA molecule of the human mitochondrion is circular and contains 16,569 base pairs. This genome codes for large and small ribosomal RNA molecules, transfer RNA (tRNA) molecules (each identified by a superscript with the three-letter abbreviation for the amino acid it carries), and subunits of a number of the proteins that make up the mitochondrial electron transport system complexes. The tRNA genes are very short because the RNA molecules they encode each contain only about 75 nucleotides. Notice that there are two tRNA genes for leucine and two for serine; they code for slightly different versions of tRNAs for these amino acids. The mitochondrial genome is extremely compact, with little noncoding DNA between genes.

The size of the mitochondrial genome varies considerably among organisms. Mammalian mitochondria typically have about 16,500 bp of DNA, yeast mitochondrial DNA is five times larger, and plant mitochondrial DNA is larger yet. It is not clear, however, that larger mitochondrial genomes necessarily code for correspondingly more polypeptides. A comparison of yeast and human mitochondrial DNA, for example, suggests that most of the additional DNA present in the yeast mitochondrion consists of noncoding sequences. In addition to these species-specific differences in mitochondrial genome size, some mitochondrial DNA sequences are unique to a given species. For example, a 648-nucleotide sequence, sometimes called the “*DNA bar code*,” can be used to precisely identify one closely related species from another.

Chloroplasts typically possess circular DNA molecules measuring around 120,000 bp in length and containing about 120 genes. Besides the ribosomal and transfer RNAs and polypeptides involved in protein synthesis, the chloroplast genome also codes for a few polypeptides involved in photosynthesis. These include several polypeptide components of photosystems I and II and one of the two subunits of ribulose-1,5-bisphosphate carboxylase, the carbon-fixing enzyme of the Calvin cycle.

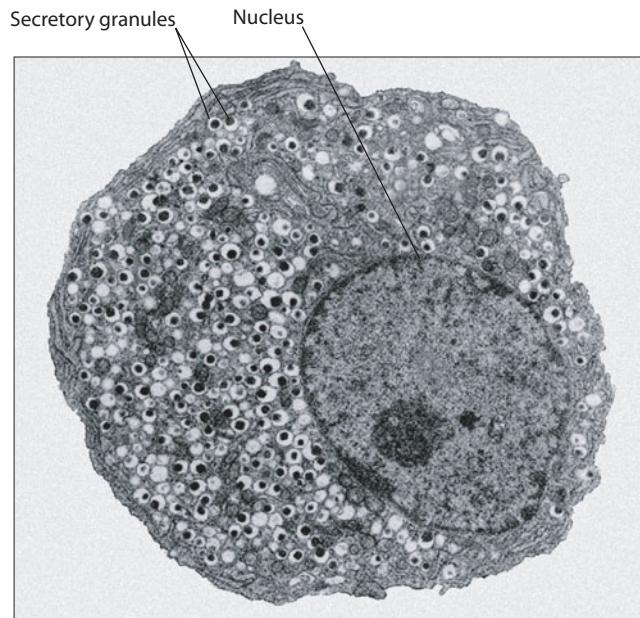

Interestingly, most polypeptides encoded by mitochondrial or chloroplast genomes are components of multimeric proteins that also contain subunits encoded by the nuclear genome. In other words, organelle proteins that contain subunits encoded within the organelle are typically hybrid

protein complexes containing polypeptides encoded and synthesized within the organelle plus polypeptides encoded by the nuclear genome and synthesized by cytoplasmic ribosomes. This raises intriguing questions about how polypeptides synthesized in the cytoplasm enter the organelle, a topic we will cover in Chapter 22.

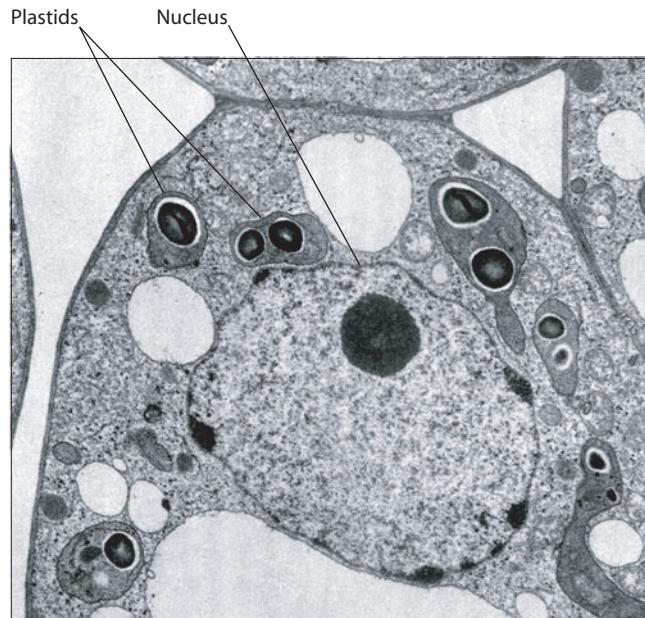

The Nucleus

So far in this chapter, we have discussed DNA as the genetic material of the cell, the genome as a complete set of DNA instructions for the cells of a particular species, and the chromosome as the physical means of packaging DNA within cells. Now we come to the **nucleus**, the site within the eukaryotic cell where the chromosomes are localized and replicated and where the DNA they contain is transcribed. The nucleus is therefore both the repository of most of the cell’s genetic information and the control center for the expression of that information.

The nucleus is one of the most prominent and distinguishing features of eukaryotic cells (Figure 18-26). In fact, the term *eukaryon* means “true nucleus.” This means that the very essence of a eukaryotic cell is its membrane-bound nucleus, which compartmentalizes the activities of the genome—both replication and transcription—from the rest of cellular metabolism. In the following discussion, we focus first on the membrane envelope that forms the boundary of the nucleus. Then we turn our attention to the pores that perforate the envelope, the structural

FIGURE 18-27 Structural Organization of the Nucleus and Nuclear Envelope. (a) An electron micrograph of the nucleus from a mouse liver cell, with prominent structural features labeled (TEM). The nuclear envelope is a double membrane perforated by nuclear pores. Internal structures include the nucleolus, euchromatin, and heterochromatin. (b) A drawing of a typical nucleus. Structural features included here but not visible in the micrograph include the nuclear lamina, ribosomes on the outer nuclear membrane, and the continuity between the outer nuclear membrane and the rough ER.

matrix inside the nucleus, the arrangement of the chromatin fibers, and finally, the organization of the nucleolus. **Figure 18-27** provides an overview of some of these nuclear structures.

A Double-Membrane Nuclear Envelope Surrounds the Nucleus

The existence of a membrane around the nucleus was first suggested in the late nineteenth century, based primarily on the osmotic properties of the nucleus. Since light microscopy reveals only a narrow, fuzzy border at the outer surface of the nucleus, little was known about the structure of this membranous boundary before the advent of electron microscopy. Transmission electron microscopy revealed that the nucleus is bounded by a **nuclear envelope** composed of two membranes—the inner and outer nuclear membranes—separated by a **perinuclear space** measuring about 20–40 nm across (see Figure 18-27b). The outer nuclear membrane is continuous with the endoplasmic reticulum, making the perinuclear space continuous with the lumen of the ER. Like membranes of the rough ER, the outer membrane is often studded on its outer surface with ribosomes engaged in protein synthesis. Several proteins in the outer

membrane bind to actin and intermediate filaments of the cell's cytoskeleton, thereby anchoring the nucleus within the cell and providing a mechanism for nuclear movements. Tubular invaginations of the nuclear envelope, collectively known as the *nucleoplasmic reticulum*, may project into the internal nuclear space and increase the area of the nucleus that makes direct contact with the inner nuclear membrane.

One of the most distinctive features of the nuclear envelope is the presence of specialized channels called **nuclear pores**, which are especially easy to see when the nuclear envelope is examined by freeze-fracture microscopy (Figure 18-28). Each pore is a small cylindrical channel extending through both membranes of the nuclear envelope, thereby providing direct continuity between the cytosol and the **nucleoplasm** (the name for the interior space of the nucleus other than the region occupied by the nucleolus). The number of pores varies greatly with cell type and activity. A typical mammalian nucleus has about 3000–4000 pores, or about 10–20 pores per square micrometer of membrane surface area.

At each pore, the inner and outer membranes of the nuclear envelope are fused together, forming a channel that is lined with an intricate protein structure called the

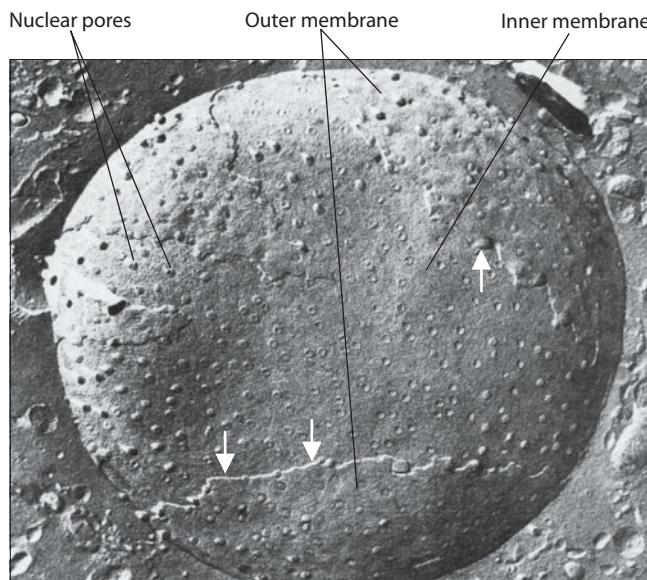

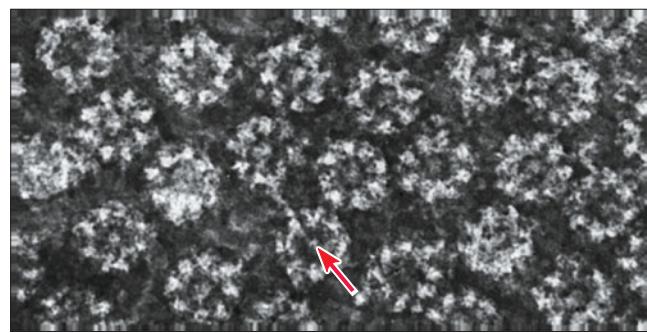

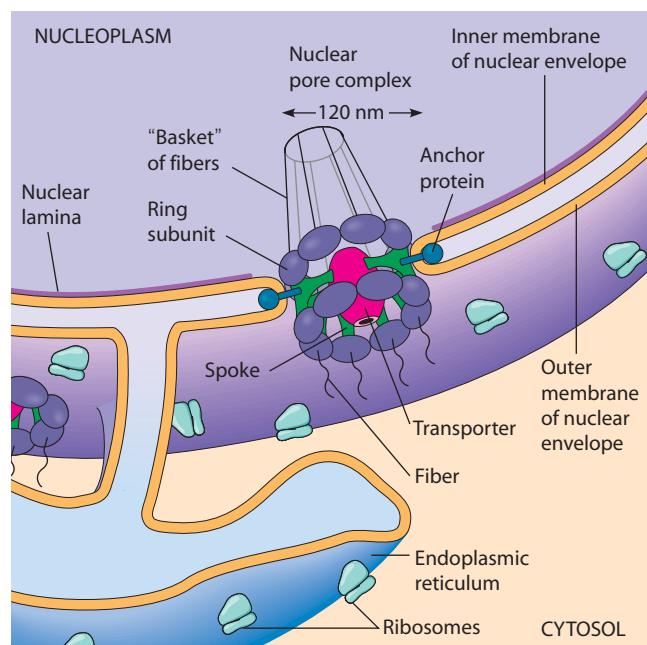

FIGURE 18-28 Nuclear Pores. Numerous nuclear pores are visible in this freeze-fracture micrograph of the nuclear envelope of an epithelial cell from a rat kidney. The fracture plane reveals faces of both the inner membrane and the outer membrane. The arrows point to ridges that represent the perinuclear space delimited by the two membranes (TEM).

nuclear pore complex (NPC). The NPC has an outer diameter of ~120 nm and is built from about 30 different proteins called *nucleoporins*. In electron micrographs, the most striking feature of the pore complex is its octagonal symmetry. Micrographs such as the one in **Figure 18-29a** show rings of eight subunits arranged in an octagonal pattern. In other views, the eight subunits are seen to protrude on both the cytoplasmic and nucleoplasmic sides of the envelope. Notice that central granules can be seen in some of the nuclear pore complexes in Figure 18-29a. Although these granules were once thought to consist solely of particles in transit through the pores, they are now thought to also contain components that are an integral part of the pore complex.

Figure 18-29b illustrates the main components of the nuclear pore complex. Examination of this diagram reveals that the pore complex as a whole is shaped somewhat like a wheel lying on its side within the nuclear envelope. Two parallel rings, outlining the rim of the wheel, each consist of the eight subunits seen in electron micrographs. Eight spokes (shown in green) extend from the rings to the wheel's hub (dark pink), which is the "central granule" seen in many electron micrographs. This granule is sometimes called the *transporter* because it is thought to contain components that are involved in moving macromolecules across the nuclear envelope. Proteins extending from the rim into the perinuclear space may help anchor the pore complex to the envelope. Fibers also extend from the rings into the cytosol and nucleoplasm, with those on the nucleoplasm side forming a basket (sometimes called a "cage" or "fishtrap").

FIGURE 18-29 Structure of the Nuclear Pore. (a) Negative staining of an oocyte nuclear envelope reveals the octagonal pattern of the nuclear pore complexes. The arrow shows a central granule. This nuclear envelope is from an oocyte of the newt *Taricha granulosa* (TEM). (b) A nuclear pore is formed by fusion of the inner and outer nuclear membranes and is lined by an intricate protein structure called the nuclear pore complex. The structure is roughly wheel-shaped and has octagonal symmetry. Two parallel rings, each consisting of eight subunits (dark purple), outline the rim of the wheel. Eight spokes (green) connect the two rings (two of the spokes are omitted from the drawing) and extend to the central transporter (dark pink) at the hub of the wheel; the transporter is thought to contain components involved in moving particles through the pore. Fibers extend above and below the complex, with those on the nucleoplasmic side forming a basket of unknown function.

Molecules Enter and Exit the Nucleus Through Nuclear Pores

The nuclear envelope solves one problem but creates another. As a means of localizing chromosomes and their activities to one region of the cell, it is an example of the general eukaryotic strategy of compartmentalization.

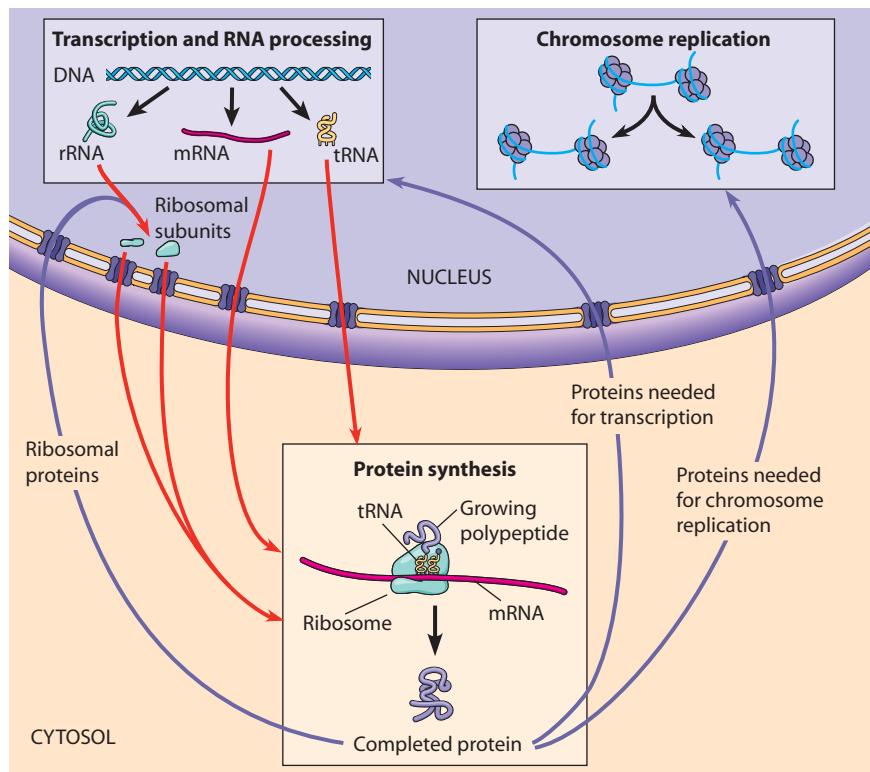

FIGURE 18-30 Macromolecular Transport into and out of the Nucleus. Because eukaryotic cells store their genetic information in the nucleus but synthesize proteins in the cytoplasm, all the proteins needed in the nucleus must be transported inward from the cytoplasm (purple arrows), and all the RNA molecules and ribosomal subunits needed for protein synthesis in the cytoplasm must be transported outward from the nucleus (red arrows). The three kinds of RNA molecules required for protein synthesis are ribosomal RNA (rRNA), messenger RNA (mRNA), and transfer RNA (tRNA).

Presumably, it is advantageous for a nucleus to possess a barrier that keeps in the chromosomes and keeps out organelles such as ribosomes, mitochondria, lysosomes, and microtubules. For example, the nuclear envelope protects newly synthesized RNA from being acted upon by cytoplasmic organelles or enzymes before it has been fully processed.

But in the act of separating immature RNA molecules and chromosomes from the cytoplasm, the nuclear envelope creates several formidable transport problems for eukaryotic cells that are unknown in prokaryotes. All the enzymes and other proteins required for chromosome replication and transcription of DNA in the nucleus must be imported from the cytoplasm, and all the RNA molecules and partially assembled ribosomes needed for protein synthesis in the cytoplasm must be obtained from the nucleus (**Figure 18-30**). In response to these transport problems, specialized pores have evolved that mediate virtually all transport into and out of the nucleus.

To get some idea of how much traffic must travel through the nuclear pores, consider the flow of ribosomal subunits from the nucleus to the cytoplasm. Ribosomes are partially assembled in the nucleus as two classes of subunits, each of which is a complex of RNA and proteins. These subunits move to the cytoplasm and, when needed for protein synthesis, are combined into functional ribosomes containing one of each type of subunit. An actively growing mammalian cell can easily be synthesizing 20,000 ribosomal subunits per minute. We already know that such a cell has about 3000–4000 nuclear pores, so ribosomal subunits must be transported to the cytosol at a rate

of about 5–6 subunits per minute per pore. Traffic in the opposite direction is, if anything, even heavier. When chromosomes are being replicated, histones are needed at the rate of about 300,000 molecules per minute. The rate of inward movement must therefore be about 100 histone molecules per minute per pore! In addition to all this macromolecular traffic, the pores mediate the transport of smaller particles, molecules, and ions.

Simple Diffusion of Small Molecules Through Nuclear Pores. The idea that small particles can diffuse freely back and forth through nuclear pores first received experimental support from studies in which colloidal gold particles of various sizes were injected into the cytoplasm of cells that were then examined by electron microscopy. Shortly after injection, the gold particles could be seen passing through the nuclear pores and into the nucleus. The rate of particle entry into the nucleus is inversely related to the particle's diameter—that is, the larger the gold particle, the slower it enters the nucleus. Particles larger than about 10 nm in diameter are excluded entirely. Since the overall diameter of a nuclear pore complex is much larger than such gold particles, it was concluded that the pore complex contains tiny, *aqueous diffusion channels* through which small particles and molecules can freely move.

To determine the diameter of these channels, investigators have injected radioactive proteins of various sizes into the cytoplasm of cells and observed how long it takes for the proteins to appear in the nucleus. A globular protein with a molecular weight of 20,000 takes only a few

minutes to equilibrate between the cytoplasm and nucleus, but most proteins of 60,000 daltons or more are barely able to penetrate into the nucleus at all. These and other transport measurements indicate that the aqueous diffusion channels are about 9 nm in diameter, a size that creates a permeability barrier for molecules significantly larger than ~30,000 in molecular weight. Researchers initially assumed that each nuclear pore complex has one such channel. However, more recent evidence suggests there may be eight separate 9-nm channels at the periphery of the pore complex—between the spokes—and perhaps an additional 9-nm channel at the center of the transporter. These aqueous channels are thought to be freely permeable to ions and small molecules (including small proteins) because such substances quickly cross the nuclear envelope after being injected into cells. Thus, the nucleoside triphosphates required for DNA and RNA synthesis probably diffuse freely through the pores, as do other small molecules needed for metabolic pathways that function within the nucleus.

Active Transport of Large Proteins and RNA Through Nuclear Pores

Many of the proteins involved in DNA packaging, replication, and transcription are small enough to pass through a 9-nm-wide channel. Histones, for example, have molecular weights of 21,000 or less and should therefore passively diffuse through the nuclear pores with little problem. Some nuclear proteins are very large, however. The enzymes involved in DNA and RNA synthesis, for example, have subunits with molecular weights in excess of 100,000, which is too large to fit through a 9-nm opening. Messenger RNA molecules pose a challenge, too, because they leave the nucleus bound to proteins in the form of RNA-protein (“ribonucleoprotein”) complexes that are quite large. Ribosomal subunits must also be exported to the cytoplasm after being assembled in the nucleus. Clearly, transporting all these particles through the nuclear pores is a significant challenge.

A large body of evidence suggests that such large molecules and particles are actively transported through nuclear pores by a selective process. Like active transport across single membranes, active transport through nuclear pores requires energy and involves specific binding of the transported substance to membrane proteins, which in this case are part of the pore complex. The underlying molecular mechanism is best understood for proteins that are actively transported from the cytosol into the nucleus. Such proteins possess one or more **nuclear localization signals (NLS)**, which are amino acid sequences that enable the protein to be recognized and transported by the nuclear pore complex. An NLS is usually 8–30 amino acids in length and often contains proline as well as the positively charged (basic) amino acids lysine and arginine.

The role played by NLS sequences in targeting proteins for the nucleus has been established by experiments

in which gold particles larger than 9 nm in diameter—too large to pass through the aqueous diffusion channels of the nuclear pores—were coated with NLS-containing polypeptides and then injected into the cytoplasm of frog oocytes. After such treatment, gold particles as large as 26 nm in diameter are rapidly transported through the nuclear pore complexes and into the nucleus. Thus, the maximum diameter for *active* transport across the nuclear envelope seems to be 26 nm (versus 9 nm for simple diffusion). This is only one of many examples in which a short stretch of amino acids has been found to target a molecule or particle to a specific cellular site.

The process of transporting cytoplasmic proteins into the nucleus through nuclear pores is illustrated in **Figure 18-31a**. In step ①, a cytoplasmic protein containing an NLS is recognized by a special type of receptor protein called an **importin**, which binds to the NLS and mediates the movement of the NLS-containing protein to a nuclear pore. In step ②, the importin-NLS protein complex is transported into the nucleus by the transporter at the center of the nuclear pore complex (NPC). After arriving in the nucleus, the importin molecule associates with a GTP-binding protein called *Ran*. This interaction between importin and Ran causes the NLS-containing protein to be released for use in the nucleus (step ③). The Ran-GTP-importin complex is then transported back through a nuclear pore to the cytoplasm (step ④), where the importin is released for reuse accompanied by hydrolysis of the Ran-bound GTP (step ⑤). Evidence that this GTP hydrolysis step provides the energy for nuclear import has come from experiments showing that nuclear transport can be inhibited by exposing cells to nonhydrolyzable analogs of GTP but not by exposing cells to nonhydrolyzable analogs of ATP.

For exporting material out of the nucleus, comparable mechanisms operate. The main difference is that transport out of the nucleus is used mainly for RNA molecules that are synthesized in the nucleus but function in the cytoplasm, whereas nuclear import is devoted largely to importing proteins that are synthesized in the cytoplasm but function in the nucleus. Although the main cargo for nuclear export is RNA rather than protein, RNA export is mediated by proteins that bind to the RNA. These adaptor proteins contain amino acid sequences called **nuclear export signals (NES)**, which target the protein—and hence its bound RNA—for export through the nuclear pores. NES sequences are recognized by nuclear transport receptor proteins called **exportins**, which bind to molecules containing NES sequences and mediate their transport out through the nuclear pores by a mechanism resembling that used by importins to transport cytoplasmic molecules into the nucleus (Figure 18-31b).

The difference in direction between importin- and exportin-mediated transport is governed by the interaction between Ran-GTP and these two classes of molecules, accompanied by a concentration gradient of Ran-GTP across the nuclear envelope. The Ran-GTP concentration

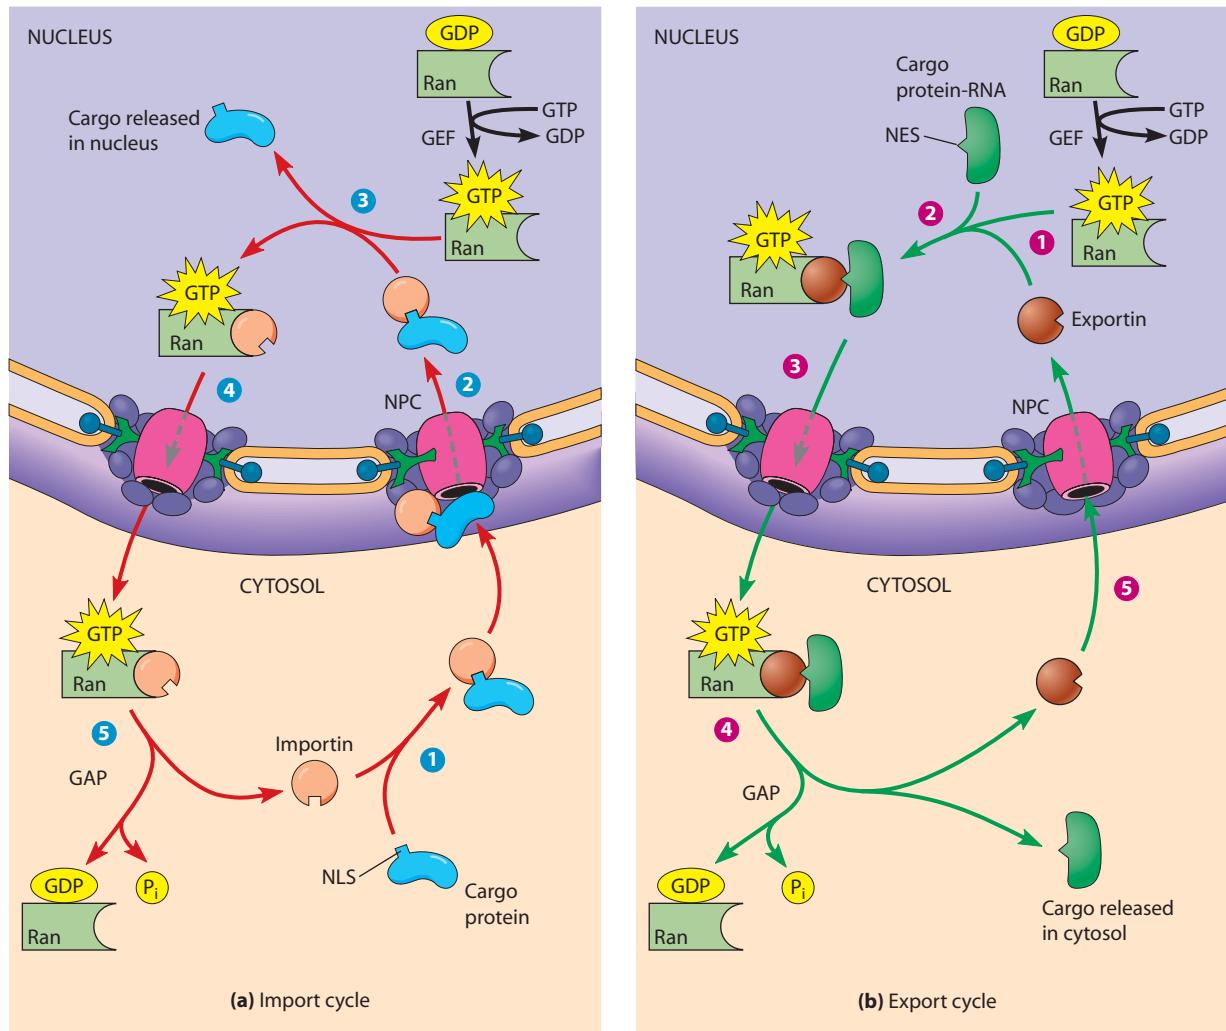

FIGURE 18-31 Transport Through the Nuclear Pore Complex. (a) Import cycle. Proteins made in the cytosol and destined for use in the nucleus contain a nuclear localization sequence (NLS) that targets them as “cargo” for transport through the nuclear pore complex. ① An NLS-containing cargo protein binds to importin, and ② the importin-cargo complex is then transported through the nuclear pore complex. ③ Nuclear Ran-GTP binds to importin, triggering the release of the cargo protein in the nucleus. ④ The Ran-GTP-importin complex is transported back to the cytosol, where ⑤ the hydrolysis of GTP to GDP is accompanied by the release of importin. (b) Export cycle. The main cargo for nuclear export is RNA rather than protein, but RNAs are generally transported out of the nucleus by proteins containing a nuclear export signal (NES). During the export cycle, ① Ran-GTP binds to exportin in the nucleus, which ② promotes the binding of exportin to its cargo, in this case a protein-RNA complex. ③ The exportin-cargo-Ran-GTP complex is exported through the nuclear pore to the cytosol, where ④ the exportin and its cargo are released from Ran, accompanied by hydrolysis of GTP to GDP. ⑤ Exportin then moves back into the nucleus, where it can repeat the export cycle. The import and export cycles are both driven by a concentration gradient of Ran-GTP that is maintained by the presence of a GEF (guanine-nucleotide exchange factor) in the nucleus and a GAP (GTPase activating protein) in the cytosol.

is maintained at high levels inside the nucleus by a *guanine-nucleotide exchange factor* (GEF) that promotes the binding of GTP to Ran in exchange for GDP. In contrast, the cytosol contains a *GTPase activating protein* (GAP) that promotes the hydrolysis of GTP by Ran, thereby lowering the Ran-GTP concentration outside the nucleus. The relatively high concentration of Ran-GTP inside the nucleus has two effects: first, nuclear Ran-GTP promotes the release of NLS-containing cargo from importin (Figure 18-31a, step ③); second, nuclear Ran-

GTP promotes the binding of NES-containing cargo to exportin (Figure 18-31b, step ②). The net result is that the direction of transport for any given cargo molecule is determined by the type of targeting sequence it contains (NLS or NES), which dictates whether importins will release the cargo in the nucleus and bind it in the cytoplasm or exportins will bind the cargo in the nucleus and release it in the cytoplasm.

The nuclear transport cycle poses a recycling problem for the cell: Ran-GTP is exported along with molecules

that leave the nucleus. If Ran were not recycled back to the nucleus, nuclear Ran would soon be depleted. A specific nuclear transport protein, *NTF2* (for nuclear transport factor 2), solves this problem by shuttling Ran-GDP back into the nucleus.

The Nuclear Matrix and Nuclear Lamina Are Supporting Structures of the Nucleus

Roughly 80–90% of the nuclear mass is accounted for by chromatin fibers, so you might expect that removing the chromatin would cause the nucleus to collapse into a relatively structureless form. However, in the early 1970s researchers discovered that an insoluble fibrous network retaining the overall shape of the nucleus remains behind after more than 95% of the chromatin has been removed by a combination of nuclease and detergent treatments. This network, called the **nuclear matrix** or **nucleoskeleton**, is thought to help maintain the shape of the nucleus and provide an organizing skeleton for the chromatin fibers. The existence of such an organizing skeleton has not been accepted by all cell biologists, however. The fibrous network is visible only in certain micrographs (Figure 18-32), leading skeptics to question whether it is an artifact introduced during sample preparation.

In recent years, additional evidence has bolstered the case for the presence of a structural skeleton that organizes nuclear activities. For example, a close connection between chromatin fibers and an underlying matrix is suggested by the discovery that isolated nuclear matrix preparations always contain small amounts of tightly bound DNA and RNA. Nucleic acid hybridization techniques have revealed that the tightly

bound DNA is enriched in sequences that are being actively transcribed into RNA. Moreover, when cells are incubated with ^3H -thymidine, a radioactive precursor for DNA synthesis, the newly synthesized radioactive DNA is found to be preferentially associated with the nuclear matrix. These observations suggest that an underlying skeletal network may be involved in anchoring chromatin fibers at locations where DNA or RNA is being synthesized, thereby organizing the DNA for orderly replication and transcription and perhaps even providing tracks that guide and propel newly formed messenger RNA to the nuclear pores for transport to the cytoplasm.

While the exact makeup and role of the nuclear matrix remain to be elucidated, the nucleus contains one skeletal structure that is well understood. This structure, called the **nuclear lamina**, is a thin, dense meshwork of fibers that lines the inner surface of the inner nuclear membrane and confers mechanical strength to the nucleus. The nuclear lamina is about 10–40 nm thick and is constructed from intermediate filaments made of proteins called *lamins* (described in more detail in Chapter 15). Inherited abnormalities in these proteins have been linked to more than a dozen human diseases, including several involving severe muscle wasting or premature aging. For example, a single base mutation in one lamin gene is responsible for *Hutchinson–Gilford progeria*, a disease in which symptoms of old age—such as hair loss, cardiovascular disease, and degeneration of skin, muscle, and bone—appear in young children and usually cause death by the early teenage years. The cells of such individuals exhibit severe abnormalities in nuclear shape, although it is not clear how such nuclear changes relate to the various disease symptoms.

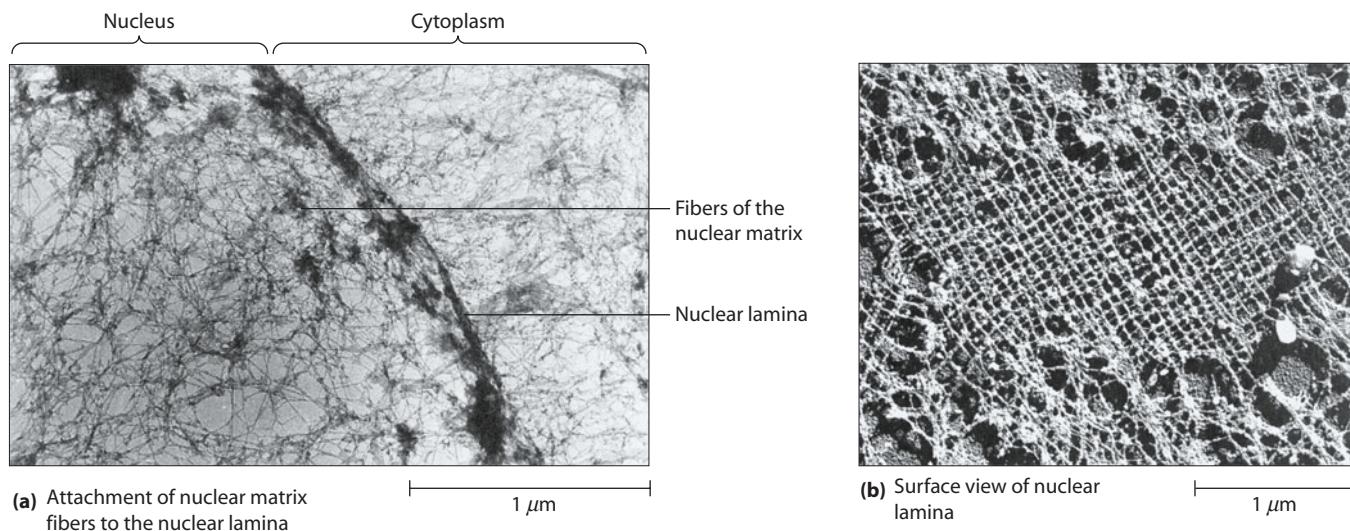

FIGURE 18-32 The Nuclear Matrix and the Nuclear Lamina. (a) This electron micrograph of part of a mammalian cell nucleus shows a branched network of nuclear matrix filaments traversing the nucleus. These filaments seem attached to the nuclear lamina, the dense layer of filaments that lines the nucleoplasm side of the nuclear envelope. (b) A surface view of the nuclear lamina of a frog oocyte (TEMs).

Chromatin Fibers Are Dispersed Within the Nucleus in a Nonrandom Fashion

Other than during cell division, a cell's chromatin fibers tend to be highly extended and dispersed throughout the nucleus. You might therefore guess that the chromatin threads corresponding to each individual chromosome are randomly distributed and highly intertwined within the nucleus. Perhaps surprisingly, this seems not to be the case. Instead, the chromatin of each chromosome has its own discrete location. This idea was first proposed in 1885, but evidence that it is true in a variety of cells awaited the techniques of modern molecular biology. Experiments using nucleic acid probes that hybridize to the DNA of specific chromosomes (one example of a technique known as *in situ hybridization*) have now shown that the chromatin fibers corresponding to individual chromosomes occupy discrete compartments within the nucleus, referred to as *chromosome territories* (**Figure 18-33**). The positions of these territories do not seem to be fixed, however. They vary from cell to cell of the same organism and change during a cell's life cycle, likely reflecting changes in gene activity of the different chromosomes.

The nuclear envelope helps organize chromatin by binding parts of it to the inner nuclear envelope at sites that are closely associated with the nuclear pores. These chromatin regions are highly compacted—that is, they are heterochromatin. In electron micrographs, this material appears as a dark irregular layer around the nuclear periphery, as we saw in Figure 18-27a. Most of it seems to be the type called **constitutive heterochromatin**, which exists in a highly condensed form at virtually all times in all cells of the organism. The DNA of constitutive heterochromatin consists of simple-sequence repeated DNA (recall that these are short sequences that repeat tandemly and are not transcribed). Two major chromosomal regions

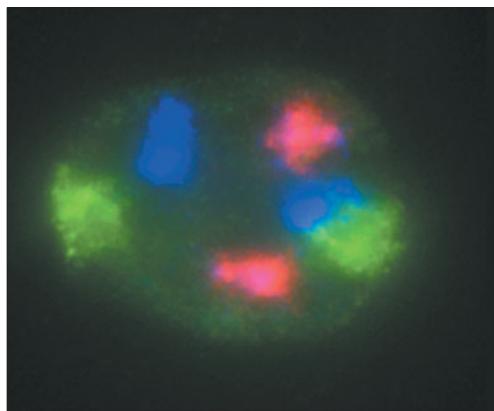

FIGURE 18-33 Chromosome Territories. Mouse lung cells were stained with fluorescent dyes linked to nucleic acid probes that specifically hybridize to the DNA of chromosome 12 (red), chromosome 14 (green), or chromosome 15 (blue). This view of a single nucleus observed by light microscopy shows that the DNA of each chromosome is localized to a specific region of the nucleus (each chromosome is present in two copies).

composed of constitutive heterochromatin are the centromere and the telomere. In many cases, it is chromosomal telomeres—the highly repeated DNA sequences located at the ends of chromosomes—that are attached to the nuclear envelope at times other than during cell division.

In contrast to constitutive heterochromatin, **facultative heterochromatin** varies with the particular activities carried out by the cell. Thus, this type of chromatin differs from tissue to tissue and can even vary from time to time within a given cell. Facultative heterochromatin appears to represent chromosomal regions that have become specifically inactivated in a specific cell type. The formation of facultative heterochromatin may be an important means of inactivating entire blocks of genetic information during embryonic development.

The Nucleolus Is Involved in Ribosome Formation

A prominent structural component of the eukaryotic nucleus is the **nucleolus** (plural **nucleoli**), the ribosome factory of the cell. Typical eukaryotic cells contain one or two nucleoli, but the occurrence of several more is not uncommon; in certain situations, hundreds or even thousands may be present. The nucleolus is usually spherical, measuring several micrometers in diameter, but wide variations in size and shape are observed. Because of their relatively large size, nucleoli are easily seen with the light microscope and were first observed more than 200 years ago. However, it was not until the advent of electron microscopy in the 1950s that the structural components of the nucleolus were clearly identified. In thin-section electron micrographs, each nucleolus appears as a membrane-free organelle consisting of fibrils and granules (**Figure 18-34**). The fibrils contain DNA that is being transcribed into *ribosomal RNA (rRNA)*, the RNA component of ribosomes. The granules are rRNA molecules being packaged with proteins (imported from the cytoplasm) to form ribosomal subunits. As we saw earlier, the ribosomal subunits are subsequently exported through the nuclear pores to the cytoplasm. Because of their role in synthesizing RNA, nucleoli become heavily radiolabeled when the cell is exposed to radioactive precursors of RNA (**Figure 18-35**).

The earliest evidence associating the nucleolus with ribosome formation was provided in the early 1960s by Robert Perry, who employed a microbeam of ultraviolet light to destroy the nucleoli of living cells. Such cells lost their ability to synthesize rRNA, suggesting that the nucleolus is involved in manufacturing ribosomes. Additional evidence emerged from studies carried out by Donald Brown and John Gurdon on the African clawed frog, *Xenopus laevis*. Through genetic crosses, it is possible to produce *Xenopus* embryos whose cells lack nucleoli. Brown and Gurdon discovered that such embryos, termed *anucleolate mutants*, cannot synthesize rRNA and therefore die during early development—again implicating the nucleolus in ribosome formation.

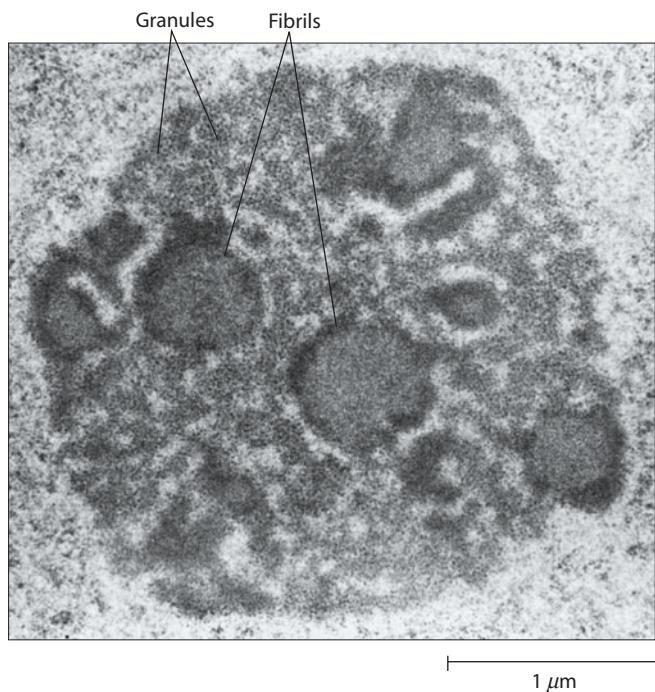

FIGURE 18-34 The Nucleolus. The nucleolus is a prominent intranuclear structure composed of a mass of fibrils and granules. The fibrils are DNA and rRNA; the granules are newly forming ribosomal subunits. Shown here is a nucleolus of a spermatogonium, a cell that gives rise to sperm cells (TEM).

If rRNA is synthesized in the nucleolus, then the DNA sequences coding for this RNA must reside in the nucleolus as well. This prediction has been verified by showing that isolated nucleoli contain the **nucleolus organizer region (NOR)**—a stretch of DNA carrying multiple copies of rRNA genes. These multiple rRNA genes occur in all genomes and are thus an important example of repeated DNA that carries genetic information. The number of copies of the rRNA genes varies greatly from species to species, but animal cells generally contain hundreds of copies and plant cells often contain thousands. The multiple copies are grouped into one or more NORs, which may reside on more than one chromosome; in each NOR, the multiple gene copies are tandemly arranged. A single nucleolus may contain rRNA genes derived from more than one NOR. For example, the human genome has five NORs per haploid chromosome set—or ten per diploid nucleus—each located near the tip of a different chromosome. But instead of ten separate nucleoli, the typical human nucleus has a single large nucleolus containing loops of chromatin derived from ten separate chromosomes.

The size of the nucleolus is correlated with its level of activity. In cells having a high rate of protein synthesis and hence a need for many ribosomes, nucleoli tend to be large and can account for 20–25% of the total volume of the nucleus. In less-active cells, nucleoli are much smaller.

The nucleolus disappears during mitosis, at least in the cells of higher plants and animals. As the cell approaches

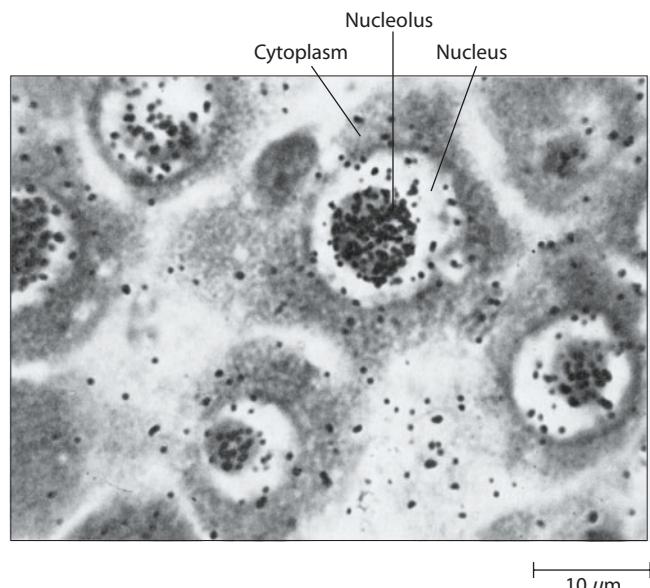

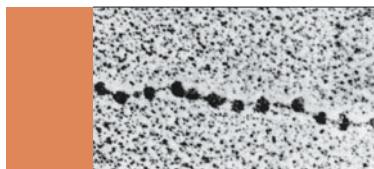

FIGURE 18-35 The Nucleolus as a Site of RNA Synthesis. To demonstrate the role of the nucleolus in RNA synthesis, a rat was injected with ³H-cytidine, a radioactively labeled RNA precursor. Five hours later, liver tissue was removed and subjected to autoradiography. The black spots over the nucleoli in this autoradiograph indicate that the ³H is concentrated in the nucleoli (TEM).

division, chromatin condenses into compact chromosomes accompanied by the shrinkage and then disappearance of the nucleoli. With our current knowledge of nucleolar composition and function, this makes perfect sense: The extended chromatin loops of the nucleolus cease being transcribed as they are coiled and folded, and any remaining rRNA and ribosomal protein molecules disperse or are degraded. Then, as mitosis is ending, the chromatin uncoils, the NORs loop out again, and rRNA synthesis resumes. In human cells, this is the only time the ten NORs of the diploid nucleus are apparent; as rRNA synthesis begins again, ten tiny nucleoli become visible, one near the tip of each of ten chromosomes. As these nucleoli enlarge, they quickly fuse into the single large nucleolus found in human cells that are not in the process of dividing.

In addition to the nucleolus, microscopists have also identified several kinds of small, non-membrane-enclosed nuclear structures. These nuclear bodies are thought to play a variety of roles related to the processing and handling of RNA molecules produced in the nucleus. These include *Cajal bodies* (named for the scientist who discovered them), *Gemini of Cajal bodies* (GEMs; so named because they appear similar to Cajal bodies), *speckles*, and *promyelocytic leukemia bodies* (PML bodies). Cajal bodies and GEMs are involved in maturation and processing of small nucleolar RNA (snoRNA) and small nuclear RNA (snRNA). Speckles, sometimes called *interchromatin granule clusters*, are rich in RNAs and proteins necessary for splicing of messenger RNA precursors into mature messenger RNAs. Current research is aimed at clarifying the roles of these nuclear bodies.

SUMMARY OF KEY POINTS

Chemical Nature of the Genetic Material

- DNA was discovered in the nineteenth century by Miescher, but it was not until the mid-twentieth century that studies with pneumococcal bacteria and bacteriophage T2 revealed that genes are made of DNA.

DNA Structure

- Watson and Crick discovered that DNA is a double helix in which the base A is paired with T, and the base G is paired with C. Supercoiling of the double helix affects the ability of DNA to interact with other molecules.
- Under experimental conditions, the two strands of the double helix can be separated from each other (denaturation) and rejoined (renaturation).

The Organization of DNA in Genomes

- The DNA (or RNA in some viruses) that contains one complete set of an organism's genetic information is called its genome. Viral or prokaryotic genomes consist of one or a small number of DNA molecules. Eukaryotes have a nuclear genome divided among multiple chromosomes, each containing one long DNA molecule, plus a mitochondrial genome; plants and algae possess a chloroplast genome as well.
- The study of genomes has been facilitated by the development of automated techniques for rapid DNA sequencing; these techniques have allowed the complete DNA sequences of numerous organisms, including humans, to be determined. Several online databases and software tools help researchers sort through the enormous amount of data being collected on DNA and protein sequences.
- In the nuclear genomes of multicellular eukaryotes, much of the DNA consists of repeated sequences that do not code for RNA or proteins. Some of this noncoding DNA performs structural or regulatory roles, but most of it has no obvious function.

DNA Packaging

- Due to their enormous size, DNA molecules need to be efficiently packaged by proteins that bind to the DNA. In eukaryotic chromosomes, short stretches of DNA are wrapped around protein particles composed of eight histone molecules to form a basic structural unit called the nucleosome. Chains of nucleosomes ("beads on a string") are packed together to form a 30-nm chromatin fiber, which can then loop and fold further.
- In eukaryotic cells that are actively transcribing DNA, much of the chromatin is in an extended, uncoiled form called euchromatin. Other portions are in a highly condensed, transcriptionally inactive state called heterochromatin. During cell division, all the chromatin becomes highly compacted, forming discrete chromosomes that can be seen with a light microscope.

The Nucleus

- Eukaryotic chromosomes are contained within a nucleus that is bounded by a double-membrane nuclear envelope.
- The nuclear envelope is perforated with nuclear pores that mediate two-way transport of materials between the nucleoplasm and the cytosol. Ions and small molecules diffuse passively through aqueous channels in the pore complex; larger molecules and particles are actively transported through it.
- The nucleolus is a specialized nuclear structure involved in the synthesis of ribosomal RNA and the assembly of ribosomal subunits. Other nuclear bodies perform functions related to processing of RNA.
- The nucleus appears to contain a fibrous skeleton that localizes certain activities, such as DNA replication and messenger RNA production, to discrete regions of the nucleus. One well-defined skeletal structure is the nuclear lamina—a thin, dense meshwork of fibers lining the inner surface of the inner nuclear membrane that confers mechanical strength to the nucleus.

MAKING CONNECTIONS

In this chapter we have introduced you to the properties of DNA—the molecule that stores genetic information—and to the cell nucleus, the site within eukaryotic cells where the bulk of the DNA is localized, replicated, and transcribed. In the next chapter, you will see how DNA replication is carried out by a process that unwinds the two strands of the double helix, thereby allowing each strand to guide the synthesis of a new complementary strand. You will also see how DNA replication is coordinated with mitosis, a type of cell division in which one cell gives rise to

two daughter cells containing the same DNA as the original parental cell. Chapter 20 covers another type of cell division, called meiosis, in which the genetic information in DNA is recombined during formation of the sperm and egg cells that make sexual reproduction possible. In Chapters 21 and 22, you will see how the genetic information stored in DNA is used to guide the synthesis of specific protein molecules. Finally, Chapter 23 describes the various ways in which cells regulate the expression of the genetic information contained in their DNA.

PROBLEM SET

More challenging problems are marked with a •.

18-1 Prior Knowledge. Virtually every experiment performed by biologists builds on knowledge provided by earlier experiments.

- (a) Of what significance to Avery and his colleagues was the finding (made in 1932 by J. L. Alloway) that the same kind of transformation of R cells into S cells that Griffith observed to occur in mice could also be demonstrated in culture with isolated pneumococcus cells?
 - (b) Of what significance to Hershey and Chase was the following suggestion (made in 1951 by R. M. Herriott)? "A virus may act like a little hypodermic needle full of transforming principles; the virus as such never enters the cell; only the tail contacts the host and perhaps enzymatically cuts a small hole through the outer membrane and then the nucleic acid of the virus head flows into the cell."
 - (c) Of what significance to Watson and Crick were the data of their colleagues at Cambridge suggesting that the particular forms in which A, G, C, and T exist at physiologic pH permit the formation of specific hydrogen bonds?
 - (d) How did the findings of Hershey and Chase help explain an earlier report (by T. F. Anderson and R. M. Herriott) that bacteriophage T2 loses its ability to reproduce when it is burst open osmotically by suspending the viral particles in distilled water before adding them to a bacterial culture?

18-2 DNA Base Composition. Based on your understanding of the rules of complementary base pairing, answer the following questions:

- (a) You analyze a DNA sample and find that its base composition is 30% A, 20% T, 30% G, and 20% C. What can you conclude about the structure of this DNA?
 - (b) For a double-stranded DNA molecule in which 40% of the bases are either G or C, what can you conclude about its content of the base A?
 - (c) For a double-stranded DNA molecule in which 40% of the bases are either G or T, what can you conclude about its content of the base A?
 - (d) For a double-stranded DNA molecule in which 15% of the bases are A, what can you conclude about its content of the base C? Would you expect the T_m of this DNA to be above or below 90°C? (Hint: Refer to Figure 18-9.)

18-3 DNA Structure. Carefully inspect the double-stranded DNA molecule shown here, and notice that it has twofold rotational symmetry:

Label each of the following statements as T if true or F if false.

- (a) There is no way to distinguish the right end of the double helix from the left end.
 - (b) If a solution of these molecules were heated to denature them, every single-stranded molecule in the solution would be capable of hybridizing with every other molecule.

- (c) If the molecule were cut at its midpoint into two halves, it would be possible to distinguish the left half from the right half.
 - (d) If the two single strands were separated from each other, it would not be possible to distinguish one strand from the other.
 - (e) In a single strand from this molecule, it would be impossible to determine which is the 3' end and which is the 5' end.

18-4 Restriction Mapping of DNA. The genome of a newly discovered bacteriophage is a linear DNA molecule 10,500 nucleotide pairs in length. One sample of this DNA has been incubated with restriction enzyme X and another sample with restriction enzyme Y. The lengths (in thousands of base pairs) of the restriction fragments produced by the two enzymes have been determined by gel electrophoresis to be as follows:

Enzyme X: Fragment X-1 = 4.5; X-2 = 3.6; X-3 = 2.4
Enzyme Y: Fragment Y-1 = 5.2; Y-2 = 3.8; Y-3 = 1.5

Next, the fragments from the enzyme X reaction are isolated and treated with enzyme Y, and the fragments from the enzyme Y reaction are treated with enzyme X. The results are as follows:

X fragments treated with Y: X-1 → 4.5 (unchanged)

$$X-2 \rightarrow 2.1 + 1.5$$

$$X-3 \rightarrow 1.7 + 0.7$$

Y fragments treated with X: Y-1 → 4.5 + 0.7

$$Y-2 \rightarrow 2.1 + 1.7$$

Y-3 → 1.5 (unchanged)

Draw a restriction map of the phage DNA, indicating the positions of all enzyme X and enzyme Y restriction sites and the lengths of DNA between them.

18-5 DNA Sequencing. You have isolated the DNA fragment shown in Problem 18-3 but do not know its complete sequence. From knowledge of the specificity of the restriction enzyme used to prepare it, you know the first four bases at the left end and have prepared a single-stranded DNA primer of sequence 5' T-C-G-C 3'. Explain how you would determine the rest of the sequence using dye-labeled dideoxynucleotides. Draw the gel pattern that would be observed, indicating the base sequence of the DNA in each band and the color pattern that would be detected by the camera in a DNA sequencing machine.

- **18-6 DNA Melting.** Figure 18-36 shows the melting curves for two DNA samples that were thermally denatured under the same conditions.

- (a) What conclusion can you draw concerning the base compositions of the two samples? Explain.
 - (b) How might you explain the steeper slope of the melting curve for sample A?
 - (c) Formamide and urea are agents known to form hydrogen bonds with pyrimidines and purines. What effect, if any,

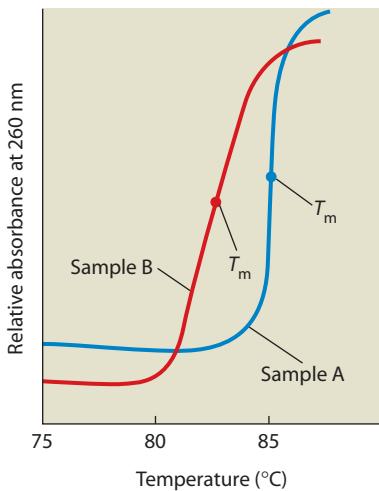

FIGURE 18-36 Thermal Denaturation of Two DNA Samples. See Problem 18-6.

would the inclusion of a small amount of formamide or urea in the incubation mixture have on the melting curves?

• **18-7 DNA Renaturation.** You are given two samples of DNA, each of which melts at 92°C during thermal denaturation. After denaturing the DNA, you mix the two samples together and then cool the mixture to allow the DNA strands to reassociate. When the newly reassociated DNA is denatured a second time, the sample now melts at 85°C.

- (a) How might you explain the lowering of the melting temperature from 92°C to 85°C?
- (b) What kind of experiment could be carried out to test your hypothesis?
- (c) If the newly reassociated DNA had melted at 92°C instead of 85°C, what conclusions might you have drawn concerning the base sequences of the two initial DNA samples?

• **18-8 Nucleosomes.** You perform an experiment in which chromatin is isolated from sea urchin sperm cells and briefly digested with micrococcal nuclease. When the chromatin proteins are removed and the resulting purified DNA is analyzed by gel electrophoresis, you observe a series of DNA fragments that are multiples of 260 base pairs in length (that is, 260 bp, 520 bp, 780 bp, and so forth).

- (a) Although these results differ somewhat from the typical results discussed in the chapter, explain why they still point to the likely existence of nucleosomes in this cell type.
- (b) What can you conclude about the amount of DNA that is associated with each nucleosome?
- (c) If the chromatin had been analyzed by density gradient centrifugation immediately after digestion with micrococcal nuclease, describe what you would expect to see.
- (d) Suppose you perform an experiment in which the chromatin is digested for a much longer period of time with micrococcal nuclease before removal of chromatin proteins. When

the resulting DNA preparation is analyzed by electrophoresis, all of the DNA appears as fragments 146 bp in length. What does this suggest to you about the length of the linker DNA in this cell type?

18-9 Nuclear Structure and Function. Indicate the implications for nuclear structure or function of each of the following experimental observations.

- (a) Sucrose crosses the nuclear envelope so rapidly that its rate of movement cannot be accurately measured.
- (b) Colloidal gold particles with a diameter of 5.5 nm equilibrate rapidly between the nucleus and cytoplasm when injected into an amoeba, but gold particles with a diameter of 15 nm do not.
- (c) Nuclear pore complexes sometimes stain heavily for RNA and protein.
- (d) If gold particles up to 26 nm in diameter are coated with a polypeptide containing a nuclear localization signal (NLS) and are then injected into the cytoplasm of a living cell, they are transported into the nucleus. If they are injected into the nucleus, however, they remain there.
- (e) Many of the proteins of the nuclear envelope appear from electrophoretic analysis to be the same as those found in the endoplasmic reticulum.
- (f) Ribosomal proteins are synthesized in the cytoplasm but are packaged with rRNA into ribosomal subunits in the nucleus.
- (g) If nucleoli are irradiated with a microbeam of ultraviolet light, synthesis of ribosomal RNA is inhibited.
- (h) Treatment of nuclei with the nonionic detergent Triton X-100 dissolves the nuclear envelope but leaves an otherwise intact nucleus.

• **18-10 Nuclear Transport.** Budding yeast with temperature-sensitive mutations in NTF2 have been identified. In such mutants, NTF2 functions at 25°C. Raising the temperature to 37°C, however, causes the NTF2 protein to stop functioning. What effects would you predict raising these mutant yeast to 37°C would have on nuclear transport? Explain your answer.

18-11 Nucleoli. Indicate whether each of the following statements is true (T) or false (F). If false, reword the statement to make it true.

- (a) Nucleoli are membrane-bounded structures present in the eukaryotic nucleus.
- (b) The fibrils seen in electron micrographs of nucleoli contain DNA and RNA.
- (c) The DNA of nucleoli carries the cell's tRNA genes, which are present in clusters of multiple copies.
- (d) A single nucleolus always corresponds to a single nucleolus organizer region (NOR).
- (e) Nucleoli become heavily radiolabeled when radioactive ribonucleotides are provided to the cell.
- (f) In animals and plants, the disappearance of nucleoli during mitosis correlates with cessation of ribosome synthesis.

The Cell Cycle, DNA Replication, and Mitosis

The ability to grow and reproduce is a fundamental property of living organisms. However, growth of single cells is fundamentally limited. As new proteins, nucleic acids, carbohydrates, and lipids are synthesized, their accumulation causes the volume of a cell to increase, forcing the plasma membrane to expand to prevent the cell from bursting. But cells cannot continue to enlarge indefinitely; as a cell grows larger, there is an accompanying decrease in its surface area/volume ratio and hence in its capacity for effective exchange with the environment. Therefore, cell growth is generally accompanied by **cell division**, whereby one cell gives rise to two new daughter cells. (The term *daughter* is used by convention and does not indicate that cells have gender.) For single-celled organisms, cell division increases the total number of individuals in a population. In multicellular organisms, cell division either increases the number of cells, leading to growth of the organism, or replaces cells that have died. In an adult human, for example, about 2 million stem cells in bone marrow divide every second to maintain a constant number of red blood cells in the body. Although often cell growth and cell division are coupled, there is a notable exception. A fertilized animal egg typically undergoes many divisions without the growth of its cells, dividing the volume of the egg into smaller and smaller parcels. Here as well, however, tight regulation of where and when cells divide is crucial.

When cells grow and divide, the newly formed daughter cells are usually genetic duplicates of the parent cell, containing the same (or virtually the same) DNA sequences. Therefore, all the genetic information in the nucleus of the parent cell must be duplicated and carefully distributed to the daughter cells during the division process. In accomplishing this task, a cell passes through a series of discrete stages, collectively known as the **cell cycle**. In this chapter, we will examine the events associated with the cell cycle, focusing first on the mechanisms that ensure that

each new cell receives a complete set of genetic instructions and then examining how the cell cycle is regulated to fit the needs of the organism.

Overview of the Cell Cycle

The **cell cycle** begins when two new cells are formed by the division of a single parental cell and ends when one of these cells divides again into two cells (**Figure 19-1**). To early cell biologists studying eukaryotic cells under the microscope, the most dramatic events in the life of a cell were those associated with the point in the cycle when cell actually divides. This division process, called **M phase**, involves two overlapping events in which nucleus divides first and the cytoplasm second. Nuclear division is called **mitosis**, and the division of the cytoplasm to produce two daughter cells is termed **cytokinesis**.

The stars of the mitotic drama are the chromosomes. As you can see in Figure 19-1a, the beginning of mitosis is marked by condensation (coiling and folding) of the cell's chromatin, which generates chromosomes that are thick enough to be individually discernible under the microscope. Because DNA replication has already taken place, each chromosome actually consists of two chromosome copies that remain attached to each other until the cell divides. As long as they remain attached, the two new chromosomes are referred to as **sister chromatids**. As the chromatids become visible, the nuclear envelope breaks into fragments. Then, in a stately ballet guided by the microtubules of the *mitotic spindle*, the sister chromatids separate and—each now a full-fledged chromosome—move to opposite ends of the cell. By this time, cytokinesis has usually begun, and new nuclear membranes envelop the two groups of daughter chromosomes as cell division is completed.

While visually striking, the events of M phase account for a relatively small portion of the total cell cycle; for a

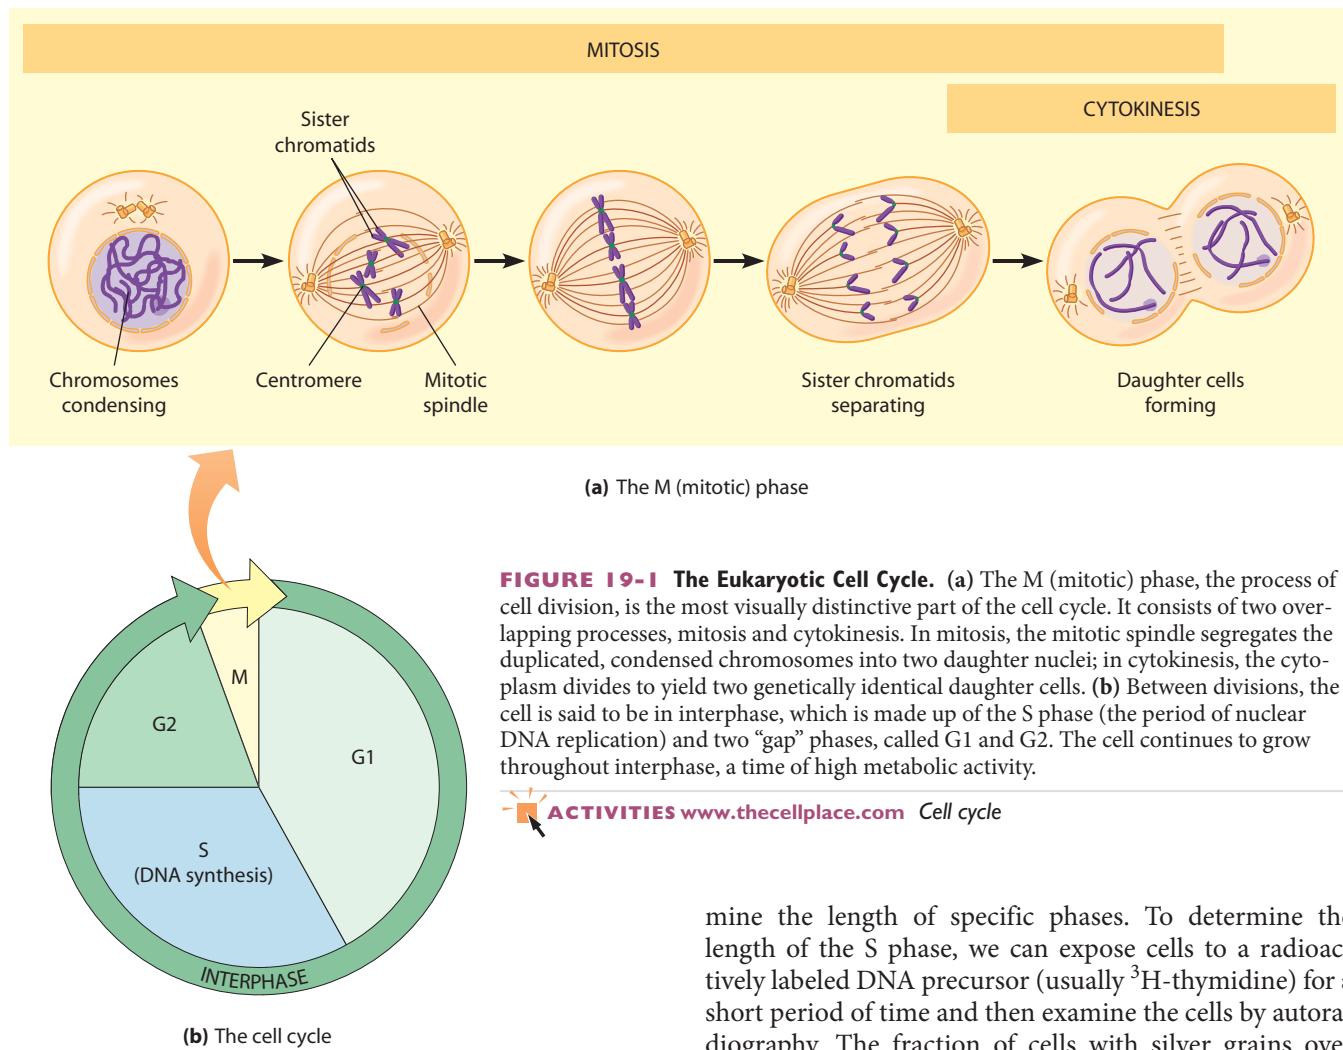

FIGURE 19-1 The Eukaryotic Cell Cycle. (a) The M (mitotic) phase, the process of cell division, is the most visually distinctive part of the cell cycle. It consists of two overlapping processes, mitosis and cytokinesis. In mitosis, the mitotic spindle segregates the duplicated, condensed chromosomes into two daughter nuclei; in cytokinesis, the cytoplasm divides to yield two genetically identical daughter cells. (b) Between divisions, the cell is said to be in interphase, which is made up of the S phase (the period of nuclear DNA replication) and two “gap” phases, called G1 and G2. The cell continues to grow throughout interphase, a time of high metabolic activity.

ACTIVITIES www.thecellplace.com Cell cycle

typical mammalian cell, M phase usually lasts less than an hour. Cells spend most of their time in the growth phase between divisions, called **interphase** (Figure 19-1b). Most cellular contents are synthesized continuously during interphase, so cell mass gradually increases as the cell approaches division. During interphase the amount of nuclear DNA doubles, and experiments using radioactive DNA precursors have shown that the new nuclear DNA is synthesized during a specific portion of interphase named the **S phase** (S for synthesis). A time gap called **G1 phase** separates S phase from the preceding M phase; a second gap, the **G2 phase**, separates the end of S phase from the onset of the next M phase.

Although the cells of a multicellular organism divide at varying rates, most studies of the cell cycle involve cells growing in culture, where the length of the cycle tends to be similar for different cell types. We can easily determine the overall length of the cell cycle—the *generation time*—for cultured cells by counting the cells under a microscope and determining how long it takes for the cell population to double. In cultured mammalian cells, for example, the total cycle usually takes about 18–24 hours. Once we know the total length of the cycle, it is possible to deter-

mine the length of specific phases. To determine the length of the S phase, we can expose cells to a radioactively labeled DNA precursor (usually ^{3}H -thymidine) for a short period of time and then examine the cells by autoradiography. The fraction of cells with silver grains over their nuclei represents the fraction of cells that were somewhere in S phase when the radioactive compound was available. When we multiply this fraction by the total length of the cell cycle, the result is an estimate of the average length of the S phase. For mammalian cells in culture, this fraction is often around 0.33, which indicates that S phase is about 6–8 hours in length. Similarly, we can estimate the length of M phase by multiplying the generation time by the percentage of the cells that are actually in mitosis at any given time. This percentage is called the **mitotic index**. The mitotic index for cultured mammalian cells is often about 3–5%, which means that M phase lasts less than an hour (usually 30–45 minutes).

In contrast to the S and M phases, whose lengths tend to be similar for different mammalian cells, the length of G1 is quite variable, depending on the cell type. Although a typical G1 phase lasts 8–10 hours, some cells spend only a few minutes or hours in G1, whereas others are delayed for long periods of time. During G1, a major “decision” is made as to whether and when the cell is to divide again. Cells that become arrested in G1, awaiting a signal that will trigger reentry into the cell cycle and a commitment to divide, are said to be in **G0 (G zero)**. Other cells exit from the cell cycle entirely and undergo **terminal differentiation**, which means they are destined

never to divide again; most of the nerve cells in your body are in this state. In some cells, transient arrest of the cell cycle can also occur in G₂. In general, however, G₂ is shorter than G₁ and more uniform in duration, usually lasting 4–6 hours.

Cell cycle studies have been facilitated by the use of **flow cytometry**, a technique that permits automated analysis of the chemical makeup of millions of individual cells almost simultaneously. In this procedure, cells are first stained with one or more fluorescent dyes—for example, a red dye that stains DNA might be combined with a green dye that binds specifically to a particular cell protein. The dyed cells are then passed in a tiny, liquid stream through a beam of laser light. By analyzing fluctuations in the intensity and color of the fluorescent light emitted by each cell as it passes through the laser beam, researchers can assess the concentration of DNA and specific proteins in each individual cell. This information is then used to assess the chemical makeup of cells at different points in the cycle.

DNA Replication

Now that we have provided an overview of the cell cycle, we are ready to consider its workings in detail. Since DNA replication is a central event in the cycle, we begin by examining its underlying mechanism, which in turn depends on the double-helical structure of DNA. In fact, a month after Watson and Crick published their now-classic paper postulating a double helix for DNA, they followed it with an equally important paper suggesting how such a base-paired structure might duplicate itself. Here, in their own words, is the basis of that suggestion:

Now our model for deoxyribonucleic acid is, in effect, a pair of templates, each of which is complementary to the other. We imagine that prior to duplication the hydrogen bonds are broken, and the two chains unwind and separate. Each chain then acts as a template for the formation onto itself of a new companion chain, so that eventually we shall have two pairs of chains, where we only had one before. Moreover, the sequence of the pairs of bases will have been duplicated exactly. (Watson and Crick, 1953, p. 966)

The model Watson and Crick proposed for DNA replication is shown in **Figure 19-2**. The essence of their suggestion is that one of the two strands of every newly formed DNA molecule is derived from the parent molecule, whereas the other strand is newly synthesized. This is called **semiconservative replication** because half of the parent molecule is retained by each daughter molecule.

Equilibrium Density Centrifugation Shows That DNA Replication Is Semiconservative

Within five years of its publication, the Watson–Crick model of semiconservative DNA replication was tested and proved correct by Matthew Meselson and Franklin

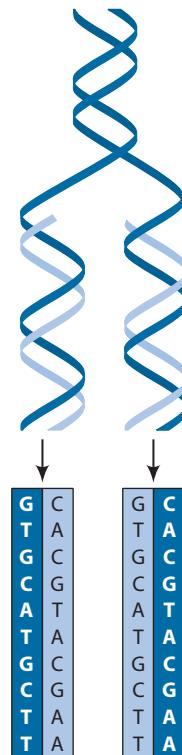

FIGURE 19-2 Watson–Crick Model of DNA Replication. In 1953, Watson and Crick proposed that the DNA double helix replicates semiconservatively, using a model like this one to illustrate the principle. The double-stranded helix unwinds, and each parent strand serves as a template for the synthesis of a complementary daughter strand, assembled according to the base-pairing rules. A, T, C, and G stand for the adenine, thymine, cytosine, and guanine nucleotides. A pairs with T, and G with C.

Stahl. The ingenuity of Meselson and Stahl's contribution lay in the method they devised, in collaboration with Jerome Vinograd, for distinguishing semiconservative replication from other possibilities. Their studies utilized two isotopic forms of nitrogen, ¹⁴N and ¹⁵N, to distinguish newly synthesized strands of DNA from old strands. Bacterial cells were first grown for many generations in a medium containing ¹⁵N-labeled ammonium chloride to incorporate this *heavy* (but nonradioactive) isotope of nitrogen into their DNA molecules. Cells containing ¹⁵N-labeled DNA were then transferred to a growth medium containing the normal *light* isotope of nitrogen, ¹⁴N. Any new strands of DNA synthesized after this transfer would therefore incorporate ¹⁴N rather than ¹⁵N.

Since ¹⁵N-labeled DNA is significantly denser than ¹⁴N-labeled DNA, the old and new DNA strands can be distinguished from each other by **equilibrium density centrifugation**, a technique we encountered earlier when discussing the separation of organelles in Chapter 12 (see Box 12A, page 327). Briefly, this technique allows organelles or macromolecules with differing densities to be separated from each other by centrifugation in a solution containing a gradient of increasing density from the top of the tube to the bottom. In response to centrifugal

force, the particles migrate “down” the tube (actually, they move *outward*, away from the axis of rotation) until they reach a density equal to their own. They then remain at this equilibrium density and can be recovered as a band at that position in the tube after centrifugation.

For DNA analysis, equilibrium density centrifugation often uses cesium chloride (CsCl), a heavy metal salt that forms solutions of very high density. The DNA to be analyzed is simply mixed with a solution of cesium chloride and then centrifuged at high speed (generating a centrifugal force of several hundred thousand times gravity for 8 hours, for example). As a density gradient of cesium chloride is established by the centrifugal force, the DNA molecules float “up” or sink “down” within the gradient to reach their equilibrium density positions. The difference in density between heavy (^{15}N -containing) DNA and light (^{14}N -containing) DNA causes them to come to rest at different positions in the gradient.

Using this approach, Meselson and Stahl analyzed DNA obtained from bacterial cells that were first grown for many generations in ^{15}N and then transferred to ^{14}N for additional cycles of replication (Figure 19-3). What results would be predicted for a semiconservative mechanism of DNA replication? After one replication cycle in ^{14}N , each DNA molecule should consist of one ^{15}N strand (the old strand) and one ^{14}N strand (the new strand), and so the overall density would be intermediate between heavy DNA and light DNA. The experiments clearly supported this model. After one replication cycle in the ^{14}N medium, centrifugation in cesium chloride revealed a single band of DNA whose density was *exactly halfway* between that of ^{15}N -DNA and ^{14}N -DNA (Figure 19-3b). Because they saw no band at the density expected for heavy DNA, Meselson and Stahl concluded that the original, double-stranded parental DNA was not preserved intact in the replication process. Similarly, the absence of a band at the density expected for light DNA indicated that no daughter DNA molecules consisted exclusively of new DNA. Instead, it appeared that a part of every daughter DNA molecule was newly synthesized and another part was derived from the parent molecule. In fact, the density halfway between that of ^{14}N -DNA and ^{15}N -DNA meant that the $^{14}\text{N}/^{15}\text{N}$ hybrid DNA molecules were one-half parental and one-half newly synthesized.

When the $^{14}\text{N}/^{15}\text{N}$ hybrid DNA was heated to separate its two strands, one strand exhibited the density of a ^{15}N -containing strand and the other exhibited the density of a ^{14}N -containing strand, just as predicted by the semiconservative model of replication. Data obtained from cells grown for additional generations in the presence of ^{14}N provided further confirmation. After the second cycle of DNA replication, for example, Meselson and Stahl saw two equal bands, one at the hybrid density of the previous cycle and one at the density of purely ^{14}N -DNA (Figure 19-3c). As the figure illustrates, this is also consistent with a semiconservative mode of replication.

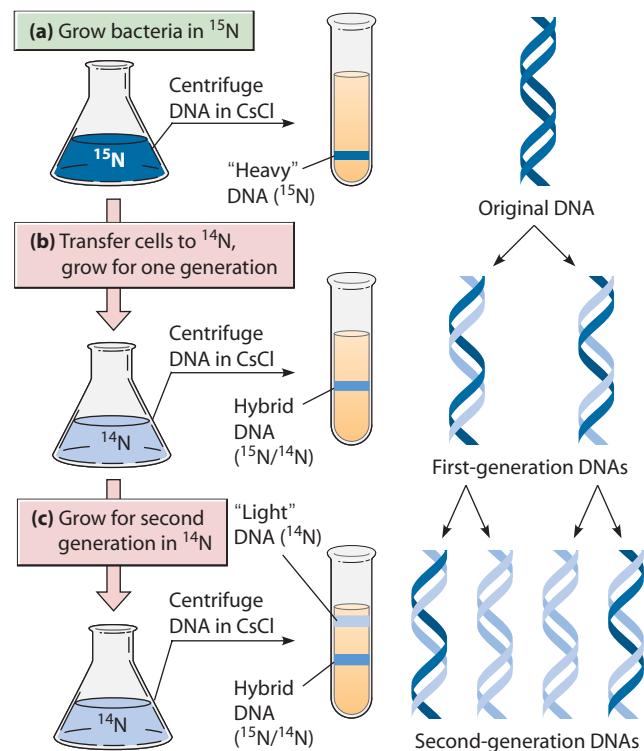

FIGURE 19-3 Semiconservative Replication of Density-Labeled DNA. Meselson and Stahl (a) grew bacteria for many generations on a ^{15}N -containing medium and then transferred the cells to a ^{14}N -containing medium for (b) one or (c) two further cycles of replication. In each case, DNA was extracted from the cells and centrifuged to equilibrium in cesium chloride (CsCl). As shown in the model on the right (where dark blue strands contain ^{15}N and light blue strands contain ^{14}N), the data are compatible with a semiconservative model of DNA replication.

ACTIVITIES www.thecellplace.com The Meselson-Stahl experiment

DNA Replication Is Usually Bidirectional

The Meselson–Stahl experiments provided strong support for the idea that, during DNA replication, each strand of the DNA double helix serves as a template for the synthesis of a new complementary strand. As biologists proceeded to unravel the molecular details of this process, it gradually became clear that DNA replication is a complex event involving numerous enzymes and other proteins—and even the participation of RNA. We will first examine the general features of this replication mechanism and then focus on some of its molecular details. In doing so, we will frequently refer to the bacterium *Escherichia coli*, for which DNA replication is especially well understood. However, studies of mammalian viruses such as SV40 and of the yeast *Saccharomyces cerevisiae* have revealed the details of eukaryotic DNA replication as well. DNA replication seems to be a drama whose plot and molecular actors are basically similar in bacterial and eukaryotic cells. This is perhaps not surprising for such a fundamental process—one that must have arisen early in the evolution of life.

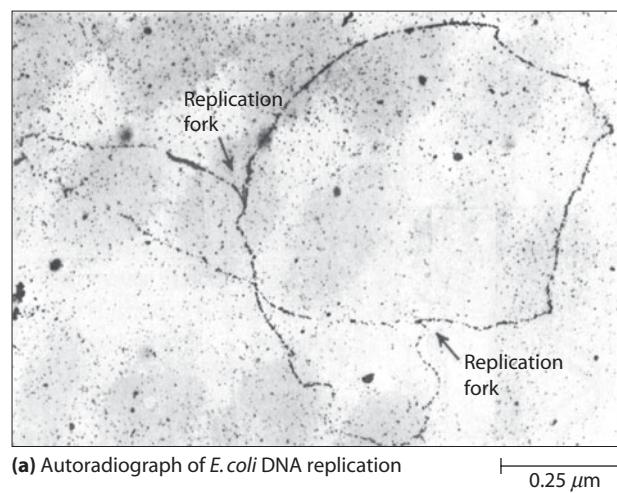

FIGURE 19-4 Replication of Circular DNA. (a) This autoradiograph shows an *E. coli* DNA molecule caught in the act of replicating. The DNA molecule was isolated from a bacterium that had been grown in a medium containing ^{3}H -thymidine, thereby allowing the DNA to be visualized by autoradiography. (b) Replication of a circular DNA molecule begins at a single origin and proceeds bidirectionally around the circle, with the two replication forks moving in opposite directions. The new strands are shown in light blue. The replication process generates intermediates that resemble the Greek letter theta (θ), from which this type of replication derives its name. (c) During the cell division cycle of bacteria containing a single circular chromosome, membrane growth between the attachment sites of the two replicating copies moves the daughter chromosomes toward opposite sides of the cell.

The first experiments to directly visualize DNA replication were carried out by John Cairns, who grew *E. coli* cells in a medium containing the DNA precursor ^{3}H -thymidine and then used autoradiography to examine the cell's single, circular DNA molecule caught in the act of replication. One such molecule is shown in Figure 19-4a. The two Y-shaped structures indicated by the arrows represent the sites where the DNA duplex is being replicated. These **replication forks** are created by a DNA replication mechanism that begins at a single point within the DNA and proceeds in a *bidirectional* fashion away from this origin. In other words, two replication forks are created that move in opposite directions away from the point of origin, unwinding the helix and copying both strands as they proceed. For circular DNA, this process is sometimes called *theta replication* because it generates intermediates that look like the Greek letter theta (θ), as you can see in Figure 19-4b. Theta replication occurs not only in bacterial genomes such as that of *E. coli* but also in the circular DNAs of mitochondria, chloroplasts, plasmids, and some viruses. At the end of a round of theta replication the two resulting DNA circles remain interlinked, and the action of a topoisomerase (page 562) is required to disconnect the two circles from each other.

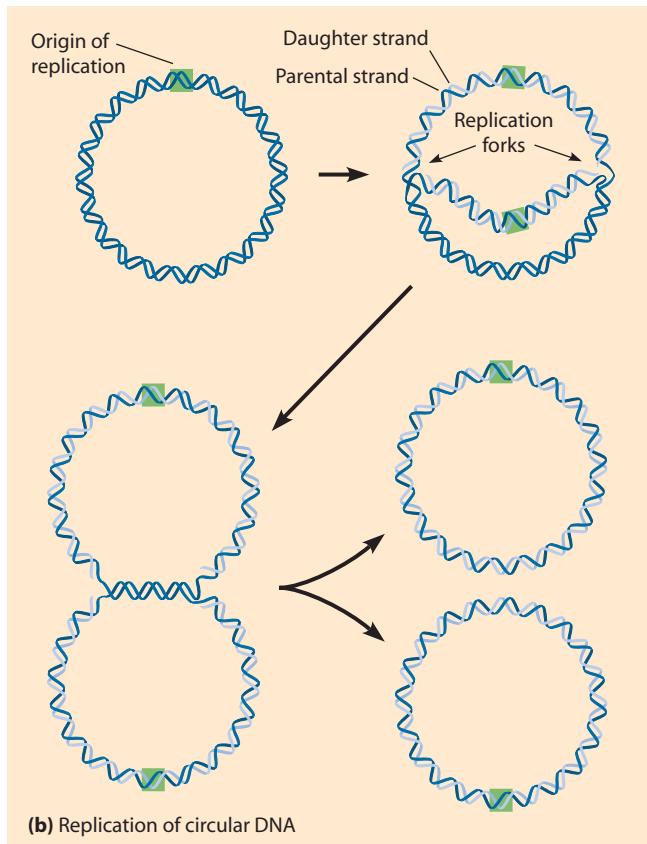

Figure 19-4c shows how these events relate to the cell division cycle of bacteria that contain a single circular chromosome. In such bacteria, the two copies of the replicating chromosome bind to the plasma membrane at their replication origins. As the cell grows in preparation for cell division, new plasma membrane is added to the region between these chromosome attachment sites, thereby pushing the chromosomes toward opposite ends of the cell. When DNA replication is complete and the cell has doubled in size, *binary fission* partitions the cell down the middle and segregates the two chromosomes into two daughter cells.

Eukaryotic DNA Replication Involves Multiple Replicons

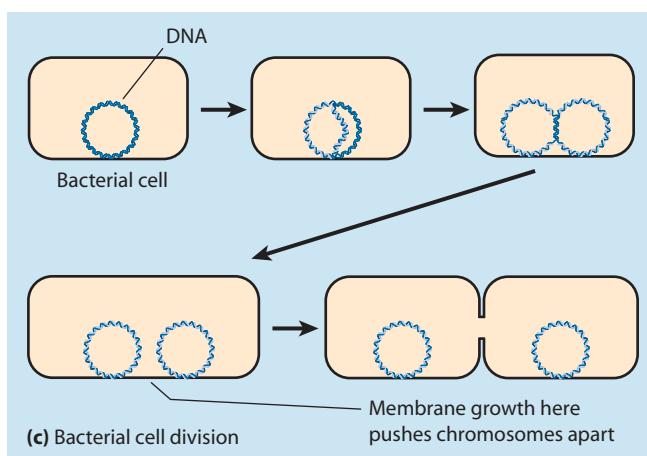

In contrast to circular bacterial chromosomes—where DNA replication is initiated at a single origin—replication of the linear DNA molecules of eukaryotic chromosomes

(a) Autoradiograph of *E. coli* DNA replication 0.25 μm

(b) Replication of circular DNA

is initiated at multiple sites, creating multiple replication units called **replicons** (Figure 19-5). The DNA of a typical large eukaryotic chromosome may contain several thousand replicons, each about 50,000–300,000 base pairs in length. At the center of each replicon is a special DNA sequence, called an **origin of replication**, where DNA synthesis is initiated by a mechanism involving several groups of *initiator proteins*. First, a multisubunit protein complex known as the *origin recognition complex* (ORC) binds to a replication origin. The next components to bind are the *minichromosome maintenance (MCM) proteins*, which include several *DNA helicases* that facilitate DNA replication by unwinding the double helix. The recruitment of MCM proteins to the replication origin requires the participation of a third set of proteins, known as *helicase loaders*, which mediate the binding of the MCM proteins to the ORC. At this point the complete group of DNA-bound proteins is called a **pre-replication complex**, and the DNA is said to be “licensed” for replication. However, replication does not actually begin until several more proteins, including the enzymes that catalyze DNA synthesis, are added.

The DNA sequences that act as replication origins exhibit a great deal of variability in eukaryotes. Such sequences were first identified in yeast cells (*S. cerevisiae*) by isolating chromosomal DNA fragments and inserting them into DNA molecules that lack the ability to replicate. If the inserted DNA fragment gives the DNA molecule the ability to replicate within the yeast cell, it is called an *autonomously replicating sequence*, or **ARS**. The number of ARS elements detected in normal yeast chromosomes is similar to the total number of replicons, suggesting that ARS sequences function as replication origins. The ARS elements of *S. cerevisiae* are 100–150 base pairs in length and contain a common

11-nucleotide core sequence, consisting largely of AT base pairs, flanked by auxiliary sequences containing additional AT-rich regions. Since the DNA double helix must be unwound when replication is initiated, the presence of so many AT base pairs serves a useful purpose at replication origins because AT base pairs, held together by two hydrogen bonds, are easier to disrupt than GC base pairs, which have three hydrogen bonds. The replication origins of multicellular eukaryotes are generally larger and more variable in sequence than the ARS elements of *S. cerevisiae*, but they also tend to contain regions that are AT-rich.

After DNA synthesis has been initiated at an origin of replication, two replication forks begin to synthesize DNA in opposite directions away from the origin, creating a “replication bubble” that grows in size as replication proceeds in both directions (Figure 19-5). When the growing replication bubble of one replicon encounters the replication bubble of an adjacent replicon, the DNA synthesized by the two replicons is joined together. In this way, DNA synthesized at numerous replication sites is ultimately linked together to form two double-stranded daughter molecules, each composed of one parental strand and one new strand.

Why does DNA replication involve multiple replication sites in eukaryotes but not in bacteria? Since eukaryotic chromosomes contain more DNA than bacterial chromosomes do, it would take eukaryotes much longer to replicate their chromosomes if DNA synthesis were initiated from only a single replication origin. Moreover, the rate at which each replication fork synthesizes DNA is slower in eukaryotes than in bacteria (presumably because the presence of nucleosomes slows down the replication process). Measurements of the length of radioactive DNA synthesized by cells exposed to ^{3}H -thymidine for varying periods of time have revealed

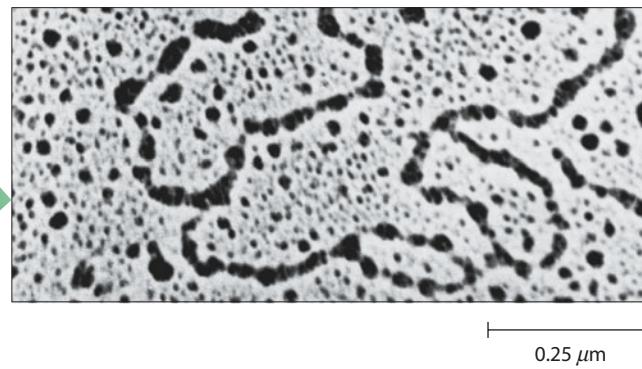

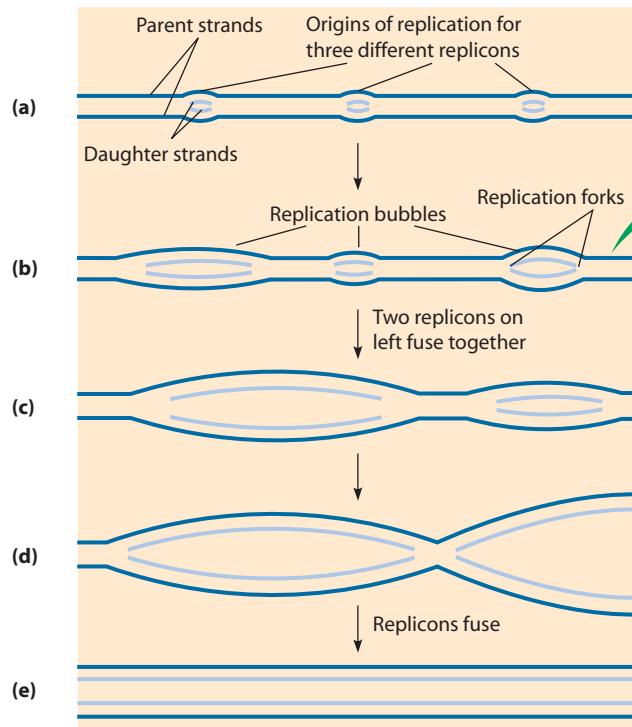

FIGURE 19-5 Multiple Replicons in Eukaryotic DNA.

Replication of linear eukaryotic DNA molecules is initiated at multiple origins along the DNA; the timing of initiation is specific for each cluster of origins. (a) Replication bubbles form at origins. (b) The bubbles grow as the replication forks move along the DNA in both directions from each origin. The micrograph shows three replication bubbles in DNA from cultured Chinese hamster cells (TEM). (c) Eventually, individual bubbles meet and fuse. (d) A Y-shaped structure forms as a replication fork reaches the end of a DNA molecule. (e) When all bubbles have fused, replication is complete and the two daughter molecules separate.

that eukaryotic replication forks synthesize DNA at a rate of about 2000 base pairs/minute, compared with 50,000 base pairs/minute in bacteria. Since the average human chromosome contains about 10^8 base pairs of DNA, it would take more than a month to duplicate a chromosome if there were only a single replication origin!

The relationship between the speed of chromosome replication and the number of replicons is nicely illustrated by comparing the rates of DNA synthesis in embryonic and adult cells of the fruit fly *Drosophila*. In the developing embryo, where cell divisions occur in quick succession, cells employ a large number of simultaneously active replicons measuring only a few thousand base pairs in length. As a result, DNA replication occurs very rapidly, and S phase takes only a few minutes. Adult cells, on the other hand, employ fewer replicons spaced at intervals of tens or hundreds of thousands of base pairs, generating an S phase that requires almost 10 hours to complete. Since the rate of DNA synthesis at any given replication fork is about the same in embryonic and adult cells, it is clear that the length of the S phase is determined by the number of replicons and the rate at which they are activated—not by the rate at which each replicon synthesizes DNA.

During the S phase of a typical eukaryotic cell cycle, replicons are not all activated at the same time. Instead, certain clusters of replicons tend to replicate early during S phase, whereas others replicate later. Information concerning the order in which replicons are activated has been obtained by incubating cells at various points during S phase with *5-bromodeoxyuridine* (BrdU), a substance that is incorporated into DNA in place of thymidine. Because DNA that contains BrdU is denser than normal DNA, it can be separated from the remainder of the DNA by equilibrium density centrifugation. The BrdU-labeled DNA is then analyzed by hybridization with a series of DNA probes that are specific for individual genes. Such studies have revealed that the genes being actively expressed in a given tissue are replicated early during S phase, whereas inactive genes are replicated later during S phase. If the same gene is analyzed in two different cell types, one in which the gene is active and one in which it is inactive, early replication is observed only in the cell type where the gene is being transcribed.

Replication Licensing Ensures That DNA Molecules Are Duplicated Only Once Prior to Each Cell Division

During the eukaryotic cell cycle it is crucial that nuclear DNA molecules undergo replication once, and only once, prior to cell division. To enforce this restriction, a process called **licensing** ensures that after DNA is replicated at any given replication origin during S phase, the DNA at that site does not become competent (licensed) for a further round of DNA replication until the cell has first passed through mitosis. The license is provided by the binding of MCM proteins to replication origins, an event that requires both ORC and helicase loaders (page 554). Once

replication begins, the MCM proteins are displaced from the origins by the traveling replication fork, and re-replication from the same origins is prevented by mechanisms that stop MCM proteins from binding to replication origins again. Thus the license to replicate is never associated with replicated DNA.

A critical player in this mechanism is *cyclin-dependent kinase* (Cdk), an enzyme whose many roles in the cell cycle will be described later in the chapter. One form of Cdk is produced at the beginning of S phase and functions both in activating DNA synthesis at licensed origins and in ensuring that these same origins cannot become licensed again. Cdk blocks relicensing by catalyzing the phosphorylation, and thereby inhibiting the function, of proteins required for licensing, such as ORC and the helicase loaders. Multicellular eukaryotes contain another inhibitor of relicensing called *geminin*, a protein made during S phase that blocks the binding of MCM proteins to DNA. After the cell completes mitosis, geminin is degraded and Cdk activity falls, so the proteins required for DNA licensing can function again for the next cell cycle (Figure 19-6).

DNA Polymerases Catalyze the Elongation of DNA Chains

When the semiconservative model of DNA replication was first proposed in the early 1950s, biologists thought that DNA replication was so complex that it could only be carried out by intact cells. But just a few years later, Arthur Kornberg showed that an enzyme he had isolated from bacteria can copy DNA molecules in a test tube. This enzyme, which he named **DNA polymerase**, requires that a small amount of DNA be initially present to act as a template. Guided by this template, DNA polymerase catalyzes the elongation of DNA chains using as substrates the triphosphate deoxynucleoside derivatives of the four bases

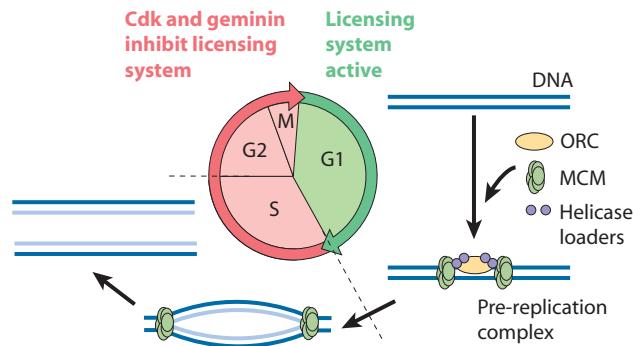

FIGURE 19-6 Licensing of DNA Replication During the Eukaryotic Cell Cycle. DNA is licensed for replication during G1 by the binding of MCM proteins to replication origins, an event that requires both ORC and helicase loaders. The licensing system is turned off at the end of G1 by the production of Cdks and/or geminin, whose activities block the functions of the proteins required for licensing (ORC, helicase loaders, and MCM). After the cell completes mitosis, geminin is degraded and Cdk activity falls, so the licensing system becomes active again for the next cell cycle.

found in DNA (dATP, dTTP, dGTP, and dCTP). As each of these substrates is incorporated into a newly forming DNA chain, its two terminal phosphate groups are released. Since deoxynucleoside triphosphates are high-energy compounds (comparable to ATP), the energy released as these phosphate bonds are broken drives what would otherwise be a thermodynamically unfavorable polymerization reaction.

In the DNA polymerase reaction, incoming nucleotides are covalently bonded to the 3' hydroxyl end of the growing DNA chain. Each successive nucleotide is linked to the growing chain by a phosphoester bond between the phosphate group on its 5' carbon and the hydroxyl group on the 3' carbon of the nucleotide added in the previous step (**Figure 19-7**). In other words, chain elongation occurs at the 3' end of a DNA strand, and the strand is therefore said to grow in the 5' → 3' direction.

Soon after Kornberg's initial discovery, several other forms of DNA polymerase were detected. (**Table 19-1** lists the main DNA polymerases used in DNA replication, along with other key proteins involved in the process.) In *E. coli*, the enzyme discovered by Kornberg has turned out not to be responsible for DNA replication in intact cells. This fact first became apparent when Peter DeLucia and John Cairns reported that mutant strains of bacteria lacking the Kornberg enzyme can still replicate their DNA

and reproduce normally. With the Kornberg enzyme missing, it was possible to detect the presence of several other bacterial enzymes that synthesize DNA. These additional enzymes are named using Roman numerals (e.g., DNA polymerases II, III, IV, and V) to distinguish them from the original Kornberg enzyme, now called DNA polymerase I. When the rates at which the various DNA polymerases synthesize DNA in a test tube were first compared, only DNA polymerase III was found to work fast enough to account for the rate of DNA replication in intact cells, which averages about 50,000 base pairs/minute in bacteria.

Such observations suggested that DNA polymerase III is the main enzyme responsible for DNA replication in bacterial cells, but the evidence would be more convincing if it could be shown that cells lacking DNA polymerase III are unable to replicate their DNA. How is it possible to grow and study cells that have lost the ability to carry out an essential function such as DNA replication? One powerful approach involves the use of **temperature-sensitive mutants**, which are cells that produce proteins that function properly at normal temperatures but become seriously impaired when the temperature is altered slightly. For example, mutant bacteria have been isolated in which DNA polymerase III behaves normally at 37°C but loses its function when the temperature is raised to 42°C. Such

Table 19-1 Some Important DNA Replication Proteins in Bacteria and Eukaryotes

Protein	Cell Type	Main Activities and/or Functions
DNA polymerase I	Bacteria	DNA synthesis; 3' → 5' exonuclease (for proofreading); 5' → 3' exonuclease; removes and replaces RNA primers used in DNA replication (also functions in excision repair of damaged DNA)
DNA polymerase III	Bacteria	DNA synthesis; 3' → 5' exonuclease (for proofreading); used in synthesis of both DNA strands
DNA polymerase α (alpha)	Eukaryotes	Nuclear DNA synthesis; forms complex with primase and begins DNA synthesis at the 3' end of RNA primers for both leading and lagging strands (also functions in DNA repair)
DNA polymerase γ (gamma)	Eukaryotes	Mitochondrial DNA synthesis
DNA polymerase δ (delta)	Eukaryotes	Nuclear DNA synthesis; 3' → 5' exonuclease (for proofreading); involved in lagging and leading strand synthesis (also functions in DNA repair)
DNA polymerase ϵ (epsilon)	Eukaryotes	Nuclear DNA synthesis; 3' → 5' exonuclease (for proofreading); thought to be involved in leading and lagging strand synthesis (also functions in DNA repair)
Primase	Both	RNA synthesis; makes RNA oligonucleotides that are used as primers for DNA synthesis
DNA helicase	Both	Unwinds double-stranded DNA
Single-stranded DNA binding protein (SSB)	Both	Binds to single-stranded DNA; stabilizes strands of unwound DNA in an extended configuration that facilitates access by other proteins
DNA topoisomerase (type I and type II)	Both	Makes single-strand cuts (type I) or double-strand cuts (type II) in DNA; induces and/or relaxes DNA supercoiling; can serve as swivel to prevent overwinding ahead of the DNA replication fork; can separate linked DNA circles at the end of DNA replication
DNA gyrase	Bacteria	Type II DNA topoisomerase that serves as a swivel to relax supercoiling ahead of the DNA replication fork in <i>E. coli</i>
DNA ligase	Both	Makes covalent bonds to join together adjacent DNA strands, including the Okazaki fragments in lagging strand DNA synthesis and the new and old DNA segments in excision repair of DNA
Initiator proteins	Both	Bind to origin of replication and initiate unwinding of DNA double helix
Telomerase	Eukaryotes	Using an integral RNA molecule as template, synthesizes DNA for extension of telomeres (sequences at ends of chromosomal DNA)

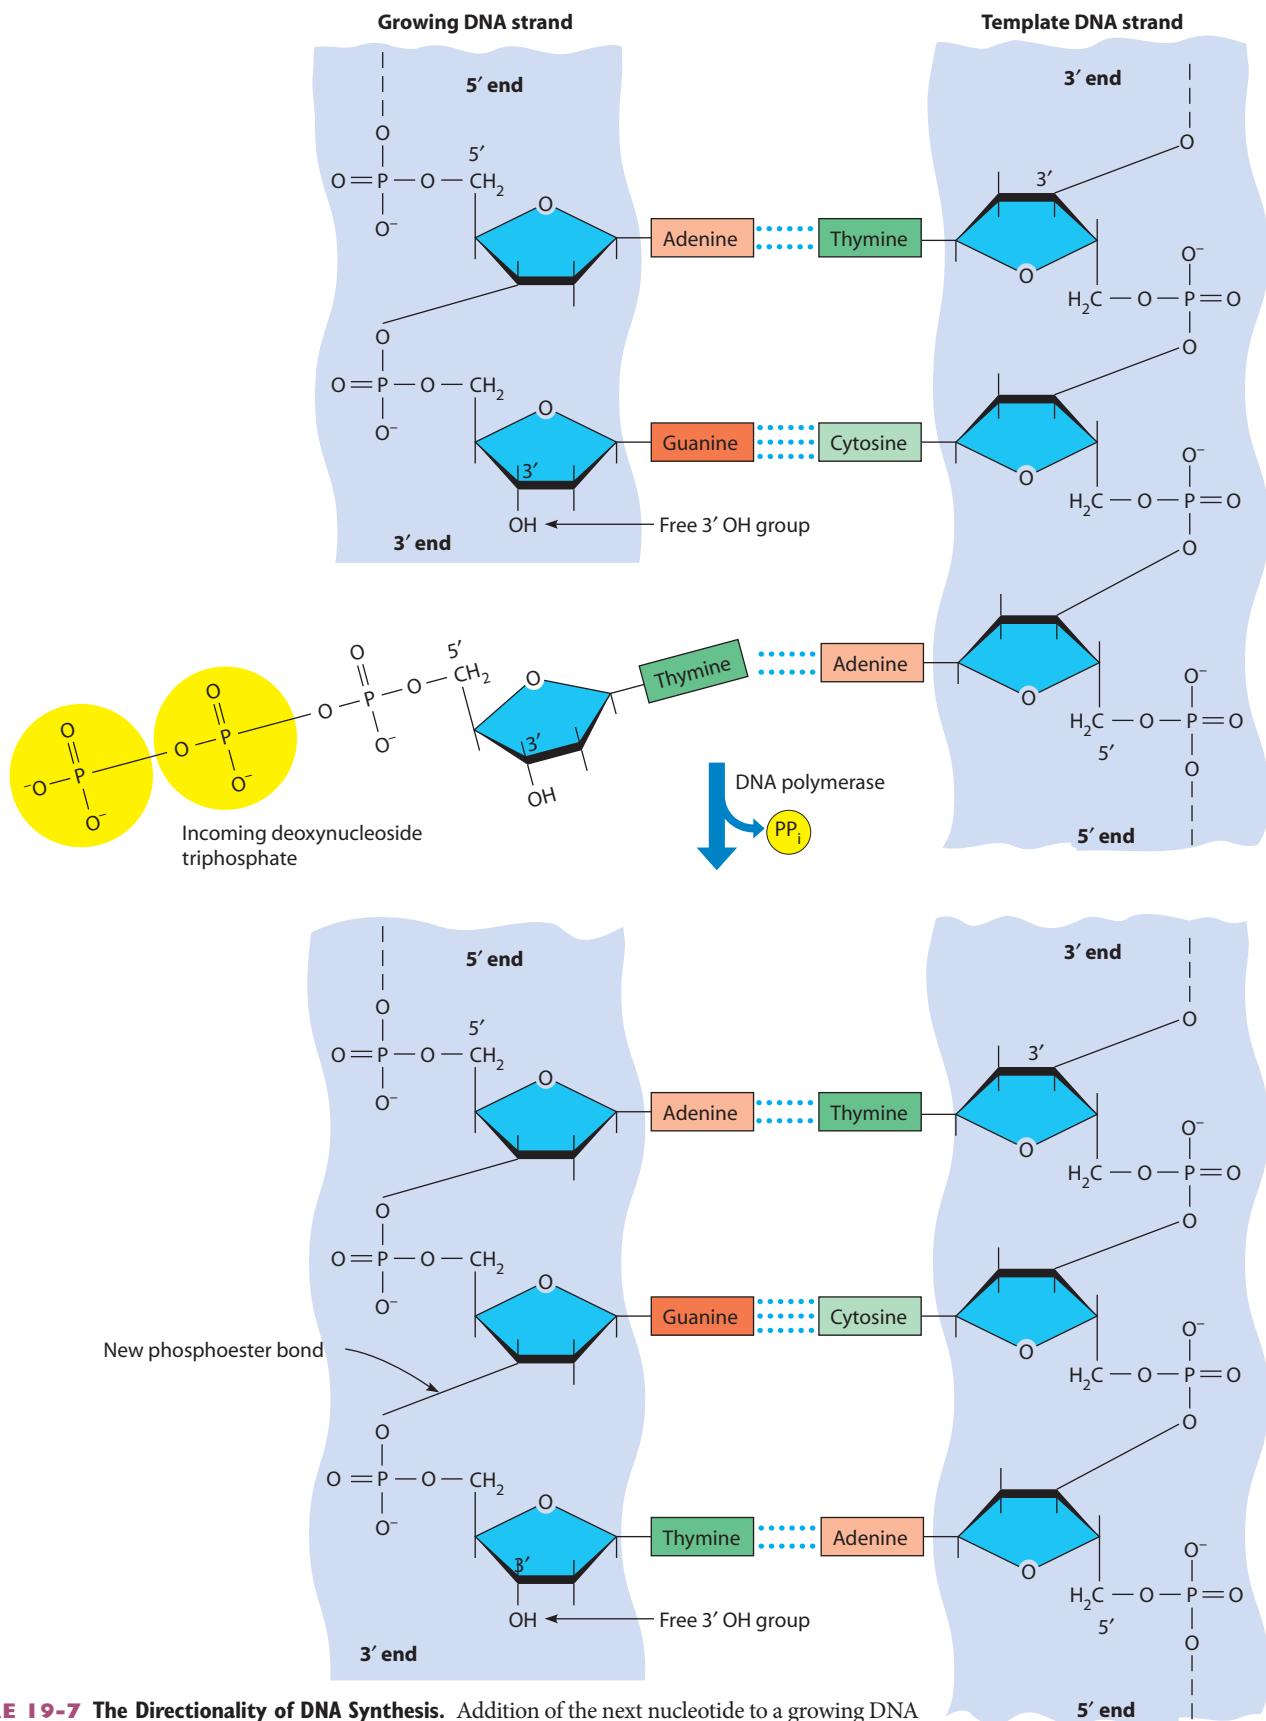

FIGURE 19-7 The Directionality of DNA Synthesis. Addition of the next nucleotide to a growing DNA strand is catalyzed by DNA polymerase and always occurs at the 3' end of the strand. A phosphoester bond is formed between the 3' hydroxyl group of the terminal nucleotide and the 5' phosphate of the incoming deoxynucleoside triphosphate (here dTTP), extending the growing chain by one nucleotide, liberating pyrophosphate (PP_i) and leaving the 3' end of the strand with a free hydroxyl group to accept the next nucleotide.

 [ACTIVITIES](http://www.thecellplace.com) www.thecellplace.com DNA biosynthesis: How a new DNA strand is made

bacteria grow normally at 37°C but lose the ability to replicate their DNA when the temperature is elevated to 42°C, indicating that DNA polymerase III plays an essential role in the process of normal DNA replication.

Though the preceding observations indicate that DNA polymerase III is central to bacterial DNA replication, it is not the only enzyme involved. As we will see shortly, a variety of other proteins are required for DNA replication, including DNA polymerase I. The other main types of bacterial DNA polymerase (II, IV, and V) play more specialized roles in events associated with DNA repair, a process to be described in detail later in the chapter.

Like bacteria, eukaryotic cells contain several types of DNA polymerase. At last count, more than a dozen different enzymes have been identified, each named with a different Greek letter. From among this group, DNA polymerases α (alpha), δ (delta), and ϵ (epsilon) are involved in nuclear DNA replication. DNA polymerase γ (gamma) is present only in mitochondria and is the main polymerase used in mitochondrial DNA replication. Most of the remaining eukaryotic DNA polymerases are involved either in DNA repair or in replication across regions of DNA damage.

In addition to their biological functions inside cells, DNA polymerases have found important practical applications in the field of biotechnology. **Box 19A** describes a technique called the *polymerase chain reaction* (PCR), in which a special type of DNA polymerase is the prime tool. Used experimentally for the rapid amplification of tiny samples of DNA, PCR is a powerful adjunct to the DNA fingerprinting method discussed in Chapter 18.

DNA Is Synthesized as Discontinuous Segments That Are Joined Together by DNA Ligase

The discovery of DNA polymerase was merely the first step in unraveling the mechanism of DNA replication. An early conceptual problem arose from the finding that DNA polymerases catalyze the addition of nucleotides *only to the 3' end of an existing DNA chain*; in other words, DNA polymerases synthesize DNA exclusively in the 5' → 3' direction. Yet the two strands of the DNA double helix run in opposite directions. So how does an enzyme that functions solely in the 5' → 3' direction manage to synthesize both DNA strands at a moving replication fork when one chain runs in the 5' → 3' direction and the other chain runs in the 3' → 5' direction?

An answer to this question was first proposed in 1968 by Reiji Okazaki, whose studies suggested that DNA is synthesized as small fragments that are later joined together. Okazaki isolated DNA from bacterial cells that had been briefly exposed to a radioactive substrate that is incorporated into newly made DNA. Analysis of this DNA revealed that much of the radioactivity was located in

small DNA fragments measuring about a thousand nucleotides in length (**Figure 19-8a**). After longer labeling periods, the radioactivity became associated with larger DNA molecules. These findings suggested to Okazaki that the smaller DNA pieces, now known as **Okazaki fragments**, are precursors of newly forming larger DNA molecules. Later research revealed that the conversion of Okazaki fragments into larger DNA molecules fails to take place in mutant bacteria that lack the enzyme **DNA ligase**, which joins DNA fragments together by catalyzing the ATP-dependent formation of a phospho-ester bond between the 3' end of one nucleotide chain and the 5' end of another (**Figure 19-8b**).

The preceding observations suggest a model of DNA replication that is consistent with the fact that DNA polymerase synthesizes DNA only in the 5' → 3' direction. According to this model, DNA synthesis at each replication fork is *continuous* in the direction of fork movement for one strand but *discontinuous* in the opposite direction for the other strand (**Figure 19-9**). The two daughter strands can therefore be distinguished based on their mode of growth. One of the two new strands, called the **leading strand**, is synthesized as a continuous chain because it is growing in the 5' → 3' direction. Due to the opposite orientation of the two DNA strands, the other newly forming strand, called the **lagging strand**, must grow in the 3' → 5' direction. But DNA polymerase cannot add nucleotides in the 3' → 5' direction, so the

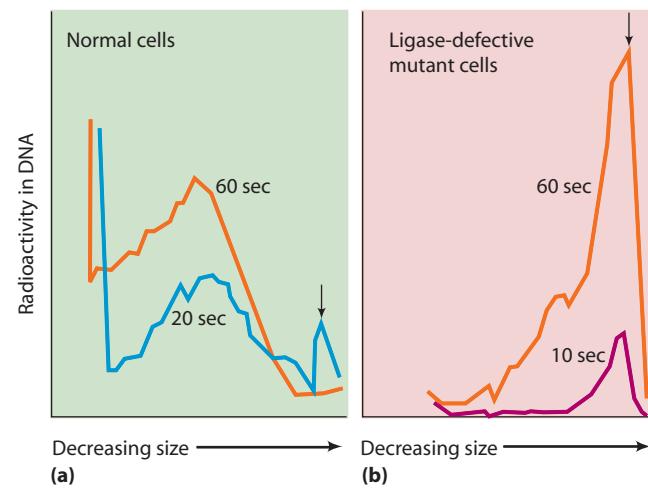

FIGURE 19-8 Summary of Okazaki's Experiments on the Mechanism of DNA Replication in Bacterial Cells. (a) Bacteria were incubated for brief periods with radioactive thymidine to label newly synthesized DNA. The DNA was then isolated, dissociated into its individual strands, and fractionated by centrifugation into molecules of differing size. In normal bacteria incubated with ^3H -thymidine for 20 seconds, a significant amount of radioactivity is present in small DNA fragments (arrow). By 60 seconds, the radioactivity present in small DNA fragments has all shifted to larger DNA molecules. (b) In bacterial mutants deficient in the enzyme DNA ligase, radioactivity remains in small DNA fragments even after 60 seconds of incubation. It was therefore concluded that DNA ligase normally functions to join small DNA fragments together into longer DNA chains.

lagging strand is instead formed as a series of short, discontinuous Okazaki fragments that are synthesized in the $5' \rightarrow 3'$ direction. These fragments are then joined together by DNA ligase to make a continuous new $3' \rightarrow 5'$ DNA strand. Okazaki fragments are generally about 1000–2000 nucleotides long in viral and bacterial systems but only about one-tenth this length in eukaryotic cells. In *E. coli*, the same DNA polymerase, polymerase III, is used for synthesizing the Okazaki fragments of the lagging strand and the continuous DNA chain of the leading strand. In eukaryotes, DNA polymerases δ and ϵ are both thought to be involved in synthesizing leading and lagging strands.

Proofreading Is Performed by the $3' \rightarrow 5'$ Exonuclease Activity of DNA Polymerase

Given the complexity of the preceding model, you might wonder why cells have not simply evolved an enzyme that synthesizes DNA in the $3' \rightarrow 5'$ direction. One possible answer is related to the need for error correction during DNA replication. About 1 out of every 100,000 nucleotides incorporated during DNA replication is incorrectly base-paired with the template DNA strand, an error rate that would yield more than 120,000 errors every time a human cell replicates its DNA. Fortunately, such mistakes are usually fixed by a **proofreading** mechanism that uses the same DNA polymerase molecules that catalyze DNA synthesis. Proofreading is made possible by the fact that almost all DNA polymerases possess $3' \rightarrow 5'$ exonuclease activity (in addition to their ability to catalyze DNA synthesis). **Exonucleases** are enzymes that degrade nucleic acids (usually DNA) from one end, rather than making internal cuts, as **endonucleases** do. A $3' \rightarrow 5'$ exonuclease is one that clips off nucleotides from the $3'$ end of a nucleotide chain. Hence, the $3' \rightarrow 5'$ exonuclease activity of DNA polymerase allows it to remove improperly base-paired nucleotides from the $3'$ end of a growing DNA chain (Figure 19-10). This ability to remove incorrect nucleotides improves the fidelity of DNA replication to an average of only a few errors for every billion base pairs replicated.

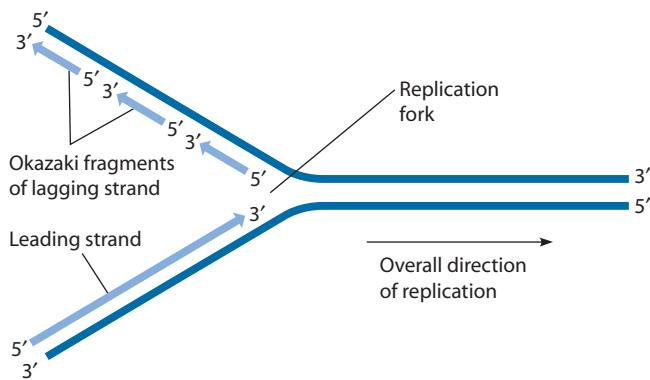

FIGURE 19-9 Directions of DNA Synthesis at a Replication Fork.

Because DNA polymerases synthesize DNA chains only in the $5' \rightarrow 3'$ direction, synthesis at each replication fork is continuous in the direction of fork movement for the leading strand but discontinuous in the opposite direction for the lagging strand. Discontinuous synthesis involves short intermediates called Okazaki fragments, which are 1000–2000 nucleotides long in bacteria and about 100–200 nucleotides long in eukaryotic cells. The fragments are later joined together by the enzyme DNA ligase. Parental DNA is shown in dark blue, and newly synthesized DNA in lighter blue. Here and in subsequent figures, arrowheads indicate the direction in which the nucleic acid chain is being elongated.

 **ACTIVITIES** www.thecellplace.com Molecular model of DNA replication

If cells did happen to possess an enzyme capable of synthesizing DNA in the $3' \rightarrow 5'$ direction, proofreading could not work because a DNA chain growing in the $3' \rightarrow 5'$ direction would have a nucleotide triphosphate at its growing $5'$ end. What if this $5'$ nucleotide contained an incorrect base that needed to be removed during proofreading? Removing this $5'$ nucleotide would eliminate the triphosphate group that provides the free energy that allows DNA polymerase to add nucleotides to a growing DNA chain, and hence the chain could not elongate further.

RNA Primers Initiate DNA Replication

Since DNA polymerase can only add nucleotides to an existing nucleotide chain, how is replication of a DNA double helix initiated? Shortly after Okazaki fragments were

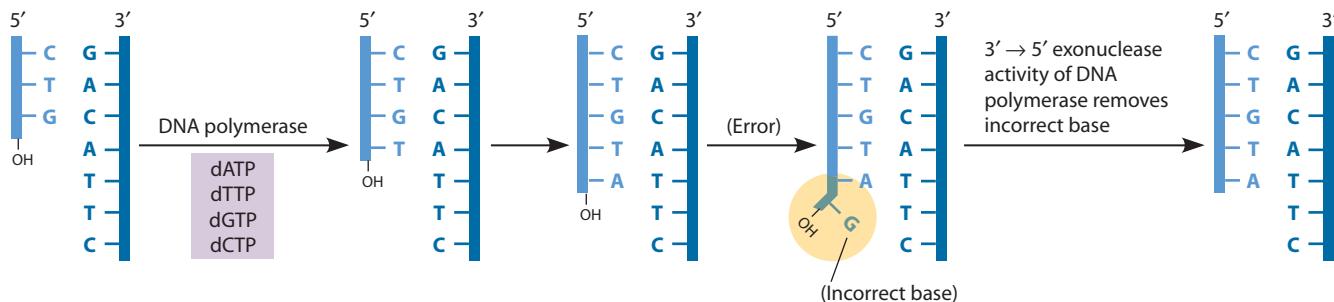

FIGURE 19-10 Proofreading by $3' \rightarrow 5'$ Exonuclease. If an incorrect base is inserted during DNA replication, the $3' \rightarrow 5'$ exonuclease activity that is part of the DNA polymerase molecule catalyzes its removal so that the correct base can be inserted.

The PCR Revolution

The ability to work with minuscule amounts of DNA is invaluable in a wide range of endeavors, from paleontology to criminology. In Chapter 18, we described how DNA fingerprinting analysis can be used to identify and characterize particular sequences contained in as little as 1 μg of DNA, the amount in a small drop of blood (see Box 18C). But sometimes even that amount of DNA may not be available. In such cases another method, called the **polymerase chain reaction (PCR)**, can come to the rescue. With PCR, it is possible to rapidly replicate, or *amplify*, selected DNA segments that are initially present in extremely small amounts. In only a few hours, PCR can make millions or even billions of copies of a particular DNA sequence, thereby producing enough material for DNA fingerprinting, DNA sequencing, or other applications.

The complex multiprotein system that cells use for DNA replication is not required for the PCR method. Instead, PCR employs an unusual DNA polymerase coupled with synthetic primers to set up a chain reaction that produces an exponentially growing population of specific DNA molecules. Biochemist Kary Mullis received a Nobel Prize in 1993 for developing this technique. To perform PCR, you first need to know part of the base sequence of the DNA segment you wish to amplify. Based on this information, short single-stranded DNA primers are chemically synthesized; these primers generally consist of DNA segments 15–20 nucleotides long that are complementary to sequences located at opposite ends of the DNA segment being amplified. (If sequences that naturally flank the sequence of interest are not known, artificial ones can be attached before running the polymerase chain reaction.) DNA polymerase is then added to catalyze the synthesis of complementary DNA strands using the two primers as starting points. The DNA polymerase routinely used for this purpose was first isolated from the bacterium *Thermus aquaticus*, an inhabitant of thermal hot springs where the waters are normally 70–80°C. The optimal temperature for this enzyme, called *Taq* polymerase, is 72°C, and it is stable at even higher temperatures—a property that made possible the automation of PCR.

Figure 19A-1 summarizes how the PCR procedure works. The ingredients of the initial reaction mixture include the DNA containing the sequence to be amplified, *Taq* DNA polymerase, the synthetic DNA primers, and the four deoxynucleoside triphosphates (dATP, dTTP, dCTP, and dGTP). Each reaction cycle begins with a short period of heating to near boiling (95°C) to denature the DNA double helix into its two strands (**1**). The DNA solution is then cooled to allow the primers to base-pair to complementary regions on the DNA strands being copied (**2**). The temperature is then raised to 72°C, and the *Taq* DNA polymerase goes to work, adding nucleotides to the 3' end of the primer (**3**). The specificity of the primers ensures the selective copying of the stretches of template DNA downstream from the primers. It takes no more than a few minutes for the *Taq* polymerase to completely copy the targeted DNA sequence, thereby doubling the amount of DNA. The reaction mixture is then heated again to melt the new double helices, more primer is bound to the DNA, and the cycle is repeated to double the amount of DNA again (**1–3**).

This reaction cycle is repeated as many times as necessary, with each cycle doubling the amount of DNA from the previous cycle. After the third cycle, more and more of the product DNA molecules will be of a uniform length that consists only of the targeted

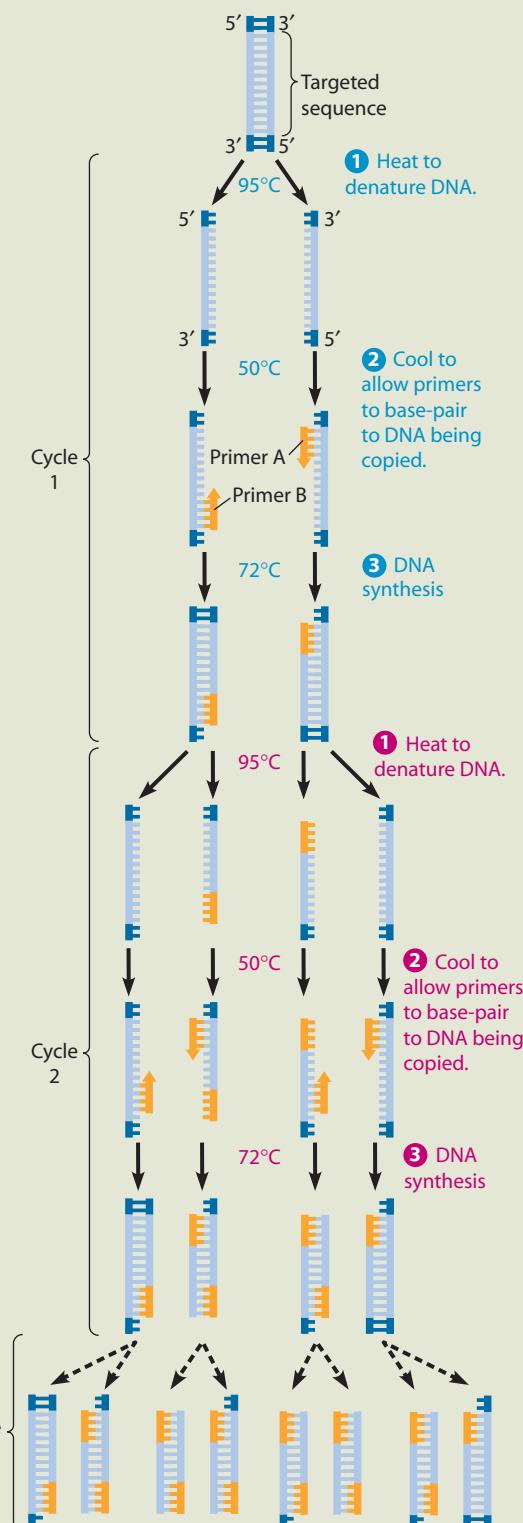

FIGURE 19A-1 DNA Amplification Using the Polymerase Chain Reaction. See the description in the box text. PCR works best when the DNA segment to be amplified—the region flanked by the two primers—is 50–2000 nucleotides long.

sequence (like the third and sixth molecules in the last line of the figure). Because heating to 95°C does not destroy the *Taq* polymerase, there is no need to add fresh enzyme for each round of the cycle. In most cases, 20–30 reaction cycles are sufficient to produce the desired quantity of DNA. The theoretical amplification accomplished by n cycles is 2^n , so 20 cycles yields an amplification of a millionfold or more ($2^{20} = 1,048,576$) and 30 cycles over a billion-fold ($2^{30} = 1,073,741,824$). Since each cycle takes less than 5 minutes, several hundred billion copies of the original DNA sequence can be produced within a few hours. This is considerably quicker than the several days required for amplifying DNA by cloning it in bacteria, a method to be discussed in Chapter 20. Furthermore, PCR can be used with as little as one molecule of DNA, and it does not require the starting DNA sample to be purified because the primers select the DNA region that will be amplified.

PCR therefore makes it possible to identify a person from the minuscule amount of DNA that is left behind when that person touches an object, inadvertently leaving a few skin cells behind. By using PCR to amplify the tiny amount of DNA in such a sample and

then performing a DNA fingerprinting analysis on the amplified DNA, it is possible to obtain a DNA fingerprint from a person's actual fingerprints! Although such techniques have enormous potential in helping to solve crimes, this extraordinary sensitivity can also cause problems. A few contaminating DNA molecules (such as from skin cells shed by a lab technician) might be amplified along with the DNA of interest, yielding misleading results.

Nevertheless, with proper precautions and controls, PCR is proving extremely valuable. As an aid in evolution research, it has been used to amplify DNA fragments recovered from ancient Egyptian mummies and a 40,000-year-old woolly mammoth frozen in a glacier, and to unravel the genome of Neanderthals. In medical diagnosis, PCR has been used to amplify DNA from single embryonic cells for rapid prenatal diagnosis, and it has made possible the detection of viral genes in cells infected with HIV or other viruses. Perhaps most importantly, PCR has revolutionized basic research in molecular genetics by allowing easy amplification of particular genes or sequences from among the thousands of genes in mammalian genomes.

first discovered, researchers implicated RNA in the initiation process through the following observations: (1) Okazaki fragments often have short stretches of RNA, usually 3–10 nucleotides in length, at their 5' ends; (2) DNA polymerase can catalyze the addition of nucleotides to the 3' end of RNA chains as well as to DNA chains; (3) cells contain an enzyme called **primase** that synthesizes RNA fragments about ten bases long using DNA as a template; and (4) unlike DNA polymerase, which adds nucleotides only to the ends of existing chains, primase can initiate RNA synthesis from scratch by joining two nucleotides together.

These observations led to the conclusion that DNA synthesis is initiated by the formation of short **RNA primers**. RNA primers are synthesized by primase, which uses a single DNA strand as a template to guide the synthesis of a complementary stretch of RNA (Figure 19-11, ①). Primase is a specific kind of RNA polymerase used only in DNA replication. Like other RNA polymerases, but unlike DNA polymerases, primases can *initiate* the synthesis of a new polynucleotide strand complementary to a template strand; they do not themselves require a primer.

In *E. coli*, primase is relatively inactive unless it is accompanied by six other proteins, forming a complex called a **primosome**. The other primosome proteins function in unwinding the parental DNA and recognizing target DNA sequences where replication is to be initiated. The situation in eukaryotic cells is slightly different, so the term *primosome* is not used. The eukaryotic primase is not as closely associated with unwinding proteins, but it is very tightly bound to DNA polymerase α , the main DNA polymerase involved in initiating DNA replication.

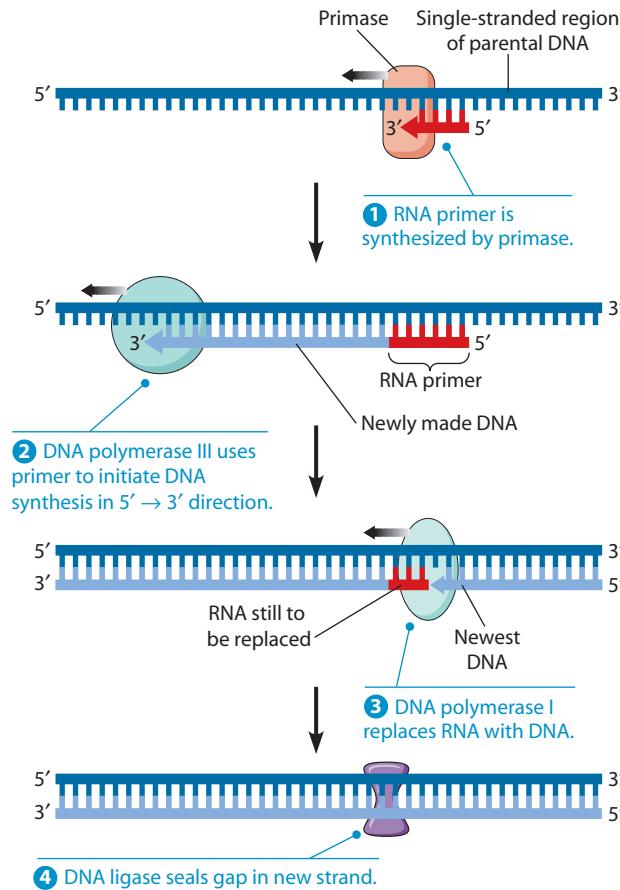

FIGURE 19-11 The Role of RNA Primers in DNA Replication. DNA synthesis is initiated with a short RNA primer in both bacteria and eukaryotes. This figure shows the process as it occurs for the lagging strand in *E. coli*.

Once an RNA primer has been created, DNA synthesis can proceed, with DNA polymerase III (or DNA polymerase α followed by polymerase δ or ϵ in eukaryotes) adding successive deoxynucleotides to the 3' end of the primer (Figure 19-11, ②). For the leading strand, initiation using an RNA primer needs to occur only once, when a replication fork first forms; DNA polymerase can then add nucleotides to the chain continuously in the 5' \rightarrow 3' direction. In contrast, the lagging strand is synthesized as a series of discontinuous Okazaki fragments, and each of them must be initiated with a separate RNA primer. For each primer, DNA nucleotides are added by DNA polymerase III until the growing fragment reaches the adjacent Okazaki fragment. No longer needed at that point, the RNA segment is removed and DNA nucleotides are polymerized to fill its place. In *E. coli*, the RNA primers are removed by a 5' \rightarrow 3' exonuclease activity inherent to the DNA polymerase I molecule (distinct from the 3' \rightarrow 5' exonuclease activity involved in proofreading). At the same time, the DNA polymerase I molecule synthesizes DNA in the normal 5' \rightarrow 3' direction to fill in the resulting gaps (Figure 19-11, ③). Adjacent fragments are subsequently joined together by DNA ligase.

Why do cells employ RNA primers that must later be removed rather than simply using a DNA primer in the first place? Again, the answer may be related to the need for error correction. We have already seen that DNA polymerase possesses a 3' \rightarrow 5' exonuclease activity that allows it to remove incorrect nucleotides from the 3' end of a DNA chain. In fact, DNA polymerase will elongate an existing DNA chain only if the nucleotide present at the 3' end is properly base-paired. But an enzyme that initiates the synthesis of a new chain cannot perform such a proof-reading function because it is not adding a nucleotide to an existing base-paired end. As a result, enzymes that initiate nucleic acid synthesis are not very good at correcting errors. By using RNA rather than DNA to initiate DNA synthesis, cells ensure that any incorrect bases inserted during initiation are restricted to RNA sequences destined to be removed by DNA polymerase I.

Unwinding the DNA Double Helix Requires DNA Helicases, Topoisomerases, and Single-Stranded DNA Binding Proteins

During DNA replication, the two strands of the double helix must unwind at each replication fork to expose the single strands to the enzymes responsible for copying them. Three classes of proteins with distinct functions facilitate this unwinding process: *DNA helicases*, *topoisomerases*, and *single-stranded DNA binding proteins* (Figure 19-12).

The proteins responsible for unwinding DNA are the **DNA helicases**. Using energy derived from ATP hydrolysis, these proteins unwind the DNA double helix in advance of the replication fork, breaking the hydrogen bonds as they go. In *E. coli*, at least two different DNA helicases are involved in DNA replication; one attaches to the lagging strand template and moves in a 5' \rightarrow 3' direction; the other attaches to the leading strand template and

moves 3' \rightarrow 5'. Both are part of the primosome, but the 5' \rightarrow 3' helicase is more important for unwinding DNA at the replication fork.

The unwinding associated with DNA replication would create an intolerable amount of supercoiling and possibly tangling in the rest of the DNA were it not for the actions of **topoisomerases**, which we discussed in Chapter 18. These enzymes create swivel points in the DNA molecule by making and then quickly resealing single- or double-stranded breaks in the double helix. Of the ten or so topoisomerases found in *E. coli*, the key enzyme for DNA replication is *DNA gyrase*, a type II topoisomerase (an enzyme that cuts both DNA strands). Using energy derived from ATP, DNA gyrase introduces negative supercoils and thereby relaxes positive ones. DNA gyrase serves as the main swivel that prevents overwinding (positive supercoiling) of the DNA ahead of the replication fork. In addition, this enzyme has a role in both initiating and completing DNA replication in *E. coli*—in opening up the double helix at the origin of replication and in separating the linked circles of daughter DNA at the end. The situation in eukaryotic cells is not as well understood, although topoisomerases of both types have been isolated.

Once strand separation has begun, molecules of **single-stranded DNA binding protein (SSB)** quickly attach to the exposed single strands to keep the DNA unwound and therefore accessible to the DNA replication machinery. After a particular segment of DNA has been replicated, the SSB molecules fall off and are recycled, attaching to the next single-stranded segment.

Putting It All Together: DNA Replication in Summary

Figure 19-13 reviews the highlights of what we currently understand about the mechanics of DNA replication in

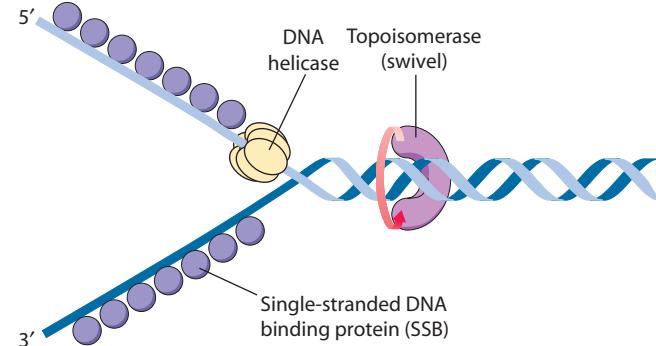

FIGURE 19-12 Proteins Involved in Unwinding DNA at the Replication Fork. Three types of proteins are involved in DNA unwinding. The actual unwinding proteins are the DNA helicases; the principal one in *E. coli*, which is part of the primosome, operates 5' \rightarrow 3' along the template for the lagging strand, as shown here. Single-stranded DNA binding proteins (SSB) stabilize the unwound DNA in an extended position. A topoisomerase forms a swivel ahead of the replication fork; in *E. coli*, this topoisomerase is DNA gyrase.

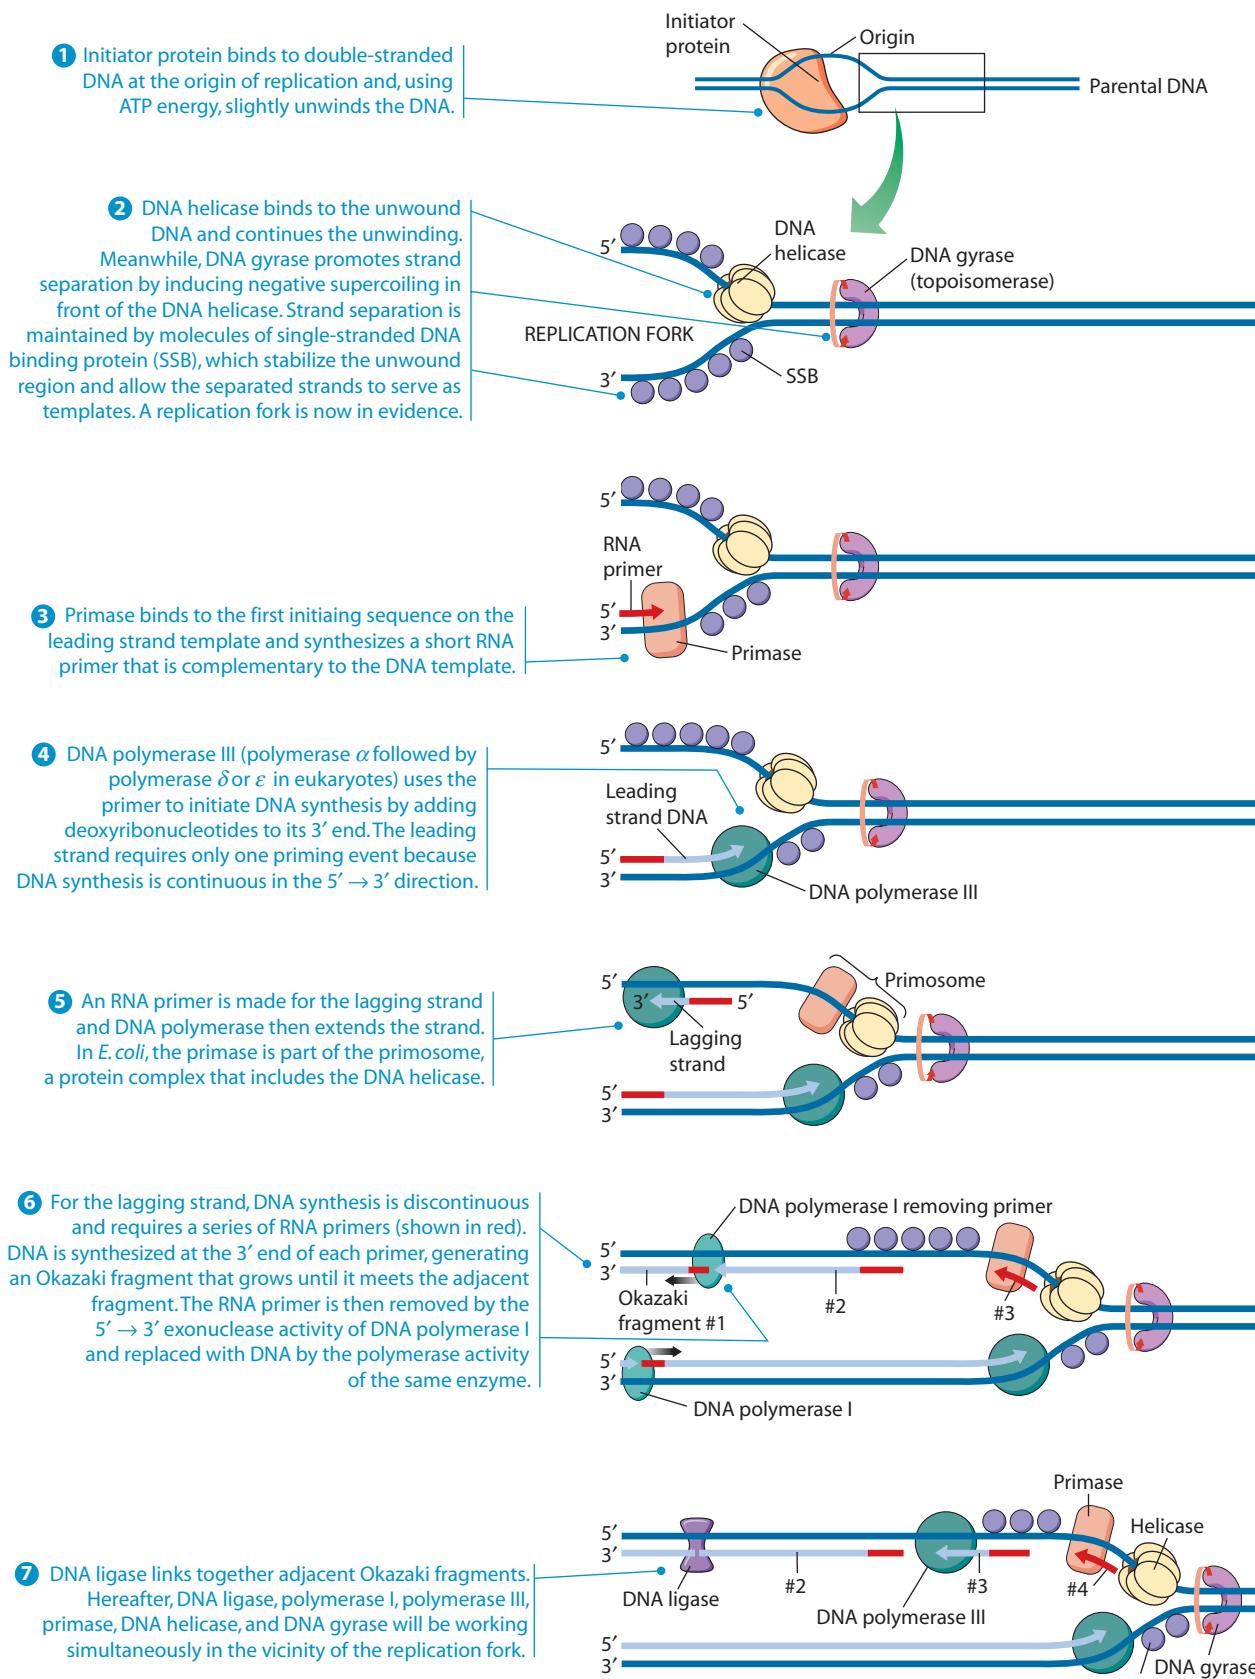

FIGURE 19-13 A Summary of DNA Replication in Bacteria. Starting with the initiation event at the replication origin, this figure depicts DNA replication in *E. coli* in seven steps. Two replication forks move in opposite directions from the origin, but only one fork is illustrated for steps **2–7**. The various proteins shown here as separate entities are actually closely associated (along with others) in a single large complex called a replisome. The primase and DNA helicase are particularly closely bound and, together with other proteins, form a primosome. Parental DNA is shown in dark blue, newly synthesized DNA in light blue, and RNA in red. This series of diagrams does not show the topological arrangement of the DNA strands.

E. coli. Starting at the origin of replication, the machinery at the replication fork sequentially adds the different proteins required for synthesizing DNA—that is, DNA helicase, DNA gyrase, SSB, primase, DNA polymerase, and DNA ligase. Several other proteins (not illustrated) are also involved in improving the overall efficiency of DNA replication. For example, a ring-shaped *sliding clamp* protein encircles the DNA double helix and binds to DNA polymerase, thereby allowing the DNA polymerase to slide along the DNA while remaining firmly attached to it.

The various proteins involved in DNA replication are all closely associated in one large complex, called a **replisome**, that is about the size of a ribosome. The activity and movement of the replisome is powered by the hydrolysis of nucleoside triphosphates. These include both the nucleoside triphosphates (used by DNA polymerases and primase as building blocks for DNA and RNA synthesis) and the ATP hydrolyzed by several other DNA replication proteins (including DNA helicase, DNA gyrase, and DNA ligase). As the replisome moves along the DNA in the direction of the replication fork, it must accommodate the fact that DNA is being synthesized in opposite directions along the template on the two strands. **Figure 19-14** provides a schematic model illustrating how this might be accomplished by folding the lagging strand template into a loop. Creating such a loop allows the DNA polymerase molecules on both the leading and lagging strands to move in the same physical direction, even though the two template strands are oriented with opposite polarity.

Eukaryotes possess much of the same replication machinery found in prokaryotes. For example, like prokaryotes, a DNA clamp protein acts along with DNA polymerase during DNA synthesis. One such eukaryotic clamp protein, *proliferating nuclear cell antigen* (PCNA), was originally identified as an antigen that is expressed in the nuclei of dividing cells during S phase. PCNA is a clamp protein for DNA polymerase δ. In eukaryotic cells, the enormous length and elaborate folding of the chromosomal DNA molecules pose additional challenges for DNA replication. For example, how are the many replication origins coordinated, and how is their activation linked to other key events in the cell cycle? Answering such questions requires a better understanding of the spatial organization of DNA replication within the nucleus. When cells are briefly incubated with DNA precursors that make the most recently formed DNA fluorescent, microscopic examination reveals that the new,

fluorescent DNA is located in a series of discrete spots scattered throughout the nucleus. Such observations suggest the existence of apparently immobile structures, known as *replication factories*, where chromatin fibers are fed through stationary replisomes that carry out DNA replication. These sites are closely associated with the inner surface of the nuclear envelope, although it is not clear whether they are anchored in the nuclear membrane or to some other nuclear support.

When a chromatin fiber is fed through a stationary replication factory, how are the histones and other chromosomal proteins removed, so the DNA can be replicated, and then added back after the two new DNA strands are formed? Unfolding the chromatin fibers ahead of the replication fork is facilitated by *chromatin remodeling* proteins, which loosen nucleosome packing to give the replication machinery access to the DNA template. As the replication fork moves, old nucleosomes slide from the parental double helix ahead of the fork to the newly forming strands behind the fork. At the same time, new nucleosomes are assembled on the newly forming strands because the two DNA molecules produced by replication require twice as many nucleosomes as the single parental DNA possessed prior to replication. When and how other chromosomal proteins are added, what controls higher levels of chromatin packing, and how all this is accomplished without tangling the chromatin are areas of current research. Meanwhile, an answer has emerged to one of the most baffling questions related to DNA replication in eukaryotes—the end-replication problem.

Telomeres Solve the DNA End-Replication Problem

If we continue the process summarized in Figure 19-13 for the circular genome of *E. coli* (or any other circular DNA), we will eventually complete the circle. The leading strand can simply continue to grow 5' → 3' until its 3' end is joined to the 5' end of the lagging strand coming around in the other direction. And for the lagging strand, the very last bit of DNA to be synthesized—the replacement for the RNA primer of the last Okazaki fragment—can be added to the free 3' OH end of the leading strand coming around in the opposite direction.

For linear DNA molecules, however, the fact that DNA polymerases can add nucleotides only to the 3' OH end of a preexisting DNA chain creates a serious problem,

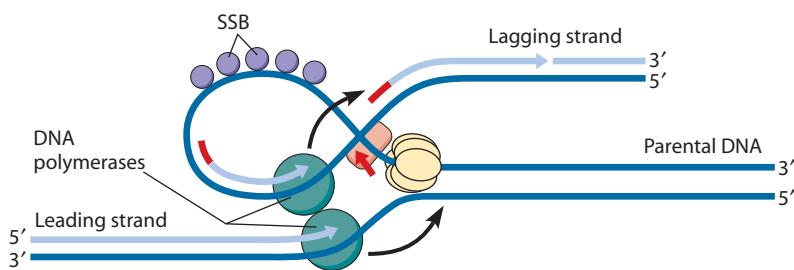

FIGURE 19-14 Arrangement of Proteins at the Replication Fork. This model shows how some of the key replication proteins illustrated in Figure 19-13 are organized at the replication fork. The main distinguishing feature is that the lagging strand DNA is folded into a loop, thereby allowing the DNA polymerase molecules on the leading and lagging strands to come together and move in the same physical direction (black arrows) even though the two template strands are oriented with opposite polarity in the parental DNA molecule.

which is depicted in **Figure 19-15**. When a growing lagging strand (lightest blue) reaches the end of the DNA molecule and the last RNA primer is removed by a $5' \rightarrow 3'$ exonuclease, the final gap cannot be filled because there is no 3' OH end that deoxynucleotides can be added to. As a result, linear DNA molecules are in danger of yielding shorter and shorter daughter DNA molecules each time they replicate. Clearly, if this trend continued indefinitely, we would not be here today!

Viruses with linear DNA genomes solve this problem in various ways. In some cases, such as bacteriophage λ , the linear DNA forms a closed circle before it replicates. In other cases, the viruses use more exotic reproduction strategies, although the DNA polymerases always progress 5' to 3', adding nucleotides to a 3' end.

Eukaryotes have solved the end-replication problem by locating highly repeated DNA sequences at the terminal ends, or **telomeres**, of each linear chromosome. These special telomeric elements consist of short, repeating sequences enriched in the base G in the 5' \rightarrow 3' strand. The sequence TTAGGG, located at the ends of human chromosomes, is an example of such a telomeric or *TEL* sequence. Human telomeres typically contain between 100 and 1500 copies of the TTAGGG sequence repeated in tandem. Such noncoding sequences at the ends of each chromosome ensure that the cell will not lose any important genetic information if a DNA molecule is shortened

slightly during the process of DNA replication. Moreover, a special DNA polymerase called **telomerase** can catalyze the formation of additional copies of the telomeric repeat sequence, thereby compensating for the gradual shortening that occurs at both ends of the chromosome during DNA replication. Elizabeth Blackburn, Carol Greider, and Jack Szostak received the 2009 Nobel Prize in Physiology or Medicine for their fundamental contributions to our understanding of telomeres and telomerase.

Telomerase is an unusual enzyme in that it is composed of RNA as well as protein. In the protozoan *Tetrahymena*, whose telomerase was the first to be isolated, the RNA component contains the sequence 3'-AACCC-5', which is complementary to the 5'-TTGGGG-3' repeat sequence that makes up *Tetrahymena* telomeres. As shown in **Figure 19-16**, this enzyme-bound RNA acts as a template for creating the DNA repeat sequence that is added to the telomere ends. After being lengthened by telomerase, the telomeres are protected by *telomere capping proteins* that bind to the exposed 3' end of the DNA. In many eukaryotes, the 3' end of the DNA can loop back and base-pair with the opposite DNA strand, generating a closed loop that likewise protects the end of the telomere (Figure 19-16, step 5).

In multicellular organisms, telomerase resides mainly in the *germ cells* that give rise to sperm and eggs and in a few other types of actively proliferating cells. The presence

- DNA replication is initiated at the origin; the replication bubble grows as the two replication forks move in opposite directions.

- Finally only one primer (red) remains on each daughter DNA molecule.

- The last primers are removed by a $5' \rightarrow 3'$ exonuclease, but no DNA polymerase can fill the resulting gaps because there is no 3' OH available to which a nucleotide can be added.

- Each round of replication generates shorter and shorter DNA molecules.

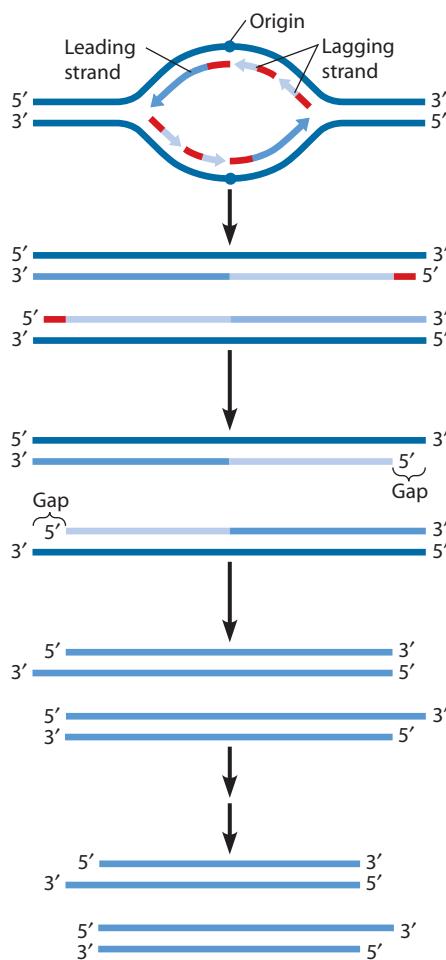

FIGURE 19-15 The End-Replication Problem.

For a linear DNA molecule, such as that of a eukaryotic chromosome, the usual DNA replication machinery is unable to replicate the ends. As a result, with each round of replication, the DNA molecules will get shorter, with potentially disastrous consequences for the cell. In this diagram, the initial parental DNA strands are dark blue, daughter DNA strands are lighter blue, and RNA primers are red. For simplicity, we show only one origin of replication and, in the last two steps, only the shortest of the progeny molecules. (The lagging strand daughter DNA is shown in the lightest blue in the first three steps to make a point unrelated to the end-replication problem—that each daughter strand is leading at one end and lagging at the other. This is apparent in this figure because it shows the entire replicating molecule, with both replication forks.)

of telomerase allows these cells to divide indefinitely without telomere shortening. Because telomerase is not found in most cells, their chromosomal telomeres get shorter and shorter with each cell division. As a result, telomere length is a counting device that reveals how many times a cell has divided. If a cell divides enough times, the telomeres are in danger of disappearing entirely, and the cell would then be at risk of eroding its coding DNA. This potential danger is averted by a cell destruction pathway set in motion by the shortened telomeric DNA. In essence, when the telomeric DNA becomes too short to bind telomeric capping proteins or generate a loop, it exposes a bare, double-stranded DNA end whose presence activates a signaling system that triggers *apoptosis*, an orchestrated type of cell death described later in this chapter.

Cell death triggered by a lifetime of telomere shortening is thought to contribute to some of the degenerative diseases

associated with human aging—for example, increased susceptibility to infections due to the death of immune cells, inefficient wound healing caused by depletion of connective tissue cells, and ulcers triggered by loss of cells in the digestive tract. People who inherit mutations in telomerase (or in other proteins affecting telomere length) experience similar degenerative changes, show symptoms of premature aging, and usually die when they are relatively young. Based on these relationships, scientists have speculated that telomerase-based therapies may one day be used to combat the symptoms of human aging and thereby extend life span.

Besides being found in germ cells and a few other types of proliferating normal cells, telomerase has also been detected in human cancers. Because cancer cells divide an abnormally large number of times, their telomeres become unusually short. This progressive telomere shortening would lead to self-destruction of the cancer

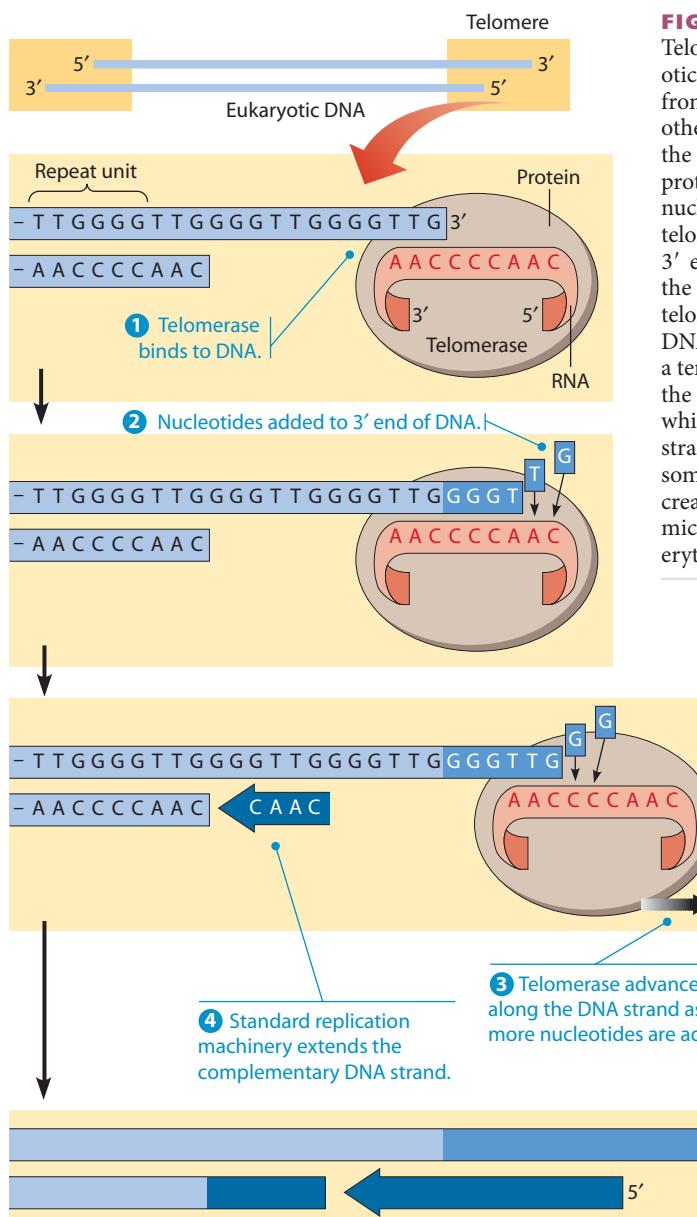

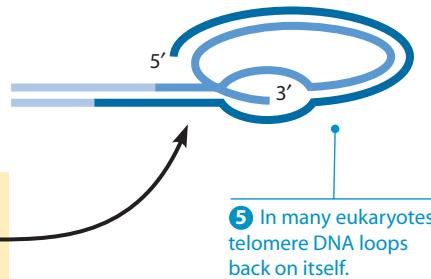

FIGURE 19-16 The Extension of Telomeres by Telomerase.

Telomeres are stretches of repeated DNA located at the ends of eukaryotic chromosomes. This figure focuses on one end of a DNA molecule from *Tetrahymena*, whose telomeric repeat unit is TTGGGG (those of other species are very similar). The 3' end of the DNA extends beyond the 5' end and is the substrate for telomerase, an enzyme composed of protein and RNA. The RNA portion of *Tetrahymena* telomerase is 159 nucleotides long and contains a 9-base sequence complementary to 1.5 telomeric repeat units. As outlined here, the telomerase ① binds to the 3' end of the telomeric DNA, positioning itself so the last few bases of the DNA are base-paired with part of the 9-base RNA sequence. ② The telomerase then catalyzes the addition of nucleotides to the 3' end of the DNA strand, with the remainder of the 9-base RNA sequence serving as a template. ③ Next, the telomerase advances along the DNA strand in the 3' direction and repeats steps ② and ③ several times. ④ Meanwhile, the standard DNA replication machinery synthesizes a lagging strand complementary to the strand elongated by telomerase. ⑤ In some eukaryotes the lengthened telomeric DNA folds back upon itself, creating a loop that caps the end of the chromosome. The electron micrograph shows such a loop in chromatin isolated from chicken erythrocytes.

unless telomerase were produced to stabilize telomere length. This is exactly what seems to happen. A survey of a large number of human cell samples—including more than 100 tumors—found telomerase activity in almost all of the cancer cells but in none of the samples from normal tissues. If telomerase is indeed an important factor in the development of cancer, it may eventually provide a useful target for anticancer drug therapy.

DNA Damage and Repair

The faithful transmission of genetic information from one generation of cells to the next requires not just that DNA be replicated accurately. Provision must also be made for repairing DNA alterations that arise both spontaneously and from exposure to DNA-damaging environmental agents. Of course, DNA alterations are occasionally beneficial because DNA base-sequence changes, or **mutations**, provide the genetic variability that is the raw material of evolution. Still, the net rate at which organisms accumulate mutations is quite low; by some estimates, an average gene retains only one mutation every 200,000 years. The underlying mutation rate is far greater than this number suggests, but most DNA damage is repaired shortly after it occurs so does not affect future generations. Moreover, since most mutations occur in cells other than sperm and eggs, they are never passed on to offspring.

DNA Damage Can Occur Spontaneously or in Response to Mutagens

During the normal process of DNA replication, several types of mutations occur spontaneously. The most common involve depurination and deamination reactions, which are spontaneous hydrolysis reactions caused by random interactions between DNA and the water molecules around it. *Depurination* refers to the loss of a purine base (either adenine or guanine) by spontaneous hydrolysis of the glycosidic bond that links it to deoxyribose (Figure 19-17a). This glycosidic bond is intrinsically unstable and is in fact so susceptible to hydrolysis that the DNA in a human cell may lose thousands of purine bases every day. *Deamination* is the removal of a base's amino group ($-\text{NH}_2$). This type of alteration, which can involve cytosine, adenine, or guanine, changes the base-pairing properties of the affected base. Of the three bases, cytosine is most susceptible to deamination, giving rise to uracil (Figure 19-17b). Like depurination, deamination is a hydrolytic reaction, usually caused by random collision of a water molecule with the bond that links the amino group of the base to the pyrimidine or purine ring. In a typical human cell, the rate of DNA damage by this means is about 100 deaminations per day.

If a DNA strand with missing purines or deaminated bases is not repaired, an erroneous base sequence may be propagated when the strand serves as a template in the next round of DNA replication. For example, where a cytosine has been converted to a uracil by deamination,

the uracil behaves like thymine in its base-pairing properties; that is, it directs the insertion of an adenine in the opposite strand, rather than guanine, the correct base. The ultimate effect of this change in base sequence may be a change in the amino acid sequence and function of a protein encoded by the affected gene.

In addition to spontaneous mutations, DNA damage can also be caused by mutation-causing agents, or *mutagens*, in the environment. Environmental mutagens fall into two major categories: chemicals and radiation. Mutagenic chemicals alter DNA structure by a variety of mechanisms. *Base analogs* resemble nitrogenous bases in structure and are incorporated into DNA; *base-modifying* agents react chemically with DNA bases to alter

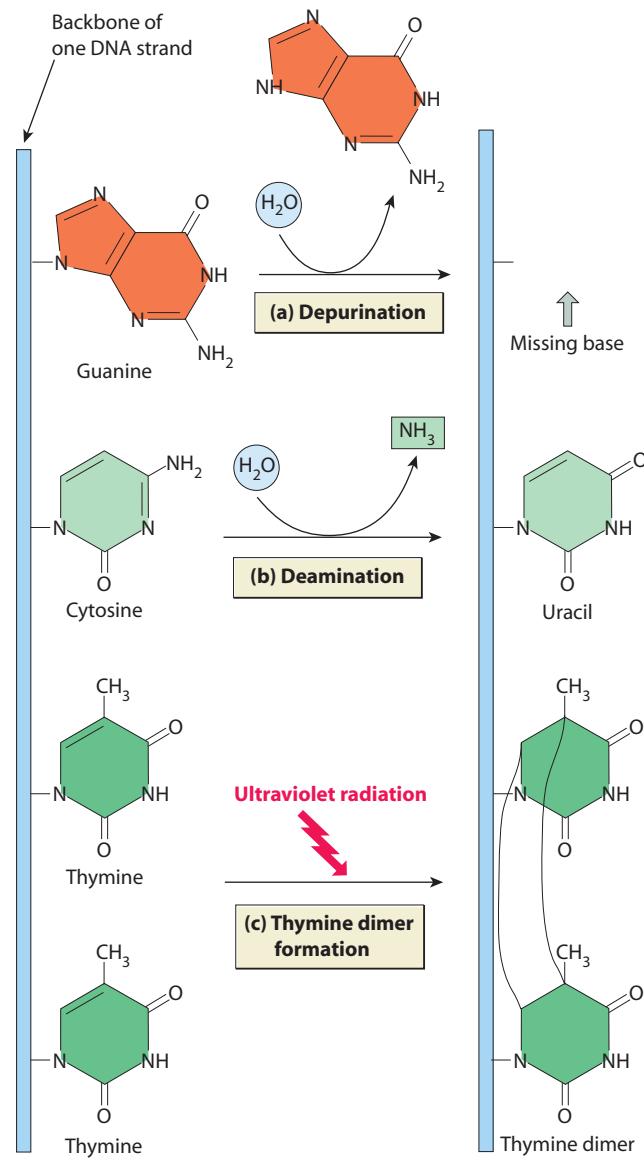

FIGURE 19-17 Some Common Types of DNA Damage. The most common kinds of chemical changes that can damage DNA are (a) depurination, (b) deamination, and (c) pyrimidine dimer formation (shown here are thymine dimers). Depurination and deamination are spontaneous hydrolytic reactions, whereas dimers result from covalent bonds induced to form by ultraviolet light.

their structure, forming what are sometimes known as *DNA adducts*; and *intercalating agents* insert themselves between adjacent bases of the double helix, thereby distorting DNA structure and increasing the chance that a base will be deleted or inserted during DNA replication. Not surprisingly, as we will see in more detail in Chapter 24, mutagens can cause cancer. Analysis of DNA from heavy cigarette smokers, for example, shows a direct correlation between how much a patient smokes and how frequently the DNA of such patients has adducts.

DNA mutations can also be caused by several types of radiation. Sunlight is a strong source of ultraviolet radiation, which alters DNA by triggering *pyrimidine dimer formation*—that is, the formation of covalent bonds between adjacent pyrimidine bases, often two thymines (Figure 19-17c). Both replication and transcription are blocked by such dimers, presumably because the enzymes carrying out these functions cannot cope with the resulting bulge in the DNA double helix. Mutations can also be caused by X-rays and related forms of radiation emitted by radioactive substances. This type of radiation is called *ionizing radiation* because it removes electrons from biological molecules, thereby generating highly reactive intermediates that cause various types of DNA damage.

Translesion Synthesis and Excision Repair Correct Mutations Involving Abnormal Nucleotides

As is perhaps not surprising for a molecule so important to an organism's health and survival, a variety of mechanisms have evolved for repairing damaged DNA. In some cases, repair is performed during the process of DNA replication using specialized DNA polymerases that carry out **translesion synthesis**—that is, the synthesis of new DNA across regions in which the DNA template is damaged. While this type of DNA synthesis is sometimes prone to error, it is also capable of synthesizing new DNA strands in which the damage has been eliminated. For example, eukaryotic DNA polymerase η (eta) can catalyze DNA synthesis across a region containing a thymine dimer, correctly inserting two new adenines in the newly forming DNA strand. Since the mutation is eliminated from the new strand but not the template strand, translesion synthesis is a damage-tolerance mechanism that can prevent an initial mutation from being passed on to newly forming DNA strands.

Once left behind by the DNA replication machinery, errors that still remain (or that subsequently arise) become the province of a different group of enzymes and proteins. In *E. coli* alone, almost 100 genes code for proteins involved in removing and replacing abnormal nucleotides. These proteins are components of **excision repair** pathways, which correct DNA defects using a basic three-step process (Figure 19-18). In the first step, the defective nucleotides are cut out from one strand of the DNA double helix. This process is carried out by special enzymes called *repair endonucleases*, which are recruited to DNA by proteins that

recognize sites of DNA damage. Repair endonucleases cleave the DNA backbone adjacent to the damage site, and other enzymes then facilitate removal of the defective nucleotide(s). For example, a DNA helicase might unwind the DNA located between two nicks to release the damaged DNA from the double helix; alternatively, an exonuclease might attach to an end created by a single nick and chew away the damaged strand one nucleotide at a time. During the second step in excision repair, the missing nucleotides are replaced with the correct ones by a DNA polymerase—in *E. coli*, usually DNA polymerase I. The nucleotide sequence of the complementary strand serves as a template to ensure correct base insertion, just as it does in DNA replication. Finally, in the third step, DNA ligase seals the remaining nick in the repaired strand by forming the missing phosphoester bond.

Excision repair pathways are classified into two main types, *base excision repair* and *nucleotide excision repair*. The first of these pathways, **base excision repair**, corrects single damaged bases in DNA. For example, deaminated bases are detected by specific *DNA glycosylases*, which recognize a specific deaminated base and remove it from the DNA molecule by cleaving the bond between the base and the sugar it is attached to. The sugar with the missing base is then recognized by a repair endonuclease that detects depurination. This repair endonuclease breaks the phosphodiester backbone on one side of the sugar lacking a

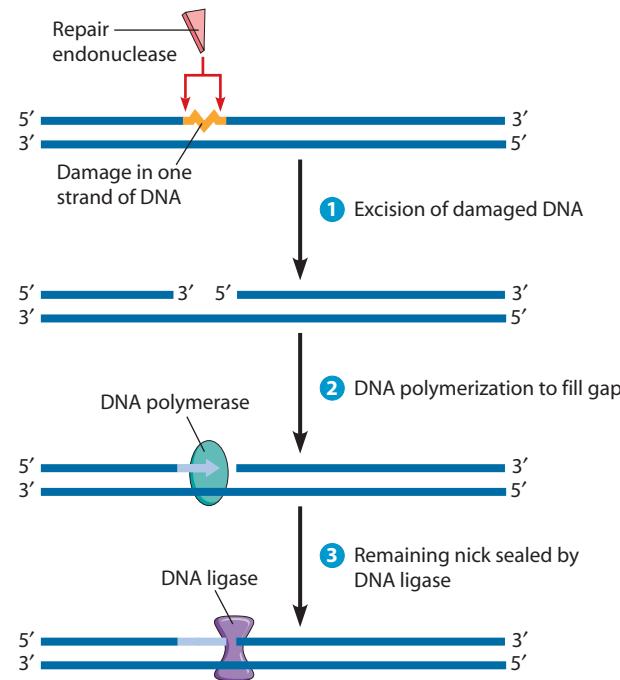

FIGURE 19-18 General Scheme for Excision Repair of DNA Damage. The three steps shown here are common to all types of excision repair of DNA damage in one strand. ① The damaged part of the DNA strand, and possibly some DNA on either side of it, is cut out (excised) from the double helix. An endonuclease, which nicks the DNA near the damage, is crucial for this step; a DNA helicase and/or exonuclease may help remove the damaged segment. ② A DNA polymerase fills in the gap by adding nucleotides to the strand's 3' end; DNA polymerase I plays this role in *E. coli*. ③ The remaining nick is sealed by DNA ligase.

base, and a second enzyme then completes the removal of the sugar-phosphate unit.

For removing pyrimidine dimers and other bulky lesions in DNA, cells employ the second type of excision repair, namely **nucleotide excision repair (NER)**. This repair system utilizes proteins that recognize major distortions in the DNA double helix and recruit an enzyme, called an *NER endonuclease* (or *excinuclease*), that makes two cuts in the DNA backbone, one on either side of the distortion. Then a DNA helicase binds to the stretch of DNA between the nicks (12 nucleotides long in *E. coli*, 29 in humans) and unwinds it, freeing it from the rest of the DNA. Finally, the resulting gap is filled in by DNA polymerase and sealed by DNA ligase.

The NER system is the most versatile of a cell's DNA repair systems, recognizing and correcting many types of damage that cannot otherwise be repaired. In some cases, the NER system is specifically recruited to DNA regions where transcription has been halted because the transcription machinery encountered an area of DNA damage. This mechanism, known as *transcription-coupled repair*, permits active genes to be repaired faster than DNA sequences located elsewhere in the genome. The importance of NER is underscored by the plight of people who have mutations affecting the NER pathway. Individuals with the disease *xeroderma pigmentosum*, for example, usually carry a mutation in any of seven genes coding for components of the NER system. As a result, they cannot repair the DNA damage caused by the ultraviolet radiation in sunlight and so have a high risk of developing skin cancer (see Box 24A, page 782).

Mismatch Repair Corrects Mutations That Involve Noncomplementary Base Pairs

Excision repair is a powerful mechanism for correcting damage involving the presence of abnormal nucleotides. This is not the only type of DNA error that cells can repair, however. An alternative repair pathway, called **mismatch repair**, targets errors made during DNA replication, when improperly base-paired nucleotides sometimes escape the normal proofreading mechanisms. Because mismatched base pairs do not hydrogen-bond properly, their presence can be detected and corrected by the mismatch repair system. But to operate properly, this repair system must solve a problem that puzzled biologists for many years: How is the *incorrect* member of an abnormal base pair distinguished from the *correct* member? Unlike the situation in excision repair, neither of the bases in a mismatched pair exhibits any structural alteration that would allow it to be recognized as an abnormal base. The pair is simply composed of two normal bases that are inappropriately paired with each other, such as the base A paired with C or G paired with T. If the incorrect member of an AC base pair were the base C and the repair system instead removed the base A, the repair system would create a permanent mutation instead of correcting a mismatched base pair!

To solve this problem, the mismatch repair system must be able to recognize which of the two DNA strands

was newly synthesized during the previous round of DNA replication (the new strand would be the one that contains the incorrectly inserted base). The bacterium *E. coli* employs a detection system that is based on the fact that a methyl group is normally added to the base adenine (A) wherever it appears in the sequence GATC in DNA. This process of *DNA methylation* does not take place until a short time after a new DNA strand has been synthesized; hence, the bacterial mismatch repair system can detect the new DNA strand by its unmethylated state. A repair endonuclease then introduces a single nick in the unmethylated strand, and an exonuclease removes the incorrect nucleotides from the nicked strand.

Although the initial evidence for the existence of mismatch repair came largely from studies of bacterial cells, comparable repair systems have been detected in eukaryotes as well. Eukaryotic mismatch repair differs from the bacterial process in that eukaryotes use mechanisms other than DNA methylation for distinguishing the newly synthesized DNA strand. The importance of mismatch repair for eukaryotes is highlighted by the discovery that one of the most common hereditary cancers, *hereditary nonpolyposis colon cancer (HNPCC)*, results from mutations in genes coding for proteins involved in mismatch repair.

Damage Repair Helps Explain Why DNA Contains Thymine Instead of Uracil

For many years, it was not clear why DNA contains thymine instead of the uracil found in RNA. Both bases pair with adenine, but thymine has a methyl group not present on uracil (Figure 19-19). Because the methylation step used to create thymine is energetically expensive, it might seem more efficient for DNA to contain uracil. But now that we understand how deamination damage is repaired, we also understand why thymine, rather than uracil, is present in DNA.

When DNA is damaged through deamination reactions, cytosine is converted to uracil (see Figure 19-17b), which is then detected and removed by the DNA repair enzyme, *uracil-DNA glycosylase*. But if uracil were present as a normal component of DNA, DNA repair would not work because these normal uracils would not be distinguishable from the uracils generated by the accidental deamination of cytosine. By using thymine in DNA in place of uracil, cells ensure that DNA damage caused by the deamination of cytosine can be recognized and repaired without causing other changes in the DNA molecule.

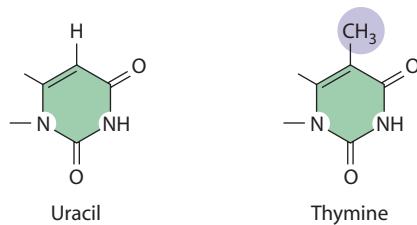

FIGURE 19-19 Uracil and Thymine Compared.

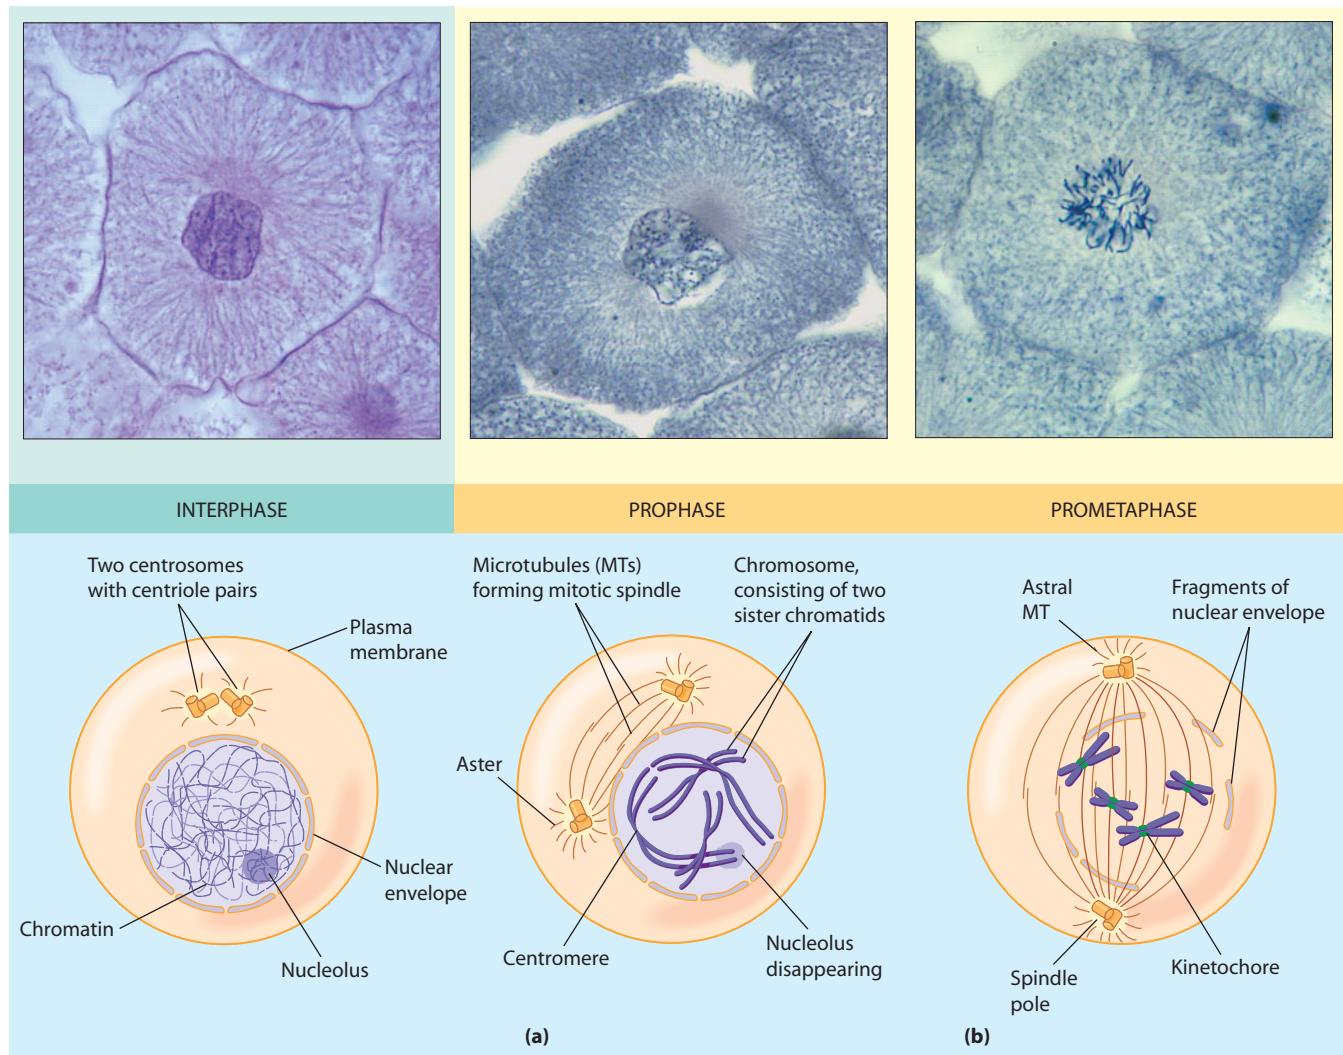

FIGURE 19-20 The Phases of Mitosis in an Animal Cell. The micrographs show mitosis in cells from a fish embryo viewed by light microscopy. The mitotic spindle, including asters, is visible in the metaphase and anaphase micrographs. At this low magnification (about 600-fold), we see spindle “fibers” rather than individual microtubules; each fiber consists of a number of microtubules. The drawings are schematic and include details not visible in the micrographs; for simplicity, only four chromosomes are drawn (MT = microtubule).

 [ACTIVITIES www.thecellplace.com](http://www.thecellplace.com) *Mitosis and cytokinesis*

Double-Strand DNA Breaks Are Repaired by Nonhomologous End-Joining or Homologous Recombination

The repair mechanisms described thus far—excision and mismatch repair—are effective in correcting DNA damage involving chemically altered or incorrect bases. In such cases a “cut-and-patch” pathway removes the damaged or incorrect nucleotides from one DNA strand, and the resulting gap is filled using the intact strand as template. But some types of damage, such as double-strand breaks in the DNA double helix, cannot be handled this way. Repair is more difficult for double-strand breaks because, with other types of DNA damage, one strand of the double helix remains undamaged and can serve as a template for aligning and repairing the defective strand. In contrast, double-strand breaks completely cleave the DNA double

helix into two separate fragments; the repair machinery is therefore confronted with the problem of identifying the correct two fragments and rejoining their broken ends without losing any nucleotides.

Two main pathways are employed in such cases. One, called **nonhomologous end-joining**, uses a set of proteins that bind to the ends of the two broken DNA fragments and join them together. Unfortunately, this mechanism is error-prone because it cannot prevent the loss of nucleotides from the broken ends and has no way of ensuring that the correct two DNA fragments are being joined to each other. A more precise method for fixing double-strand breaks, called **homologous recombination**, takes advantage of the fact that cells generally possess two copies of each chromosome; if the DNA molecule in one chromosome incurs a double-strand break, another intact copy of the chromosomal DNA is still available to

serve as a template for guiding the repair of the broken chromosome. Besides its role in repairing double-strand breaks, homologous recombination is involved in the exchange of genetic information between chromosomes during the meiotic cell divisions that are used to produce sperm and egg cells. We will therefore delay a discussion of the molecular mechanisms involved in homologous recombination until Chapter 20, where meiosis and genetic recombination are described in detail.

Now that we have considered the various types of DNA repair, it is important to emphasize that some of the same proteins are used in more than one repair pathway. Moreover, many of these “repair” proteins play additional roles in other important activities, including DNA replication, gene transcription, genetic recombination, and control of the cell cycle. In other words, the same molecular tool kit appears to be used for a variety of DNA-related activities.

Nuclear and Cell Division

Having examined the mechanisms involved in DNA replication and repair, we can now turn to the question of how the two copies of each chromosomal DNA molecule

created during the S phase of the cell cycle are subsequently separated from each other and partitioned into daughter cells. These events occur during M phase, which encompasses both nuclear division (mitosis) and cytoplasmic division (cytokinesis).

Mitosis Is Subdivided into Prophase, Prometaphase, Metaphase, Anaphase, and Telophase

Mitosis has been studied for more than a century, but only in the past few decades has significant progress been made toward understanding the mitotic process at the molecular level. We will begin by surveying the morphological changes that occur in a cell as it undergoes mitosis, and we will then examine the underlying molecular mechanisms.

Mitosis is subdivided into five stages based on the changing appearance and behavior of the chromosomes. These five phases are *prophase*, *prometaphase*, *metaphase*, *anaphase*, and *telophase*. (An alternative term for prometaphase is simply *late prophase*.) The micrographs and schematic diagrams of **Figure 19-20** illustrate the phases in a typical animal cell; **Figure 19-21** depicts the

comparable stages in plant cells. As you follow the events of each phase, keep in mind that the purpose of mitosis is to ensure that each of the two daughter nuclei receives one copy of each duplicated chromosome.

Prophase. After completing DNA replication, cells exit from S phase and enter into G2 phase (see Figure 19-1b), where final preparations are made for the onset of mitosis. Toward the end of G2, the chromosomes start to condense from the extended, highly diffuse form of interphase chromatin fibers into the compact, extensively folded structures that are typical of mitosis. Chromosome condensation is an important event because interphase chromatin fibers are so long and intertwined that in an uncompact form, they would become impossibly tangled during distribution of the chromosomal DNA at the time of cell division. Although the transition from G2 to prophase is not sharply defined, a cell is considered to be in **prophase** when individual chromosomes have condensed to the point of being visible as discrete objects in the light microscope. Because the chromosomal DNA molecules have replicated during S phase, each prophase chromosome is composed of two sister chromatids that are tightly attached to each other. In animal cells, the nucleoli usually disperse as the chromosomes condense; plant cell nucleoli may either remain as discrete entities, undergo partial disruption, or disappear entirely.

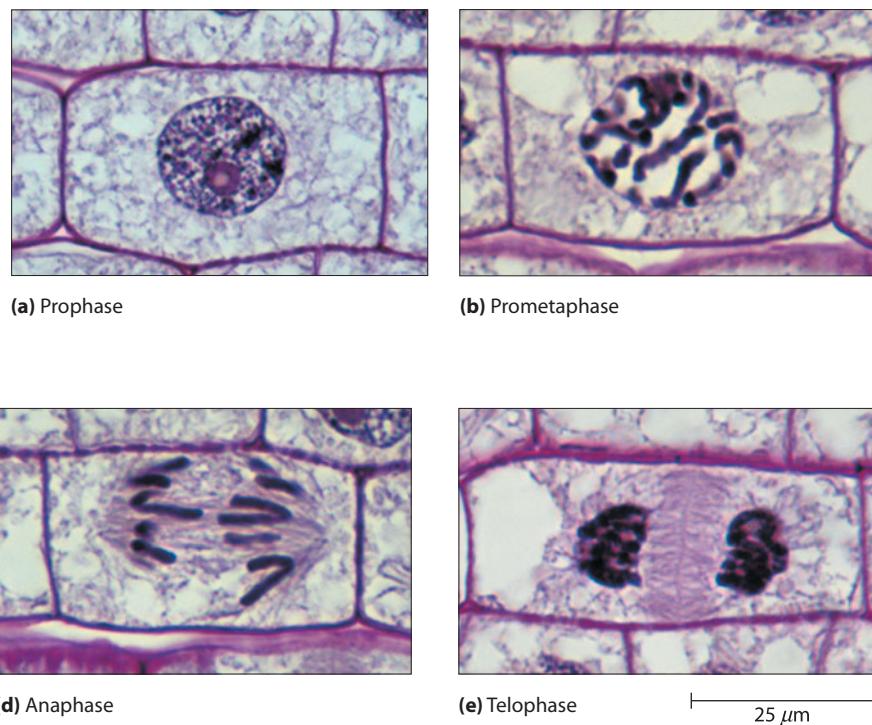

Meanwhile, another important organelle has sprung into action. This is the **centrosome**, a small zone of granular material located adjacent to the nucleus. As described in Chapter 15, the centrosome functions as a *microtubule-organizing center (MTOC)* where microtubules are

assembled and anchored. Some studies also suggest that centrosomes may be involved in orienting the spindle within the cell, which in turn determines the position of the cleavage plane during cell division. During each cell cycle, the centrosome is duplicated prior to mitosis, usually during S phase. At the beginning of prophase the two centrosomes then separate from each other and move toward opposite sides of the nucleus. As they move apart, each centrosome acts as a nucleation site for microtubule assembly and the region between the two centrosomes begins to fill with microtubules destined to form the **mitotic spindle**, the structure that distributes the chromosomes to the daughter cells later in mitosis. During this process, cytoskeletal microtubules disassemble and their tubulin subunits are added to the growing mitotic spindle. At the same time, a dense starburst of microtubules called an *aster* forms in the immediate vicinity of each centrosome.

Embedded within the centrosome of animal cells is a pair of small, cylindrical, microtubule-containing structures called *centrioles* (page 430), often oriented at right angles to each other. Because centrioles are absent in certain cell types, including most plant cells, they cannot be essential to the process of mitosis. They do, however, play an essential role in the formation of cilia and flagella (page 453).

Prometaphase. The onset of **prometaphase** is marked by fragmentation of the membranes of the nuclear envelope. As the centrosomes complete their movement toward opposite sides of the nucleus (Figure 19-20b), the breakdown of the nuclear envelope allows the spindle microtubules to enter the nuclear area and make contact

FIGURE 19-21 The Phases of Mitosis in a Plant Cell. These micrographs show mitosis in cells of an onion root viewed by light microscopy.

with the chromosomes, which still consist of paired chromatids at this stage. The spindle microtubules are destined to attach to the chromatids in the region of the **centromere**, a constricted area where the two members of each chromatid pair are held together. The DNA of each centromere consists of simple-sequence, tandemly repeated *CEN sequences*, whose makeup varies considerably among species. Despite this diversity, a common feature of centromere regions is the presence of specialized nucleosomes in which histone H3 is replaced by a related protein, which in humans is called *CENP-A* (*centromere protein A*).

CENP-A plays a key role in recruiting additional proteins to the centromere to form the **kinetochore**, which is the structure that attaches the paired chromatids to the spindle microtubules. Kinetochore proteins begin to associate with the centromere shortly after DNA is replicated during S phase; additional proteins are sequentially added later until mature kinetochores, containing more than 50 different proteins, have been assembled. As shown in **Figure 19-22a**, each chromosome eventually acquires two kinetochores facing in opposite directions, one associated with each of the two chromatids. During prometaphase some spindle microtubules bind to these kinetochores, thereby attaching the chromosomes to the spindle. Forces exerted by these **kinetochore microtubules** then throw the chromosomes into agitated motion and gradually move them toward the center of the cell, in a process known as *congression* (Figure 19-22b).

In addition to kinetochore microtubules, there are two other kinds of microtubules in the spindle. Those that interact with microtubules from the opposite pole of the cell are called **polar microtubules**; the shorter ones that form the

asters (from the Greek word for “star”) at each pole are called **astral microtubules**. Some of the astral microtubules appear to interact with proteins lining the plasma membrane.

Metaphase. A cell is said to be in **metaphase** when the fully condensed chromosomes all become aligned at the **metaphase plate**, the plane equidistant between the two poles of the mitotic spindle (Figure 19-20c). Agents that interfere with spindle function, such as the drug *colchicine*, can be used to arrest cells at metaphase. Microscopic examination of such cells allows individual chromosomes to be identified and classified based on differences in size and shape, generating an analysis known as a **karyotype** (Figure 19-23).

At metaphase the chromosomes appear to be relatively stationary, but this appearance is misleading. Actually, the two sister chromatids of each chromosome are already being actively tugged toward opposite poles. They appear stationary because the forces acting on them are equal in magnitude and opposite in direction; the chromatids are the prizes in a tug-of-war between two equally strong opponents. (We will discuss the source of these opposing forces shortly.)

Anaphase. Usually the shortest phase of mitosis, **anaphase** typically lasts only a few minutes. At the beginning of anaphase, the two sister chromatids of each chromosome abruptly separate and begin moving toward opposite spindle poles at a rate of about $1 \mu\text{m}/\text{min}$ (Figure 19-20d).

Anaphase is characterized by two kinds of movements, called **anaphase A** and **anaphase B** (Figure 19-24). In **anaphase A**, the chromosomes are pulled, centromere

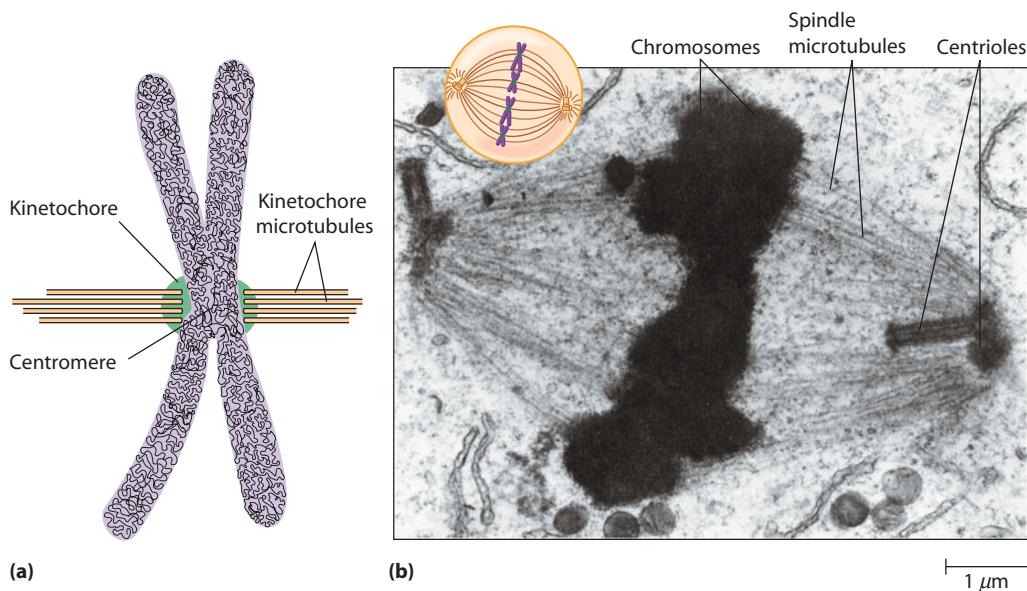

FIGURE 19-22 Attachment of Chromosomes to the Mitotic Spindle. (a) A schematic model summarizing the relationship between the centromere, kinetochores, and kinetochore microtubules. (b) This electron micrograph shows the mitotic spindle of a metaphase cell from a rooster. The centrioles at the two poles and the spindle between the poles are clearly visible. The chromosomes appear as a single mass aligned at the spindle equator. Although individual chromosomes cannot be distinguished in this type of micrograph, the individual chromosomes remain distinct from one another at this stage of mitosis (TEM).

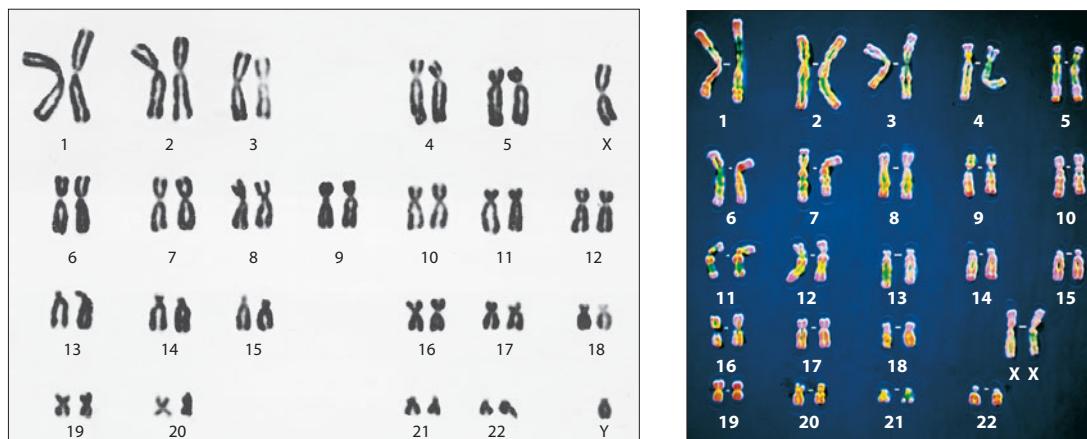

FIGURE 19-23 Mitotic Karyotype of Human Chromosomes from Metaphase-Arrested Cells. (Left) This set of human male chromosomes was stained with a dye that reacts uniformly with the entire body of the chromosome. Human males contain 22 pairs of chromosomes, plus one X and one Y chromosome. The chromosomes in the karyotype have been arranged according to size and centromere position. (Right) This set of human female chromosomes was stained with dyes that selectively react with certain chromosome regions, creating a unique banding pattern for each type of chromosome.

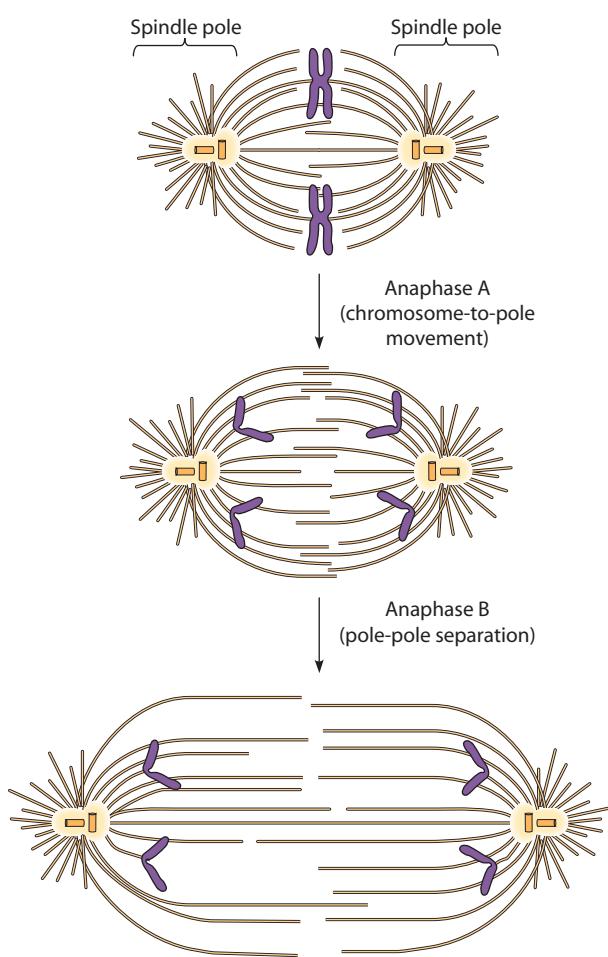

FIGURE 19-24 The Two Types of Movement Involved in Chromosome Separation During Anaphase. Anaphase A involves the movement of chromosomes toward the spindle poles. Anaphase B is the movement of the two spindle poles away from each other. Anaphase A and anaphase B may occur simultaneously.

[VIDEOS www.thecellplace.com](http://www.thecellplace.com) Spindle formation during mitosis

first, toward the spindle poles as the kinetochore microtubules get shorter and shorter. In **anaphase B**, the poles themselves move away from each other as the polar microtubules lengthen. Depending on the cell type involved, anaphase A and B may take place at the same time, or anaphase B may follow anaphase A.

Telophase. At the beginning of **telophase**, the daughter chromosomes have arrived at the poles of the spindle (Figure 19-20e). Next the chromosomes uncoil into the extended fibers typical of interphase chromatin, nucleoli develop at the nucleolar organizing sites on the DNA, the spindle disassembles, and nuclear envelopes form around the two groups of daughter chromosomes. During this period the cell usually undergoes cytokinesis, which divides the cell into two daughter cells.

The Mitotic Spindle Is Responsible for Chromosome Movements During Mitosis

The central purpose of mitosis is to separate the two sets of daughter chromosomes and partition them into the two newly forming daughter cells. To understand the mechanisms that allow this to be accomplished, we need to take a closer look at the microtubule-containing apparatus responsible for these events, the mitotic spindle.

Spindle Assembly and Chromosome Attachment. We saw in Chapter 15 that the tubulin subunits of a microtubule all face in the same direction, thereby giving microtubules an inherent *polarity*; that is, the two ends of each microtubule are chemically different (Figure 19-25). The end where microtubule assembly is initiated—located at the centrosome for spindle microtubules—is the minus (−) end. The end where most growth occurs, located away from the centrosome, is the plus (+) end. Microtubules are dynamic structures (see

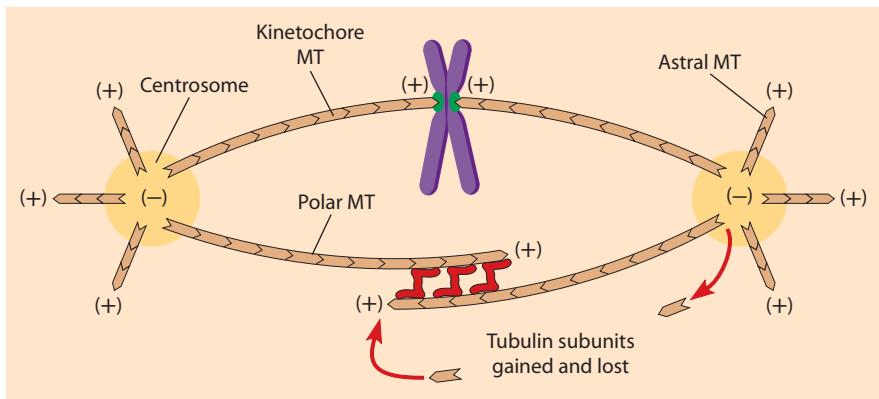

FIGURE 19-25 Microtubule Polarity in the Mitotic Spindle. This diagram shows only a few representatives of the many microtubules making up a spindle. The orientation of the tubulin subunits constituting a microtubule (MT) make the two ends of the MT different. The minus end is at the initiating centrosome; the plus end points away from the centrosome. MTs lengthen by adding tubulin subunits and shrink by losing subunits. In general, lengthening is due to addition at the plus ends and shortening to loss at the minus ends, but subunits can also be removed from the plus ends. The red structures between the plus ends of the polar MTs shown here represent proteins that crosslink them.

Chapter 15), in that tubulin subunits are continually being added and subtracted from both ends. When more subunits are being added than removed, the microtubule gets longer. In general, the plus end is the site favored for the addition of tubulin subunits and the minus end favored for subunit removal, so increases in microtubule length come mainly from addition of subunits to the plus end.

During late prophase, microtubule growth speeds up dramatically and initiation of new microtubules at the centrosomes increases. Once the nuclear envelope disintegrates at the beginning of prometaphase, contact between microtubules and chromosomal kinetochores becomes possible. When contact is made between a kinetochore and the plus end of a microtubule, they bind to each other and the microtubule becomes known as a kinetochore microtubule. This binding slows down depolymerization at the plus end of the microtubule, although polymerization and depolymerization can still occur there.

Figure 19-26 is an electron micrograph of a metaphase chromosome with two sets of attached microtubules, whose plus ends are embedded in the two kinetochores. Each kinetochore is a platelike, three-layered structure made of proteins attached to CEN sequences located in the centromere's DNA. Kinetochores of different species vary in size. In yeast, for example, they are small and bind only one spindle microtubule each, whereas the kinetochores of mammalian cells are much larger, each binding 30–40 microtubules.

Because the two kinetochores are located on opposite sides of a chromosome, they usually attach to microtubules emerging from centrosomes located at opposite poles of the cell. (The orientation of each chromosome is random; either kinetochore can end up facing either pole.) Meanwhile, the other main group of microtubules—the polar microtubules—make direct contact with polar microtubules coming from the opposite centrosome. When the plus-end regions of two microtubules of opposite polarity start to overlap, crosslinking proteins bind them to each other (Figure 19-25). Like the crosslinking between kinetochores and kinetochore microtubules, this crosslinking stabilizes the polar microtubules. Thus, we

can picture a barrage of microtubules rapidly shooting out from each centrosome during late prophase and prometaphase. The ones that successfully hit a kinetochore or a microtubule of opposite polarity are stabilized; the others retreat by disassembling.

One shortcoming of the preceding mechanism is that it does not explain how spindles are assembled in cells lacking centrosomes, which includes most of the cells of higher plants and the oocytes (immature eggs) of many animals. Moreover, experiments using a laser microbeam to destroy centrosomes have shown that animal cells that normally contain centrosomes can assemble spindles using a centrosome-independent mechanism. In cells lacking centrosomes, chromosomes rather than centrosomes promote microtubule assembly and spindle formation. Chromosome-induced microtubule assembly requires the involvement of *Ran*, the GTP-binding protein whose role in nuclear transport was described in Chapter 18 (see Figure 18-31). Mitotic chromosomes possess a

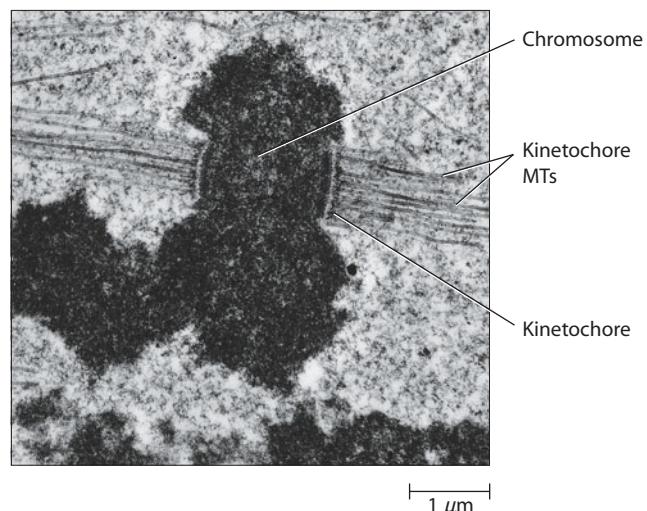

FIGURE 19-26 Kinetochores and Their Microtubules. The striped structures on either side of this metaphase chromosome are its kinetochores, each associated with one of the two sister chromatids. Numerous kinetochore MTs are attached to each kinetochore. The two sets of microtubules come from opposite poles of the cell (TEM).

protein that promotes the binding of GTP to Ran. The Ran-GTP complex then interacts with the protein *importin*, just as it does during nuclear transport, leading to the release of importin-bound proteins that promote microtubule assembly. So in cells lacking centrosomes, spindle formation is initiated in the vicinity of the chromosomes rather than at the spindle poles. Even in the more common case of cells that use centrosomes to generate spindle microtubules, Ran-GTP is thought to help organize the newly forming spindle and guide the attachment of microtubules to chromosomal kinetochores.

Chromosome Alignment and Separation. When spindle microtubules first become attached to chromosomal kinetochores during early prometaphase, the chromosomes are randomly distributed throughout the spindle. The chromosomes then migrate toward the central region of the spindle through a series of agitated, back-and-forth motions generated by at least two different kinds of forces. First, the kinetochore microtubules exert a “pulling” force, moving the chromosomes toward the pole that the microtubules are attached to. This force can be demonstrated experimentally by using glass microneedles to tear individual chromosomes away from the spindle. A chromosome that has been removed from the spindle remains motionless until new microtubules attach to its kinetochore, at which time the chromosome is drawn back into the spindle.

The second force tends to “push” chromosomes away if they approach either spindle pole. The existence of this pushing force has been demonstrated by studies in which a laser microbeam is used to break off one end of a chromosome. Once the broken chromosome fragment has been cut free from its associated centromere and kinetochore, the fragment tends to move away from the nearest spindle pole, even though it is no longer attached to the spindle by microtubules. The nature of the pushing force that propels chromosomes in the absence of microtubule attachments has not yet been clearly identified.

The combination of pulling and pushing forces exerted on the chromosomes drives them to the metaphase plate, their most stable location, where they line up in random order. Although the chromosomes appear to stop moving at this point, careful microscopic study of living cells reveals that they continue to make small jerking movements, indicating that the chromosomes are under constant tension in both directions. If the kinetochore on one side of a metaphase chromosome is severed using a laser microbeam, the chromosome promptly moves toward the opposite spindle pole. Hence, metaphase chromosomes remain at the center of the spindle because the forces pulling them toward opposite poles are precisely balanced.

At the beginning of anaphase, the two chromatids of each metaphase chromosome split apart and start moving toward opposite spindle poles. Several molecules have been implicated in this process of chromatid separation.

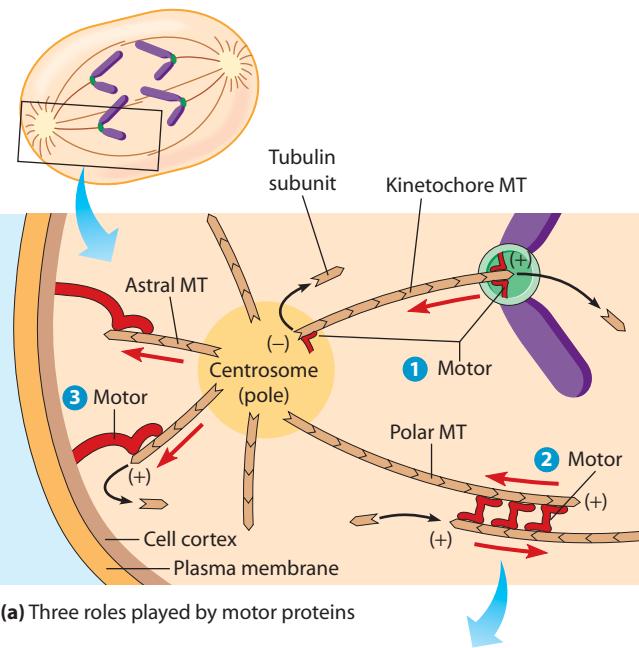

One is the enzyme topoisomerase II, which concentrates near the centromere and catalyzes changes in DNA supercoiling. In mutant cells lacking topoisomerase II, the paired chromatids still attempt to separate at the beginning of anaphase, but they tear apart and are damaged instead of being properly separated. Chromatid separation also involves changes in adhesive proteins that hold the paired chromatids together before the onset of anaphase. As we will see later in the chapter, degradation of these adhesive proteins at the beginning of anaphase allows the sister chromatids to separate.

Motor Proteins and Chromosome Movement. Once the two chromatids of each metaphase chromosome have split apart, they function as two independent chromosomes that move to opposite spindle poles. Studies of the mechanisms underlying this movement have led to the discovery of several **motor proteins** that play active roles in mitosis. As we saw in Chapters 15 and 16, motor proteins use energy derived from ATP to change shape in such a way that they exert force and cause attached structures to move. Motor proteins play at least three distinct roles in the movement of anaphase chromosomes.

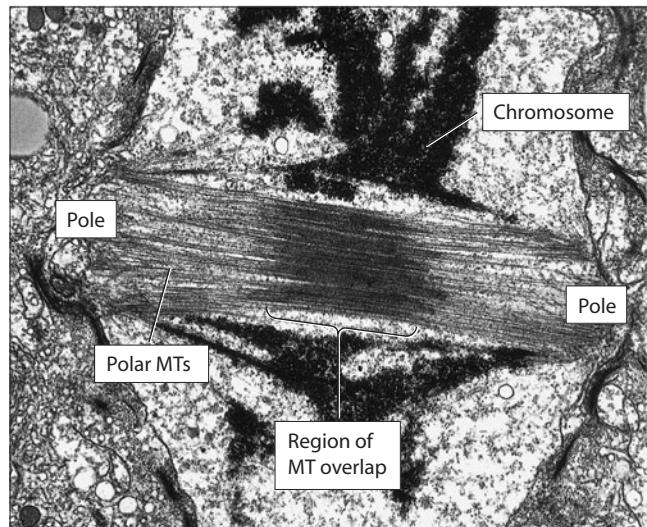

The first role involves the mechanism that moves chromosomes, kinetochores first, toward the spindle poles during anaphase A. As shown in **Figure 19-27a** (1), this type of chromosome movement is driven by motors associated with kinetochore microtubules. Considerable evidence suggests that these motors are specialized members of the *kinesin* family of proteins. In Chapter 16 we saw that some specialized kinesins can bind to the end of a microtubule and induce it to depolymerize. Two such kinesin-like motors are involved in moving chromosomes toward the spindle poles: One is located at the plus end of the kinetochore microtubules, and the other is located at the minus end. The motor located at the plus end is embedded in the kinetochore, where it induces microtubule depolymerization and thereby moves the chromosome toward the spindle pole as it “chews up” the plus end of the microtubule. At the same time, the motor located at the minus end is embedded in the spindle pole, where it induces microtubule depolymerization and thereby “reels in” the microtubules and their attached chromosomes.

Several lines of evidence support this view that microtubule depolymerization plays a crucial role in chromosome movement. For example, if cells are exposed to the drug *taxol*, which inhibits microtubule depolymerization, chromosomes do not move toward the spindle poles. Conversely, exposing cells to increased pressure, which increases the rate of microtubule depolymerization, causes chromosomes to move toward the poles more quickly. Finally, antibodies that inhibit the depolymerizing activity of either the motor protein located at the spindle pole or the motor protein located at the kinetochore have both been shown to interfere with chromosome movement.

The second role played by motor proteins during anaphase is associated with the movement of the spindle

FIGURE 19-27 Mitotic Motors. (a) A model for mitotic chromosome movement based on three roles played by motor proteins. Motor proteins are shown in red, and the small red arrows indicate the direction of movement generated by these motors. Motor proteins are associated with three types of microtubules: kinetochore MTs, polar MTs, and astral MTs. ① Kinetochore MTs have motor proteins associated with both their plus ends (embedded in the chromosomal kinetochore) and their minus ends (located in the centrosome of the spindle pole). The motor proteins located at the kinetochore “chew up” (i.e., depolymerize) the plus ends of the kinetochore MTs. In this way, the chromosome is pulled toward the spindle pole as the kinetochore MTs are shortened through the loss of tubulin subunits. Simultaneously, motor proteins located at the spindle pole depolymerize the minus ends of the kinetochore MTs, reeling in the MTs and their attached chromosomes. ② Motor proteins crosslink the polar MTs and cause them to slide apart, thereby forcing the spindle poles away from each other. As the polar MTs slide apart, they are lengthened by the addition of tubulin subunits to their plus ends where they overlap near the spindle center. ③ Astral MT motor proteins link the plus ends of astral MTs to the cell cortex and exert a pull on the spindle poles by inducing astral MT depolymerization at their plus ends. (b, c) The two electron micrographs provide evidence for the sliding of polar MTs driven by polar MT motors. During metaphase, the polar MTs from opposite ends of the cell overlap significantly. During anaphase, the polar MT motors cause these two groups of MTs to slide away from each other, thereby resulting in a reduced region of overlap (TEMs). (MT = microtubule)

poles away from each other during anaphase B. In this case, bipolar kinesin motors bind to overlapping polar microtubules coming from opposite spindle poles, causing the polar microtubules to slide apart, thereby forcing the spindle poles away from each other (Figure 19-27a, ②). As the microtubules slide apart, they are lengthened by the addition of tubulin subunits to their plus ends near the center of the spindle, where microtubules coming from opposite spindle poles overlap. Microtubule sliding can be experimentally induced by exposing isolated spindles to ATP, indicating that the motor proteins use energy derived from ATP hydrolysis to cause the overlapping microtubules to slide away from one another. During anaphase B, this motor activity may be the primary force that elongates the spindle, while the lengthening of the polar microtubules is secondary. In Figure 19-27, parts b and c provide electron microscopic evidence for the sliding of overlapping polar microtubules during anaphase B.

The third type of motor-produced force detected during anaphase involves *cytoplasmic dynein*, which is associated with astral microtubules (Figure 19-27a, ③). The plus ends of astral microtubules are connected to the *cell cortex*, a layer of actin microfilaments lining the inner surface of the plasma membrane. Cytoplasmic dynein, which moves toward the minus end of microtubules, appears to pull each spindle pole toward the cortex. Such pulling—in addition to the outward push generated by the motor proteins that crosslink the overlapping polar microtubules—helps to separate the spindle poles during anaphase B in some cell types.

Mitosis therefore involves at least three separate groups of motor proteins, operating on kinetochore microtubules, polar microtubules, and astral microtubules, respectively (Figure 19-27a). The relative contributions of the pushing and pulling forces generated by these three sets of motor proteins differ among organisms. For example, in diatoms and yeast, the pushing (sliding) of microtubules against adjacent ones of opposite polarity is particularly important in anaphase B. In contrast, pulling at the asters is the main force in the cells of certain other fungi. In vertebrates both mechanisms are probably operative, although astral pulling may play a greater role, especially during spindle formation.

Cytokinesis Divides the Cytoplasm

After the two sets of chromosomes have separated during anaphase, cytokinesis divides the cytoplasm in two, thereby completing the process of cell division. Cytokinesis usually starts during late anaphase or early telophase, as the nuclear envelope and nucleoli are re-forming and the chromosomes are decondensing. Cytokinesis is not inextricably linked to mitosis, however. In some cases, a significant time lag may occur between nuclear division (mitosis) and cytokinesis, indicating that the two processes are not tightly coupled. Moreover, certain cell types can undergo many rounds of chromosome replication and nuclear division in the absence of cytokinesis, thereby producing a large, multinucleate cell known as a *syncytium*. Sometimes the multinucleate condition is permanent; in other situations, the multinucleate state is only a temporary phase in the organism's development. This is the case, for example, in the development of a plant seed tissue called *endosperm* in cereal grains. Here, nuclear division occurs for a time unaccompanied by cytokinesis, generating many nuclei in a common cytoplasm. Successive rounds of cytokinesis then occur without mitosis, walling off the many nuclei into separate endosperm cells. A similar process occurs in some insect embryos.

Despite these examples, in most cases cytokinesis does accompany or closely follow mitosis, thereby ensuring that each of the daughter nuclei acquires its own cytoplasm and becomes a separate cell.

Cytokinesis in Animal Cells. The mechanism of cytokinesis differs between animals and plants. In animal cells, cytoplasmic division is called **cleavage**. The process begins as a slight indentation or puckering of the cell surface, which deepens into a **cleavage furrow** that encircles the cell, as shown in Figure 19-28 for a fertilized frog egg. The furrow continues to deepen until opposite surfaces make contact and the cell is split in two. The cleavage furrow divides the cell along a plane that passes through the central region of the spindle (the *spindle equator*), suggesting that the location of the spindle determines where the cytoplasm will be divided. This idea has been investigated experimentally by moving the mitotic spindle

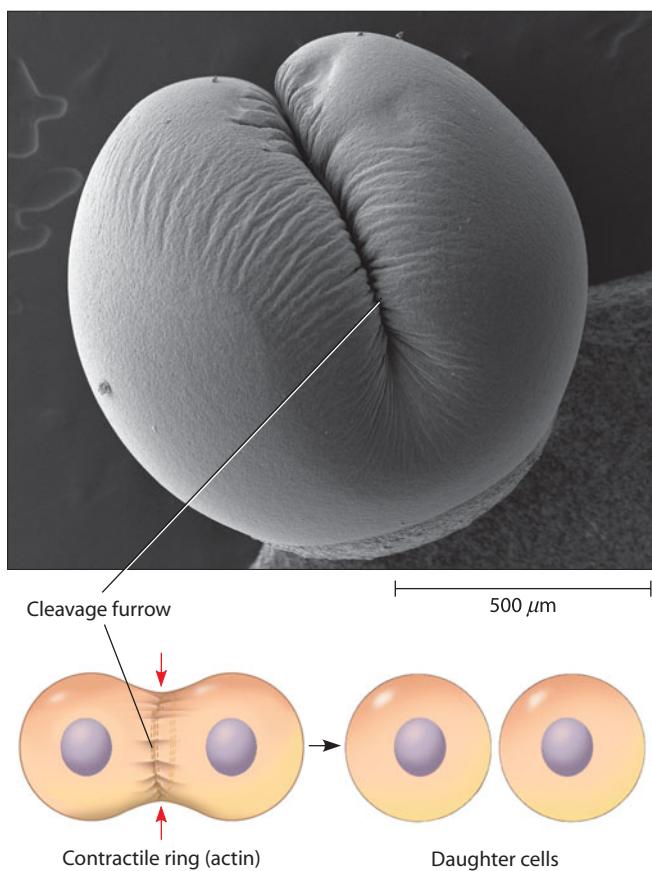

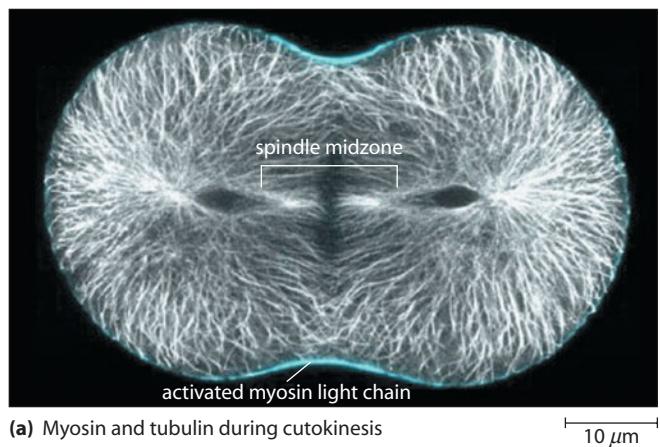

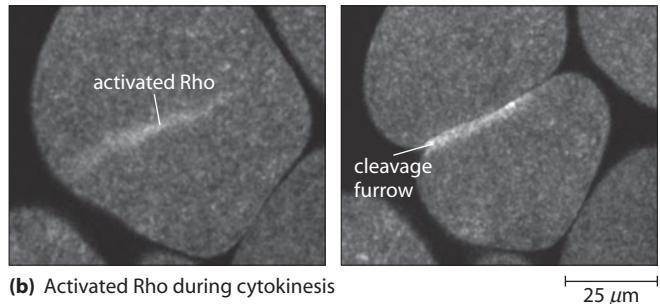

FIGURE 19-28 Cytokinesis in an Animal Cell. (Top) An electron micrograph of a fertilized frog egg caught in the act of dividing. The cleavage furrow is clearly visible as an inward constriction of the plasma membrane (SEM). (Bottom) A schematic diagram showing the position of the contractile ring during cytokinesis, which pinches the dividing cell in two (red arrows).

using either tiny glass needles or gravitational forces generated by centrifugation. If the spindle is moved before the end of metaphase, the orientation of the cleavage plane changes so that it passes through the new location of the spindle equator. There is good evidence to suggest that signals emanating from the central portion of the spindle, known as the *spindle midzone*, are important for completion of cytokinesis (Figure 19-29a). For example, in nematode worm or fruit fly cells lacking components of a multiprotein complex (known as *centralspindlin*) found in the spindle midzone, cytokinesis begins, but the cleavage furrow regresses. The activity of astral microtubules may complement the work of the spindle midzone by inhibiting formation of a cleavage furrow in other regions of the cortex.

Cleavage depends on a beltlike bundle of actin microfilaments called the **contractile ring**, which forms just beneath the plasma membrane during early anaphase (Figure 19-29a). Examination of the contractile ring with an electron microscope reveals large numbers of actin filaments oriented with their long axes parallel to the furrow. As cleavage progresses, this ring of microfilaments tightens around the cytoplasm, like a belt around the waist, eventually pinching the cell in two. Tightening of the contractile

(a) Myosin and tubulin during cytokinesis

(b) Activated Rho during cytokinesis

FIGURE 19-29 Myosin and Rho During Cytokinesis. (a) A confocal micrograph of a sea urchin zygote, showing microtubules in white and activated myosin regulatory light chain in blue. Active myosin accumulates at the cleavage furrow. (b) A fluorescent protein that binds active Rho accumulates in the cleavage furrow of cells in a *Xenopus* (frog) embryo. Accumulation of active Rho precedes furrowing (left); the same cell four minutes later has formed a furrow at the site where Rho accumulated (right).

ring is generated by interactions between the actin microfilaments and *myosin*, the motor protein whose role in muscle contraction was described in Chapter 16.

The contractile ring provides a dramatic example of how rapidly actin-myosin complexes can be assembled and disassembled in nonmuscle cells. Members of the *Rho* family of GTP-binding proteins play a central role in regulating the assembly and activation of the contractile ring. One family member, called RhoA, is recruited to the cleavage furrow (Figure 19-29b), where it helps orchestrate cytokinesis by activating proteins that promote actin polymerization. RhoA also stimulates protein kinases that phosphorylate myosin, the key step in activating myosin to perform its motor function in tightening the contractile ring.

Cytokinesis in Plant Cells. Cytokinesis in higher plants is fundamentally different from the corresponding process in animal cells. Because plant cells are surrounded by a rigid cell wall, they cannot form a contractile ring at the cell surface that pinches the cell in two. Instead, they divide by assembling a plasma membrane and a cell wall between the two daughter nuclei (Figure 19-30). In other words, rather than pinching the cytoplasm in half with a contractile ring

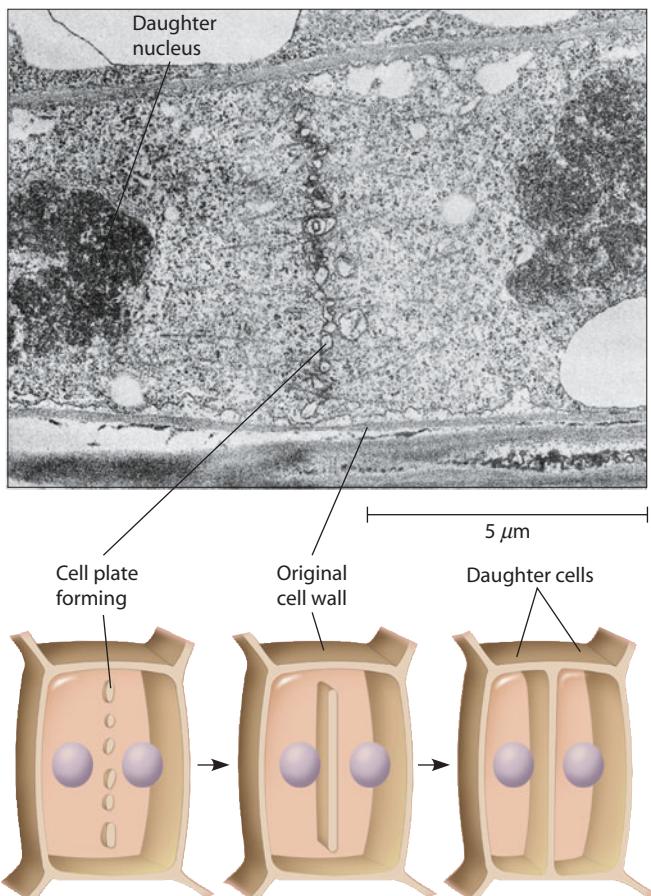

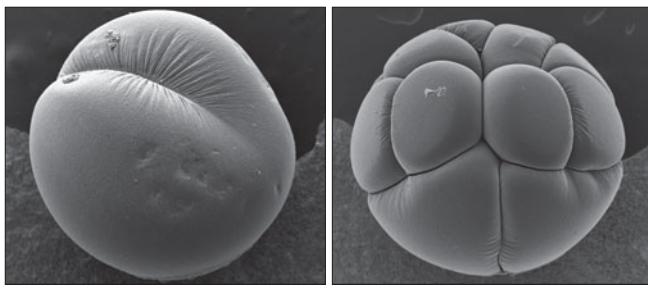

FIGURE 19-30 Cytokinesis and Cell Plate Formation in a Plant Cell. (Top) A cell from the sugar maple, *Acer saccharinum*, at late telophase. The daughter nuclei with their sets of chromosomes are partially visible as the dark material on the far right and far left of the micrograph, and the developing cell plate is seen as a line of vesicles in the midregion of the cell. The microtubules of the phragmoplast are oriented perpendicular to the cell plate (TEM). (Bottom) A schematic diagram showing the location of the cell plate and the original cell wall of a dividing plant cell.

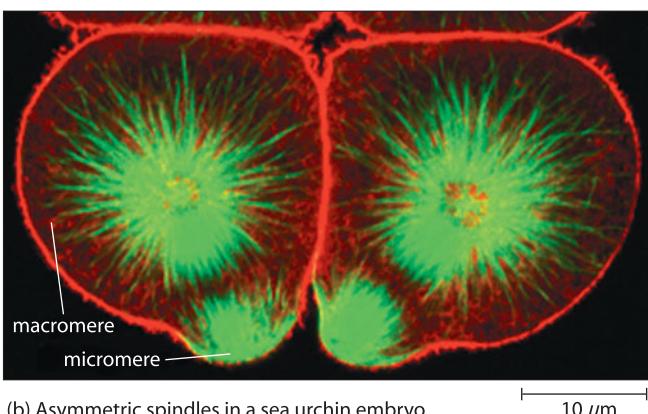

that moves from the outside of the cell toward the interior, the plant cell cytoplasm is divided by a process that begins in the cell interior and works toward the periphery.

Cytokinesis in plants is typically initiated during late anaphase or early telophase, when a group of small, membranous vesicles derived from the Golgi complex align themselves across the equatorial region of the spindle. These vesicles, which contain polysaccharides and glycoproteins required for cell wall formation, are guided to the spindle equator by the **phragmoplast**, a parallel array of microtubules derived from polar microtubules and oriented perpendicular to the direction in which the new cell wall is being formed. After arriving at the equator, the Golgi-derived vesicles fuse together to produce a large, flattened sac called the **cell plate**, which represents the cell wall in the process of formation. The contents of the sac assemble to form the noncellulose components of the primary cell wall, which expands outward as clusters of microtubules and vesicles form at the lateral edges of the

FIGURE 19-31 Asymmetric Cleavage in Animal Embryos.

(a) Amphibian eggs (left) are very large, with enough cytoplasm to sustain many rounds of cell division after fertilization. Each round of division during early development parcels the cytoplasm into smaller cells. Some cells are much larger than others (right). (b) Two cells of an 8-cell sea urchin embryo stained for microtubules (green) and actin (red). Each cell is about to divide to form a much larger cell (a “macromere”) and a smaller cell (“micromere”). The spindle is highly asymmetric in its location.

advancing cell plate. Eventually, the expanding cell plate makes contact with the original cell wall, separating the two daughter cells from each other. The new cell wall is then completed by deposition of cellulose microfibrils. The plasmodesmata that provide channels of continuity between the cytoplasms of adjacent plant cells are also present in the cell plate and the new wall as it forms.

Cell Division Is Sometimes Asymmetric

The division plane passes through the spindle equator in both animal and plant cells. When the spindle is positioned across the middle of the cell, as is typically the case, there is a roughly even division of components between the two new cells. Cytoplasmic division is not always symmetric, however. In the budding yeast *Saccharomyces cerevisiae*, for example, the mitotic spindle forms in a highly asymmetric fashion, creating one large cell and one very small cell (see Figure 1B-1). Asymmetric divisions also occur frequently during embryonic development in animal embryos. Such asymmetric division often results in cells that not only vary dramatically in size but also acquire different developmental potential (**Figure 19-31**). Asymmetric divisions also take

place in female animals during the development of egg cells from precursor cells called *oocytes*. In this case, cytokinesis divides the cytoplasm unequally so that the cell destined to become the egg receives the bulk of the cytoplasm of the original oocyte (see Figure 20-9b), thereby maximizing the content of stored nutrients in each egg.

Cell division can also involve a more subtle type of asymmetry in which daughter cells look alike but have different fates. Such differences in cell fate are generated by mechanisms in which specific molecules located in certain regions of the parental cytoplasm are distributed unequally to the two daughter cells, thereby determining their unique fates.

Regulation of the Cell Cycle

Earlier in the chapter, we described a typical eukaryotic cell cycle in which G₁, S, G₂, and M phases are completed in orderly progression over a period of roughly 24 hours. Such a pattern is common in growing organisms and in cultured cells that have not run out of nutrients or space. But many variations are also observed, especially in the overall length of the cycle, the relative length of time spent in various phases, and how closely mitosis and cytokinesis are coupled. This variability tells us that the cell cycle must be regulated to meet the needs of each cell type and organism. The molecular basis of such cell cycle regulation is a subject of intense interest, not only for understanding the life cycles of normal cells but also for understanding how cancer cells manage to escape these normal control mechanisms.

The Length of the Cell Cycle Varies Among Different Cell Types

Some of the most commonly encountered variations in the cell cycle involve differences in how fast cells divide. In multicellular organisms, generation times vary markedly among cell types, depending on their role in the organism. At one extreme are cells that divide continuously as a means of replacing cells that are constantly being lost or destroyed. Included in this category are cells involved in sperm formation and the *stem cells* that give rise to blood cells, skin cells, and the epithelial cells that form the inner lining of body organs such as the lungs and intestines. Human stem cells may have generation times as short as 8 hours.

In contrast, cells located in slow-growing tissues may have generation times of several days or more, and some cells, such as those of mature nerve or muscle tissue, do not divide at all. Still other cell types do not divide under normal conditions but can be induced to start dividing again by an appropriate stimulus. Liver cells are in this category; they do not normally proliferate in the mature liver but can be induced to do so if a portion of the liver is removed surgically. Lymphocytes (white blood cells) are another example; when exposed to a foreign protein, they begin dividing as part of the immune response.

Most of these variations in generation time are based on differences in the length of G1, although S and G2 can also vary. Cells that divide slowly may spend days, months, or even years in the offshoot of G1 called G0, whereas cells that divide very rapidly have a short G1 phase or even eliminate G1 entirely. The embryonic cells of insects, amphibians, and several other nonmammalian animals are dramatic examples of cells that have very short cell cycles, with no G1 phase and a very short S phase. For example, during early embryonic development of the frog *Xenopus laevis*, each round of division simply subdivides the initial cytoplasm into smaller and smaller cells, until the cell size typical of adult tissues is reached (see Figure 19-31a). The cell cycle takes less than 30 minutes, even though the normal length of the cell cycle in adult tissues is about 20 hours. The rapid rate of DNA synthesis needed to sustain such a quick cell cycle is achieved in part by increasing the total number of replicons, thereby decreasing the amount of DNA that each replicon must synthesize. In addition, all replicons are activated at the same time, in contrast to the sequential activation observed in adult tissues. By increasing the number of replicons and activating them all simultaneously, S phase is completed in less than 3 minutes, at least 100 times faster than in adult tissues of the same organism.

Although we know from such examples that cell growth is not essential to the cell cycle, the two are generally linked so that cells can divide without getting progressively smaller. A protein kinase called *TOR* (*target of rapamycin*) plays a central role in the signaling network that controls cell size and coordinates it with cell cycle progression. This signaling network activates TOR in the presence of nutrients and growth factors, and the activated TOR then stimulates molecules that control the rate of protein synthesis. The resulting increase in protein production leads to an increase in cell mass. Some of the molecules activated by TOR also facilitate entry into S phase, making TOR an important regulator of both cell growth and cell cycle progression.

Progression Through the Cell Cycle Is Controlled at Several Key Transition Points

The control system that regulates progression through the cell cycle must accomplish several tasks. First, it must ensure that the events associated with each phase of the cell cycle are carried out at the appropriate time and in the appropriate sequence. Second, it must make sure that each phase of the cycle has been properly completed before the next phase is initiated. Finally, it must be able to respond to external conditions that indicate the need for cell proliferation (e.g., the quantity of nutrients available or the presence of growth-signaling molecules).

The preceding objectives are accomplished by a group of molecules that act at key transition points in the cell cycle (Figure 19-32). At each of these points, conditions within the cell determine whether the cell will proceed to

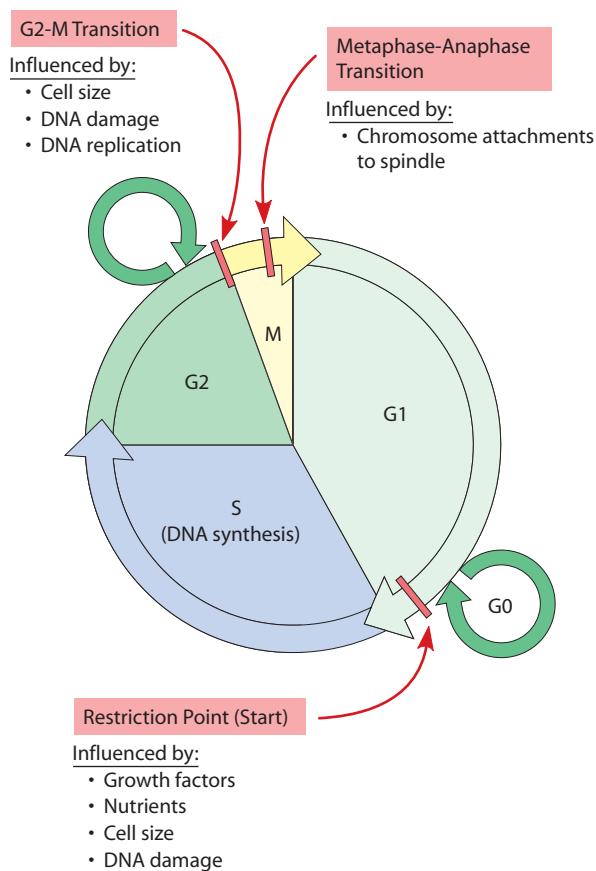

FIGURE 19-32 Key Transition Points in the Cell Cycle. The red bars mark three important transition points in the eukaryotic cell cycle where control mechanisms determine whether the cell will continue to proceed through the cycle. That determination is based on chemical signals reflecting both the cell's internal state and its external environment. The two circular, dark green arrows indicate locations in late G1 and late G2 where the cell can exit from the cycle and enter a nondividing state.

the next stage of the cycle. The first such control point occurs during late G1. We have already seen that G1 is the phase that varies most among cell types, and mammalian cells that have stopped dividing are almost always arrested during G1. For example, in cultured cells the process of cell division can be stopped or slowed by allowing the cells to run out of either nutrients or space or by adding inhibitors of vital processes such as protein synthesis. In all such cases, the cell cycle is halted in late G1, suggesting that progression from G1 into S is a critical control point in the cell cycle. In yeast, this control point is called **Start**; yeast cells must have sufficient nutrients and must reach a certain size before they can pass through Start. In animal cells, the comparable control point is called the **restriction point**. The ability to pass through the restriction point is influenced by the presence of extracellular *growth factors* (page 407), which are proteins used by multicellular organisms to stimulate or inhibit cell proliferation. Cells that have successfully passed through the restriction point are committed to S phase, whereas those that do not pass the restriction point enter into G0 and reside there for

variable periods of time, awaiting a signal that will allow them to reenter G1 and pass through the restriction point.

A second important transition point occurs at the G2-M boundary, where the commitment is made to enter into mitosis. In certain cell types, the cell cycle can be indefinitely arrested at the end of G2 if cell division is not necessary; under such conditions, the cells enter a nondividing state analogous to G0. The relative importance of controls exerted during late G2 or late G1 in regulating the rate of cell division by transiently halting the cell cycle varies with the organism and cell type. In general, arresting the cell cycle in late G1 (at the restriction point) is the more prevalent type of control in multicellular organisms. But in a few cases, such as the division of fertilized frog eggs or in some skin cells, G2 arrest is more important.

A third key transition point occurs during M phase at the junction between metaphase and anaphase, where the commitment is made to move the two sets of chromosomes into the newly forming daughter cells. Before cells can pass through this transition point and begin anaphase, it is important to have all the chromosomes properly attached to the spindle. If the two chromatids that make up each chromosome are not properly attached to opposite spindle poles, the cell cycle is temporarily arrested to allow spindle attachment to occur. Without such a mechanism, there would be no guarantee that each of the newly forming daughter cells would receive a complete set of chromosomes.

Cell behavior at the various transition points is influenced both by successful completion of preceding events in the cycle (such as chromosome attachment to the spindle) and by factors in the cell's environment (such as nutrients and growth factors). But whatever the particular influences may be, their effects on cell cycle progression are mediated by a group of related control molecules that activate or inhibit one another in chains of interactions that can be quite elaborate. Let's now see how these control molecules were identified and what functions they perform.

Studies Involving Cell Fusion and Cell Cycle Mutants Led to the Identification of Molecules That Control the Cell Cycle

The first hints concerning the identity of the molecules that drive progression through the cell cycle came from cell fusion experiments performed in the early 1970s. In these studies, two cultured mammalian cells in different phases of the cell cycle were fused to form a single cell with two nuclei—a *heterokaryon*. As **Figure 19-33a** indicates, if one of the original cells is in S phase and the other is in G1, the G1 nucleus in the heterokaryon quickly initiates DNA synthesis, even if it would not normally have reached S phase until many hours later. Such observations indicate that S phase cells contain molecules that trigger progression from G1 into S. The controlling molecules are

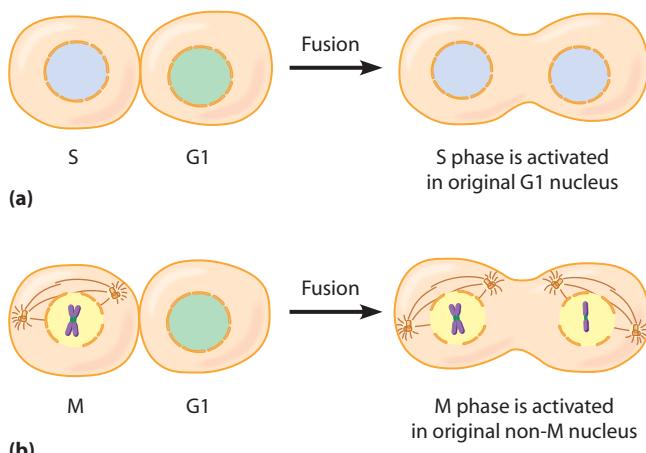

FIGURE 19-33 Evidence for the Role of Chemical Signals in Cell Cycle Regulation. Evidence was obtained from studies in which cells at two different points in the cell cycle were fused, forming a single cell with two nuclei. Cell fusion can be induced by adding certain viruses or polyethylene glycol or by applying a brief electrical pulse, which causes plasma membranes to destabilize momentarily (electroporation). (a) When cells in S phase and G1 phase are fused, DNA synthesis begins in the original G1 nucleus, suggesting that a substance that activates S phase is present in the S phase cell. (b) When a cell in M phase is fused with one in any other phase, the latter cell immediately enters mitosis. If the cell was in G1, the condensed chromosomes that appear have not replicated and therefore are analogous to single chromatids.

not simply the enzymes involved in DNA replication, since these enzymes can be present in high concentration in cells that do not enter S phase.

Cell fusion experiments have also been performed in which cells undergoing mitosis are fused with interphase cells in either G1, S, or G2. After fusion, the nucleus of such interphase cells is immediately driven into the early stages of mitosis, including chromatin condensation into visible chromosomes, spindle formation, and fragmentation of the nuclear envelope. If the interphase cell had been in G1, the condensed chromosomes will be unduplicated (Figure 19-33b).

Taken together, the preceding experiments suggested that molecules present in the cytoplasm are responsible for driving cells from G1 into S phase and from G2 into mitosis. Progress in identifying these cell cycle control molecules was facilitated by genetic studies of yeasts. Because they are single-celled organisms that can be readily grown and studied under defined laboratory conditions, yeasts are particularly convenient for investigating the genes involved in cell cycle control.

Working with the budding yeast *Saccharomyces cerevisiae*, geneticist Leland Hartwell pioneered the development of techniques for identifying yeast mutants that are “stuck” at some point in the cell cycle. It might be expected that most such mutants would be difficult or impossible to study because their blocked cell cycle would prevent them from reproducing. But Hartwell overcame this potential obstacle with a powerful strategy—the use of temperature-sensitive mutants. As mentioned earlier in

the chapter, this is a type of mutation whose harmful effects are apparent only at temperatures above the normal range for the organism. Therefore, yeast cells carrying a temperature-sensitive mutation can be successfully grown at a lower (“permissive”) temperature, even though their cell cycles would be blocked at higher temperatures. Presumably the protein encoded by the mutated cell cycle gene is close enough to the normal gene product to function at the lower temperature, while the increased thermal energy at higher temperatures disrupts its active conformation (the molecular shape needed for function) more readily than that of the normal protein.

Using this approach, Hartwell and his colleagues identified many genes involved in the cell cycle of *S. cerevisiae* and established where in the cycle their products operate. Predictably, it turned out that some of these genes produce DNA replication proteins, but others seemed to function in cell cycle regulation. A breakthrough discovery was made by Paul Nurse, who carried out similar research with the fission yeast *Schizosaccharomyces pombe*. He identified a gene called *cdc2*, whose activity is needed for initiating mitosis—that is, for moving cells through the G2-M transition. (The acronym *cdc* stands for cell division cycle.) The *cdc2* gene was soon found to have counterparts in all eukaryotic cells studied. When the properties of the protein produced by the *cdc2* gene were examined, it was discovered to be a *protein kinase*—that is, an enzyme that catalyzes the transfer of a phosphate group from ATP to other target proteins. This discovery opened the door to unraveling the mysteries of the cell cycle.

Progression Through the Cell Cycle Is Controlled by Cyclin-Dependent Kinases (Cdks)

The phosphorylation of target proteins by protein kinases, and their dephosphorylation by enzymes called *protein phosphatases*, is a common mechanism for regulating protein activity that turns out to be widely used in controlling the cell cycle. Progression through the cell cycle is driven by a series of protein kinases—including the protein kinase produced by the *cdc2* gene—that exhibit enzymatic activity only when they are bound to a special type of activator protein called a **cyclin**. Such protein kinases are therefore referred to as **cyclin-dependent kinases** or simply **Cdks**. The eukaryotic cell cycle is controlled by several different Cdks that bind to different cyclins, thereby creating a variety of Cdk-cyclin complexes.

As originally shown by Tim Hunt using sea urchin embryos, cyclins get their name because their concentration in the cell oscillates up and down with the different phases of the cell cycle. Cyclins required for the G2-M transition and the early events of mitosis are called *mitotic cyclins*, and the Cdks to which they bind are known as *mitotic Cdks*. Likewise, cyclins required for passage through the G1 restriction point (or Start) are called *G1 cyclins*, and the Cdks to which they bind are *G1*

Cdks. Yet another group of cyclins, called *S cyclins*, are required for events associated with DNA replication during S phase. The pioneering work of Hartwell, Nurse, and Hunt that led to our current understanding of Cdks and cyclins was honored by the Nobel Prize in Physiology or Medicine in 2001.

If progression through critical points in the cell cycle is controlled by an assortment of different Cdks and cyclins interacting in various combinations, how is the activity of these protein complexes regulated? One level of control is exerted by the availability of cyclin molecules, which are required for activating the protein kinase activity of Cdks, and a second type of regulation involves phosphorylation of Cdks. We will illustrate both types of control by taking a closer look at mitotic Cdk-cyclin, which controls progression from G2 into mitosis.

Mitotic Cdk-Cyclin Drives Progression Through the G2-M Transition by Phosphorylating Key Proteins Involved in the Early Stages of Mitosis

The earliest evidence for the existence of a control molecule that triggers the onset of mitosis came from experiments involving frog eggs. Mature eggs develop from precursor cells called *oocytes* through meiosis, a special type of cell division that reduces the chromosome number in half when eggs or sperm are being formed (see Chapter 20). During egg maturation, the cell cycle is halted shortly after the start of meiosis, where the oocyte waits until it is stimulated by an appropriate hormone. The oocyte then completes most of the phases of meiosis but is arrested during metaphase of the second of two meiotic divisions. It is now a “mature” egg cell, capable of being fertilized. Crucial experiments by Yoshio Masui and colleagues demonstrated that if cytoplasm taken from a mature egg cell is injected into the cytoplasm of an immature oocyte that is awaiting hormonal stimulation, the oocyte will immediately proceed through meiosis (**Figure 19-34**). Masui therefore hypothesized that a cytoplasmic chemical, which he named **MPF (maturation-promoting factor)**, induces oocyte maturation (i.e., meiotic division).

Subsequent experiments demonstrated that besides inducing meiosis, MPF also triggers mitosis when injected into fertilized frog eggs. Comparable molecules were soon detected in the cytoplasms of a broad range of dividing cell types, including yeasts, marine invertebrates, and mammals. Biochemical studies of these mitosis-inducing molecules revealed that they consist of two subunits: a Cdk and a cyclin. In other words, *MPF is a mitotic Cdk-cyclin complex*. Moreover, the mitotic Cdk portion of this complex is almost identical to the protein produced by the yeast *cdc2* gene. In fact, in yeast cells with a defective or missing *cdc2* gene, the human gene coding for mitotic Cdk can substitute perfectly well, even though the last ancestor common to yeasts and humans probably lived about a billion years ago!

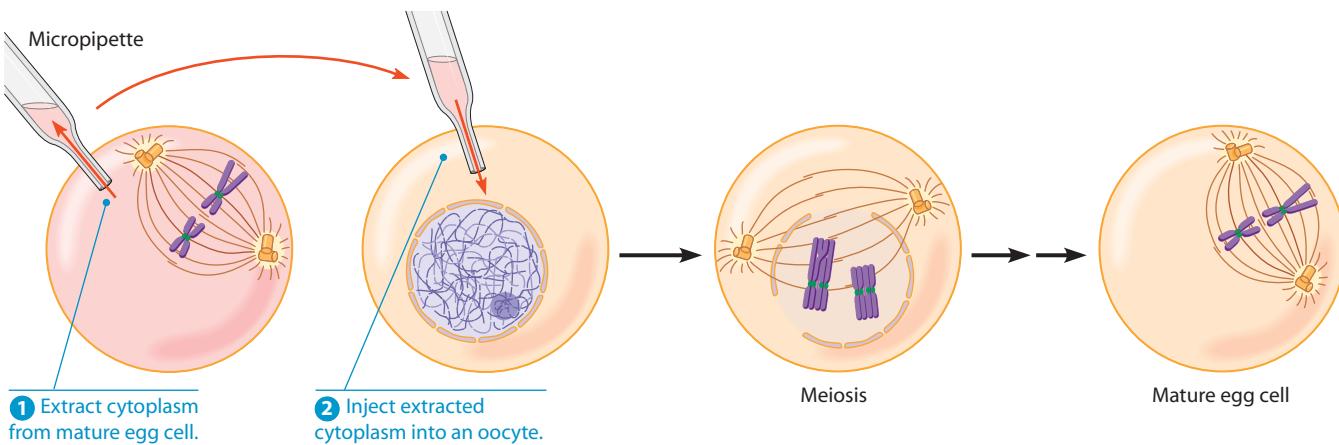

FIGURE 19-34 Evidence for the Existence of MPF. Hormones act on frog oocytes to trigger meiosis and development into mature frog eggs, which are arrested (until fertilization) in metaphase of the second meiotic division. The experiment shown here, performed by Y. Masui and C. L. Markert in 1971, established the existence of a substance involved in this process; they called it maturation-promoting factor (MPF). In their experiment, they used a micropipette to remove cytoplasm from a mature egg cell (arrested in metaphase of the second meiotic division) and injected it into an immature oocyte. The oocyte then proceeded through meiosis and became a mature egg cell. This experimental procedure could thus be used as an assay for detecting and eventually isolating MPF. The hormones that trigger oocyte maturation in the frog were presumed to act by stimulating the synthesis or activation of MPF. MPF is now known to be a mitotic Cdk-cyclin.

Having established that MPF is a mitotic Cdk-cyclin that triggers the onset of mitosis in a broad spectrum of cell types, the question arose as to how mitotic Cdk-cyclin is controlled so that it functions only at the proper moment—that is, at the end of G2. The answer is not to be found in the availability of mitotic Cdk itself because its concentration remains relatively constant throughout the cell cycle. However, mitotic Cdk is active as a protein kinase only when it is bound to mitotic cyclin, and mitotic cyclin is not always present in adequate amounts. Instead, the concentration of mitotic cyclin gradually increases during G1, S, and G2; eventually it reaches a critical threshold at the end of G2 that permits it to activate mitotic Cdk and thereby trigger the onset of mitosis (Figure 19-35). Halfway through mitosis, the mitotic cyclin molecules are abruptly destroyed. The resulting decline in mitotic Cdk activity prevents another mitosis from occurring until the mitotic cyclin concentration builds up again during the next cell cycle.

In addition to requiring mitotic cyclin, the activation of mitotic Cdk involves phosphorylation and dephosphorylation of the Cdk molecule itself. As shown in Figure 19-36, the binding of mitotic cyclin to mitotic Cdk yields a Cdk-cyclin complex that is initially inactive (step ①). To trigger mitosis, the complex requires the addition of an activating phosphate group to a particular amino acid in the Cdk molecule. Before this phosphate is added, however, inhibiting kinases phosphorylate the Cdk molecule at two other locations, causing the active site to be blocked (step ②). The activating phosphate group, highlighted with yellow in step ③, is then added by a specific activating kinase. The last step in the activation sequence is the removal of the inhibiting phosphates by a specific phosphatase enzyme (step ④). Once the phosphatase begins removing the inhibiting phosphates, a positive

feedback loop is set up: The activated mitotic Cdk generated by this reaction stimulates the phosphatase, thereby causing the activation process to proceed more rapidly.

After mitotic Cdk-cyclin has been activated through the preceding steps, its protein kinase activity triggers the onset of mitosis (Figure 19-37). We have already seen that the early events of mitosis include chromosome condensation, assembly of the mitotic spindle, and nuclear envelope breakdown. How are these changes triggered by mitotic Cdk-cyclin? In the case of nuclear envelope breakdown, the mitotic Cdk-cyclin phosphorylates (and stimulates other kinases to phosphorylate) the lamin proteins of the nuclear

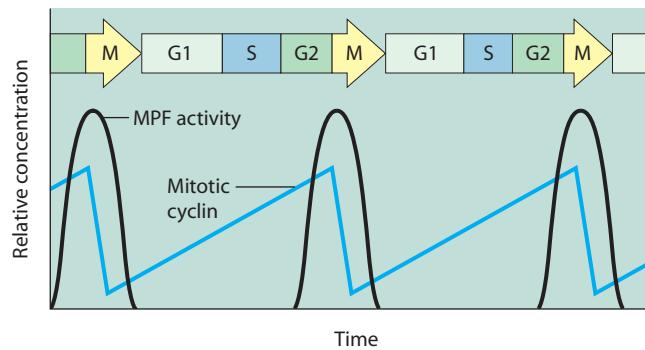

FIGURE 19-35 Fluctuating Levels of Mitotic Cyclin and MPF Activity During the Cell Cycle. Cellular levels of mitotic cyclin rise during interphase (G1, S, and G2), then fall abruptly during M phase. The peaks of MPF activity (assayed by testing for the ability to stimulate mitosis) and cyclin concentration correspond, although the rise in MPF activity is not significant until a threshold concentration of cyclin is reached. Active MPF has been found to consist of a combination of mitotic cyclin and mitotic Cdk. The mitotic Cdk itself is present at a constant concentration (not shown on the graph) because the amount of mitotic Cdk increases at a rate corresponding to the overall growth of the cell.

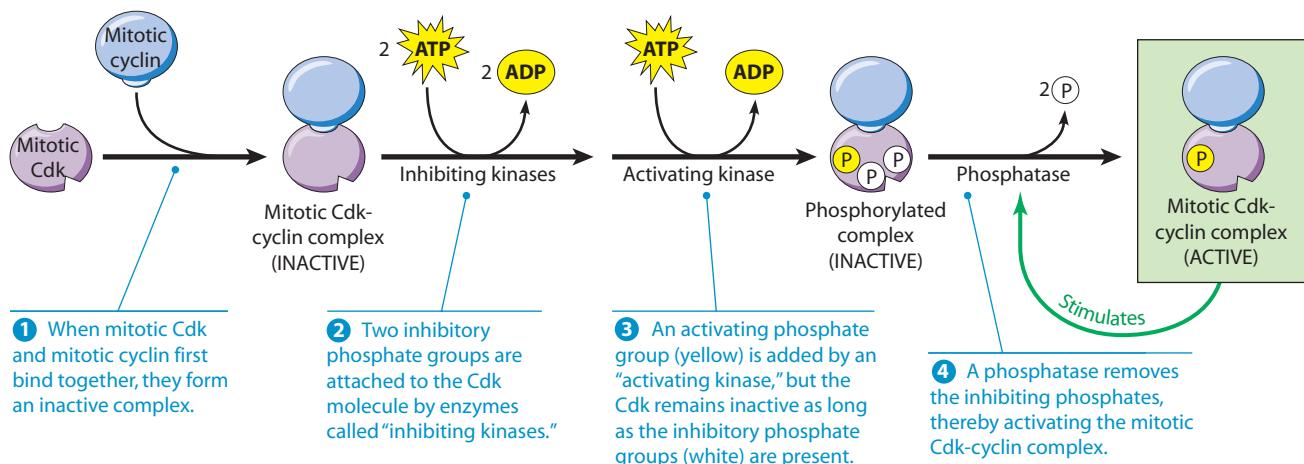

FIGURE 19-36 Regulation of Mitotic Cdk-Cyclin by Phosphorylation and Dephosphorylation. Activation of mitotic Cdk-cyclin involves the addition of inhibitory and activating phosphate groups, followed by removal of the inhibitory phosphate groups by a phosphatase. Once removal of the inhibitory phosphate groups has begun in step ④, a positive feedback loop is set up: The activated Cdk-cyclin complex generated by this reaction stimulates the phosphatase, thereby causing the activation process to proceed more rapidly.

lamina, to which the inner nuclear membrane is attached (see Figure 18-32). Phosphorylation causes the lamins to depolymerize, resulting in a breakdown of the nuclear lamina and destabilization of the nuclear envelope. The integrity of the nuclear envelope is further disrupted by phosphorylation of envelope-associated proteins, and the membranes of the envelope are soon torn apart. Phosphorylation of additional target proteins by mitotic Cdk-cyclin has been implicated in other mitotic events. For example, phosphorylation of a multiprotein complex called *condensin* is involved in condensing chromatin fibers into compact chromosomes. Finally, phosphorylation of microtubule-associated proteins by mitotic Cdk-cyclin is thought to facilitate assembly of the mitotic spindle.

The Anaphase-Promoting Complex Coordinates Key Mitotic Events by Targeting Specific Proteins for Destruction

Besides triggering the onset of mitosis, mitotic Cdk-cyclin also plays an important role later in mitosis when the decision is made to separate the sister chromatids during anaphase. Mitotic Cdk-cyclin exerts its influence on this event by phosphorylating and thereby contributing to the activation of the **anaphase-promoting complex**, a multi-protein complex that coordinates mitotic events by promoting the destruction of several key proteins at specific points during mitosis. The anaphase-promoting complex functions as a *ubiquitin ligase*, a type of enzyme that targets specific proteins for degradation by joining them to the small protein *ubiquitin*. Proteins linked to ubiquitin are subsequently destroyed by a mechanism to be described in Chapter 23.

One crucial protein targeted for destruction by the anaphase-promoting complex is **securin**, an inhibitor of

Active mitotic Cdk-cyclin stimulates:

1. Nuclear envelope breakdown
2. Chromosome condensation
3. Mitotic spindle formation
4. Targeted protein degradation

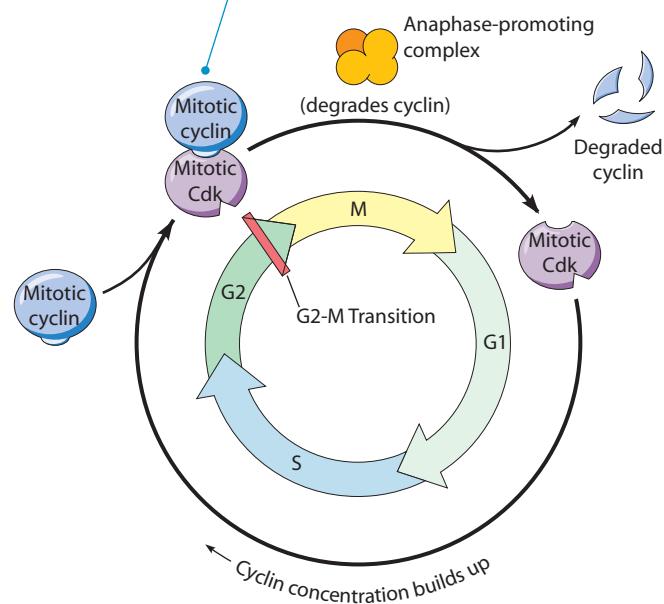

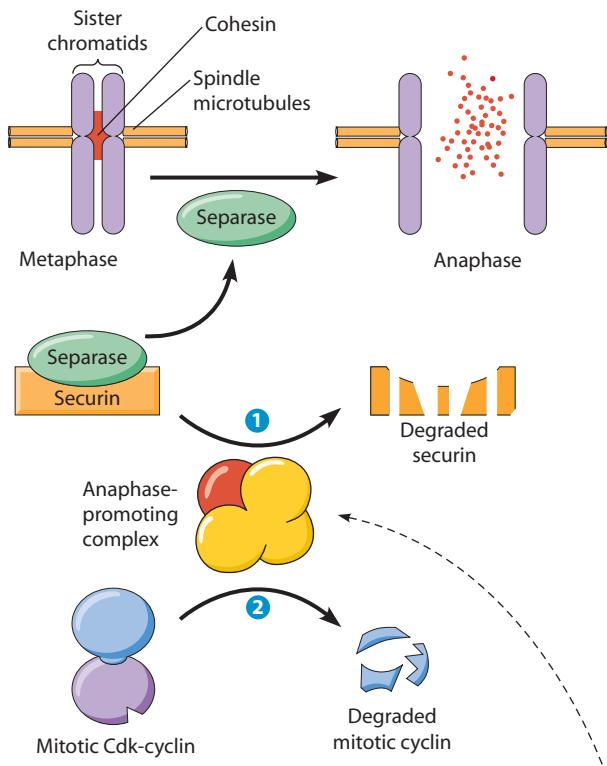

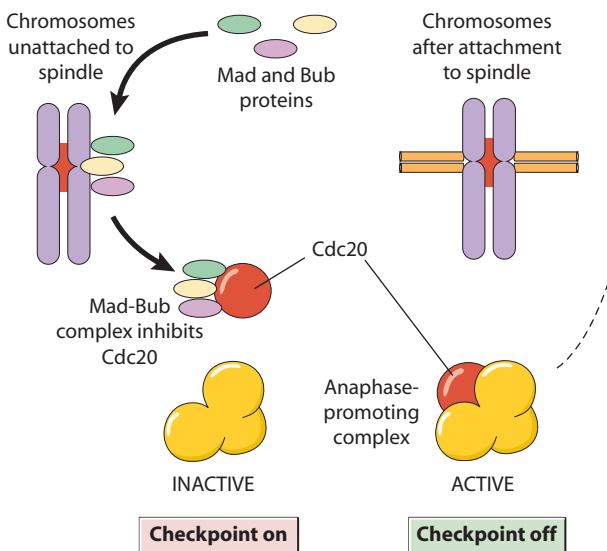

FIGURE 19-37 The Mitotic Cdk Cycle. This diagram illustrates the activation and inactivation of the mitotic Cdk protein during the cell cycle. In G1, S, and G2, mitotic Cdk is made at a steady rate as the cell grows, while the mitotic cyclin concentration gradually increases. Mitotic Cdk and cyclin form an active complex whose protein kinase activity drives the cell cycle through the G2-M transition and into mitosis by stimulating the mitotic events listed. By activating a protein-degradation pathway that degrades cyclin, the mitotic Cdk-cyclin complex also brings about its own demise, allowing the completion of mitosis and entry into G1 of the next cell cycle.

(a) The anaphase-promoting complex targets securin and mitotic cyclin for degradation. ① The destruction of securin allows separase to cleave the cohesins that hold sister chromatids together, thereby initiating anaphase. ② The degradation of mitotic cyclin depresses mitotic Cdk activity, leading to cytokinesis, chromosome decondensation, and nuclear envelope reassembly.

(b) The mitotic spindle checkpoint prevents anaphase from starting until all chromosomes are attached to the spindle. Unattached chromosomes keep the "checkpoint on" by organizing Mad and Bub proteins into a complex that prevents Cdc20 from activating the anaphase-promoting complex. After all chromosomes are attached, the Mad-Bub complex is not formed ("checkpoint off") and the anaphase-promoting complex is free to initiate anaphase.

FIGURE 19-38 The Anaphase-Promoting Complex and the Mitotic Spindle Checkpoint. (a) The anaphase-promoting complex controls the final stages of mitosis by targeting selected proteins, including securin and mitotic cyclin, for destruction. (b) A model for the mitotic spindle checkpoint shows how chromosomes that are not attached to the spindle may organize Mad and Bub proteins into a complex that inhibits the anaphase-promoting complex, thereby delaying the onset of anaphase until all chromosomes are attached to the spindle.

sister chromatid separation. As shown in **Figure 19-38a**, sister chromatids are held together prior to anaphase by adhesive proteins called **cohesins**, which become bound to newly replicated chromosomal DNA in S phase following the movement of the replication forks. Securin maintains this sister chromatid attachment by inhibiting a protease called **separase**, which would otherwise degrade the cohesins. At the beginning of anaphase, however, the anaphase-promoting complex attaches ubiquitin to securin and thereby triggers its destruction, releasing separase from inhibition. The activated separase then cleaves cohesin, which frees sister chromatids to separate from each other and begin their anaphase movements toward the spindle poles.

Besides initiating anaphase by causing cohesins to be destroyed, the anaphase-promoting complex induces events associated with the end of mitosis by targeting another crucial protein for destruction, namely mitotic cyclin. The resulting loss of mitotic cyclin causes the protein kinase activity of mitotic Cdk to fall. Evidence suggests that many changes associated with the exit from mitosis—such as cytokinesis, chromosome decondensation, and reassembly of the nuclear envelope—depend on this cyclin degradation step and the associated reduction in Cdk activity. For example, it has been shown that introducing a nondegradable form of mitotic cyclin into cells inhibits cytokinesis, blocks nuclear envelope reassembly, and stops chromosomes from decondensing, thereby preventing mitosis from being completed.

G1 Cdk-Cyclin Regulates Progression Through the Restriction Point by Phosphorylating the Rb Protein

Now that we have examined the role played by mitotic Cdk-cyclin in controlling events associated with mitosis, let's briefly see how another type of Cdk-cyclin regulates entry into S phase. As mentioned earlier, the restriction point (Start in yeast) is a control mechanism located in late G1 that determines whether a cell will enter S phase, proceed through the rest of the cell cycle, and divide. Because passing through the restriction point is the main step that commits a cell to the cell division cycle, it is subject to control by a variety of factors such as cell size, the availability of nutrients, and the presence of growth factors that signal the need for cell proliferation.

Such signals exert their effects by activating G1 Cdk-cyclin, whose protein kinase activity triggers progression

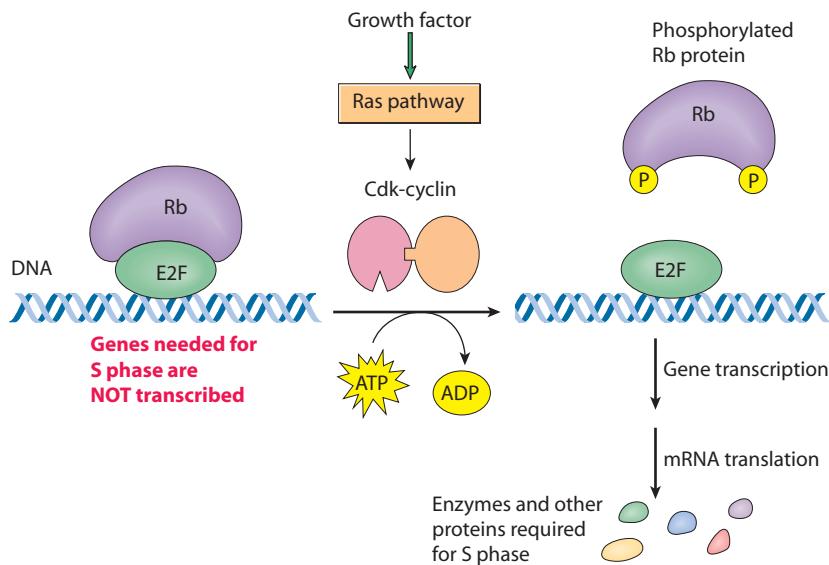

FIGURE 19-39 Role of the Rb Protein in Cell Cycle Control. In its dephosphorylated state, the Rb protein binds to the E2F transcription factor. This binding prevents E2F from activating the transcription of genes coding for proteins required for DNA replication, which are needed before the cell can pass through the restriction point into S phase. In cells stimulated by growth factors, the Ras pathway is activated (see Figure 19-41), which leads to the production and activation of a G1 Cdk-cyclin complex that phosphorylates the Rb protein. Phosphorylated Rb can no longer bind to E2F, thereby allowing E2F to activate gene transcription and trigger the onset of S phase. During the subsequent M phase (not shown), the Rb protein is dephosphorylated so that it can once again inhibit E2F.

through the restriction point by phosphorylating several target proteins. A key target is the **Rb protein**, a molecule that controls the expression of genes whose products are needed for moving through the restriction point and into S phase. The molecular mechanism by which Rb exerts this control is summarized in **Figure 19-39**. Prior to being phosphorylated by G1 Cdk-cyclins, Rb binds to and inhibits the **E2F transcription factor**, a protein that would otherwise activate the transcription of genes coding for products required for initiating DNA replication. As long as the Rb protein remains bound to E2F, the E2F molecule is inactive and these genes remain silent, thereby preventing the cell from entering into S phase. But when cells are stimulated to divide by the addition of growth factors, a pathway is triggered that produces and activates the G1 Cdk-cyclins that catalyze Rb phosphorylation. Phosphorylation of Rb abolishes its ability to bind to E2F, thereby freeing E2F to activate the transcription of genes whose products are needed for entry into S phase.

Since the Rb protein regulates such a key event—namely, the decision to proceed through the restriction point and commit to the cell division cycle—it is not surprising to discover that defects in Rb can have disastrous consequences. For example, we will see in Chapter 24 how such defects can lead to both hereditary and environmentally induced forms of cancer.

Checkpoint Pathways Monitor Chromosome-to-Spindle Attachments, Completion of DNA Replication, and DNA Damage

It would obviously create problems if cells proceeded from one phase of the cell cycle to the next before the preceding phase had been properly completed. For example, if chromosomes start moving toward the spindle poles before they have all been properly attached to the spindle, the newly forming daughter cells might receive extra copies of some chromosomes and no copies of others, a situation

known as **aneuploidy** (an = “not,” eu = “good,” and “ploidy” refers to chromosome number). Similarly, it would be potentially hazardous for a cell to begin mitosis before all of its chromosomal DNA had been replicated. To minimize the possibility of such errors, cells utilize a series of **checkpoint** mechanisms that monitor conditions within the cell and transiently halt the cell cycle if conditions are not suitable for continuing.

The checkpoint pathway that prevents anaphase chromosome movements from beginning before the chromosomes are all attached to the spindle is called the **mitotic spindle checkpoint**. It works through a mechanism in which chromosomes whose kinetochores remain *unattached* to spindle microtubules produce a “wait” signal that inhibits the anaphase-promoting complex. As long as the anaphase-promoting complex is inhibited, it cannot trigger destruction of the cohesins that hold sister chromatids together. The exact molecular basis of the wait signal remains an open question, but members of the *Mad* and *Bub* protein families are involved. One model proposes that Mad and Bub proteins accumulate at unattached chromosomal kinetochores, where they are converted into a multiprotein complex that inhibits the anaphase-promoting complex by blocking the action of one of its essential activators, the *Cdc20* protein (see Figure 19-38b). After all the chromosomes have become attached to the spindle, the Mad and Bub proteins are no longer converted into this inhibitory complex, thereby freeing the anaphase-promoting complex to initiate the onset of anaphase.

A second checkpoint mechanism, called the **DNA replication checkpoint**, monitors the state of DNA replication to help ensure that DNA synthesis is completed before the cell exits from G2 and begins mitosis. The existence of this checkpoint has been demonstrated by treating cells with inhibitors that prevent DNA replication from being finished. Under such conditions, the phosphatase that catalyzes the final dephosphorylation step involved in the activation of mitotic Cdk-cyclin (see

Figure 19-36, ④) is inhibited through a series of events triggered by proteins associated with replicating DNA. The resulting lack of mitotic Cdk-cyclin activity halts the cell cycle at the end of G2 until all DNA replication is completed.

A third type of checkpoint mechanism is involved in preventing cells with damaged DNA from proceeding through the cell cycle unless the DNA damage is first repaired. In this case, a multiple series of **DNA damage checkpoints** exist that monitor for DNA damage and halt the cell cycle at various points—including late G1, S, and late G2—by inhibiting different Cdk-cyclin complexes. A protein called **p53**, sometimes referred to as the “guardian of the genome,” plays a central role in these checkpoint pathways. As shown in **Figure 19-40**, when cells encounter agents that cause extensive double-stranded breaks in DNA, the altered DNA triggers the activation of an enzyme called *ATM protein kinase* (for *ataxia telangiectasia mutated*; mutations in the ATM gene can cause defects in the cerebellum that lead to uncoordinated movement, as well as prominent blood vessels that form in the whites of the eyes). ATM catalyzes the phosphorylation of kinases known as *checkpoint kinases*, which in turn phosphorylate p53 (and several other target proteins). Phosphorylation of p53 prevents it from interacting with *Mdm2*, a protein that would otherwise mark p53 for destruction by linking it to ubiquitin (just as the anaphase-promoting complex targets proteins for degradation by linking them to ubiquitin). ATM-catalyzed phosphorylation of p53 therefore protects it from degradation and leads to a buildup of p53 in the presence of damaged DNA. A protein related to ATM, called *ATR* (*ATM-related*) acts similarly but instead causes cell cycle arrest as a result of extensive single-stranded breaks in DNA.

The accumulating p53 in turn activates two types of events: *cell cycle arrest* and *cell death*. Both responses are based on the ability of p53 to bind to DNA and act as a transcription factor that stimulates the transcription of specific genes. One of the crucial genes activated by p53 is the gene coding for **p21**, a protein that halts progression through the cell cycle at multiple points by inhibiting the activity of several different Cdk-cyclins. Phosphorylated p53 also stimulates the production of enzymes involved in DNA repair. But if the damage cannot be successfully repaired, p53 then activates a group of genes coding for proteins involved in triggering cell death by apoptosis (page 591). A key protein in this pathway, called **Puma** (**p53 upregulated modulator of apoptosis**), promotes apoptosis by binding to and inactivating a normally occurring inhibitor of apoptosis known as *Bcl-2*.

The ability of p53 to trigger cell cycle arrest and cell death allows it to function as a molecular stoplight that protects cells with damaged DNA from proliferating and passing the damage to daughter cells. The importance of this role will be highlighted in Chapter 24, where we describe how defects in the p53 pathway contribute to the development of cancer.

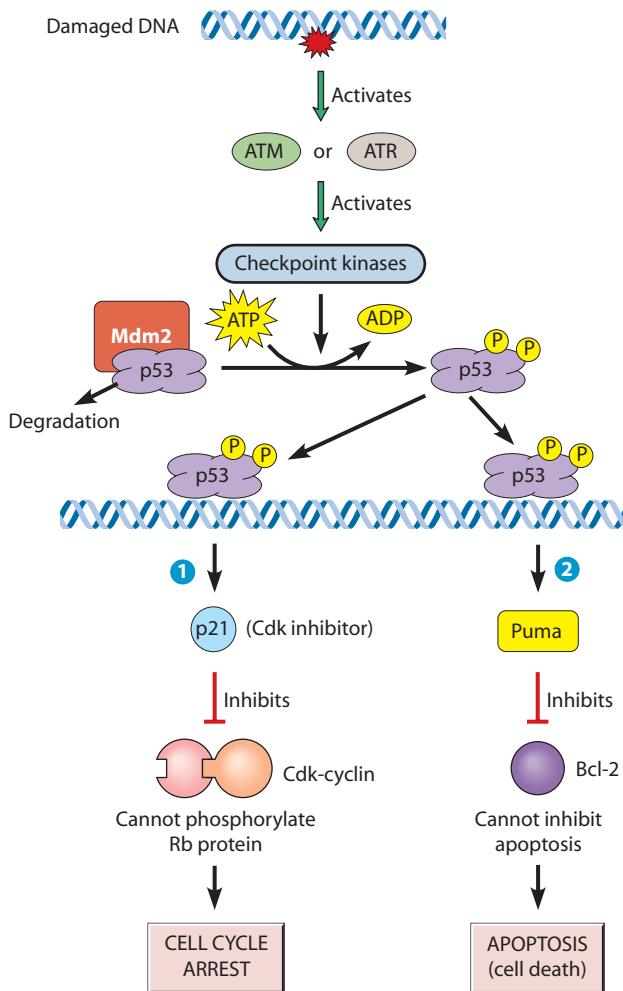

FIGURE 19-40 Role of the p53 Protein in Responding to DNA Damage. Damaged DNA activates the ATM or ATR protein kinase, leading to activation of checkpoint kinases, which leads to phosphorylation of the p53 protein. Phosphorylation stabilizes p53 by blocking its interaction with Mdm2, a protein that would otherwise mark p53 for degradation. (The degradation mechanism is not shown, but it involves Mdm2-catalyzed attachment of p53 to ubiquitin, which targets molecules to the cell's main protein destruction machine, the proteasome.) When the interaction between p53 and Mdm2 is blocked by p53 phosphorylation, the phosphorylated p53 protein accumulates and triggers two events. ① The p53 protein binds to DNA and activates transcription of the gene coding for the p21 protein, a Cdk inhibitor. The resulting inhibition of Cdk-cyclin prevents phosphorylation of the Rb protein, leading to cell cycle arrest at the restriction point. ② When the DNA damage cannot be repaired, p53 then activates genes coding for a group of proteins that trigger cell death by apoptosis. A key protein is Puma, which promotes apoptosis by binding to, and blocking the action of, the apoptosis inhibitor, Bcl-2.

Putting It All Together: The Cell Cycle Regulation Machine

Figure 19-41 is a generalized and simplified summary of the main features of the molecular “machine” that regulates the eukaryotic cell cycle. The operation of this machine can be described in terms of two fundamental, interacting mechanisms. One mechanism is an autonomous clock that

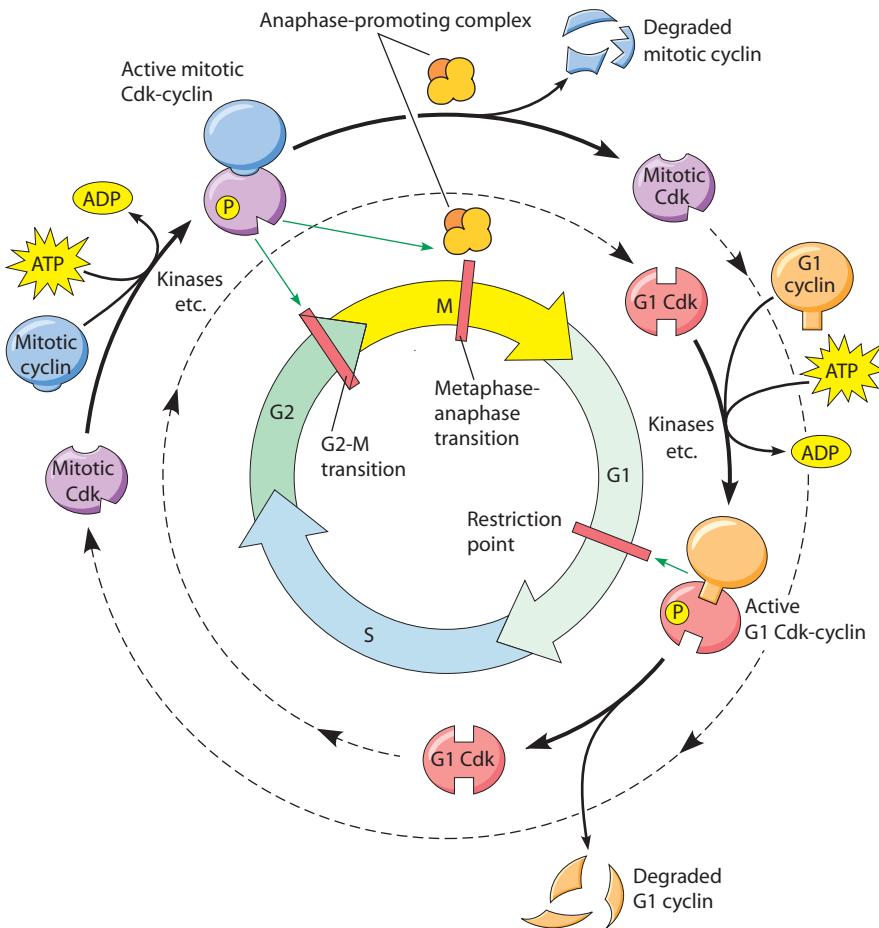

FIGURE 19-41 A General Model for Cell Cycle Regulation. Passage through the three main transition points in the cell cycle is triggered by protein complexes made of cyclin and Cdk, whose phosphorylation of other proteins induces progression through the cycle. G1 Cdk-cyclin acts at the restriction point by catalyzing phosphorylation of the Rb protein. Mitotic Cdk-cyclin acts at the G2-M boundary by catalyzing the phosphorylation of proteins involved in chromosome condensation, nuclear envelope breakdown, and spindle assembly. The same mitotic Cdk-cyclin also influences the metaphase-anaphase transition by catalyzing the phosphorylation of the anaphase-promoting complex, which in turn triggers chromosome separation and the breakdown of mitotic cyclin. Checkpoint pathways that monitor the cell for DNA damage, DNA replication, and chromosome attachment to the spindle can send signals that halt the cell cycle at one or more of these key transition points.

goes through a fixed cycle over and over again. The molecular basis of this clock is the synthesis and degradation of cyclins, alternating in a rhythmic fashion. These cyclins in turn bind to Cdk molecules, creating various Cdk-cyclin complexes that trigger the passage of cells through the main cell cycle transition points. The second mechanism adjusts the clock as needed, by providing feedback from the cell's internal and external environments. This mechanism makes use of additional proteins that, directly or indirectly, influence the activity of Cdks and cyclins. Many of these additional proteins are protein kinases or phosphatases. It is this part of the cell cycle machine that relays information about the state of the cell's metabolism—including DNA damage and replication—and about conditions outside the cell, thereby influencing whether or not the cell should commit to the process of cell division. As we will see next, growth-promoting and growth-inhibiting signaling molecules that come from outside the cell are prominent components of this regulatory mechanism.

Growth Factors and Cell Proliferation

Simple unicellular organisms, such as bacteria and yeast, live under conditions in which the presence of sufficient nutrients in the external environment is the primary factor

determining whether cells grow and divide. In multicellular organisms, the situation is usually reversed; cells are typically surrounded by nutrient-rich extracellular fluids, but the organism as a whole would be quickly destroyed if every cell were to continually grow and divide just because it had access to adequate nutrients. Cancer is a potentially lethal reminder of what happens when cell proliferation continues unabated without being coordinated with the needs of the organism as a whole. To overcome this potential problem, multicellular organisms utilize extracellular signaling proteins called *growth factors* to control the rate of cell proliferation (see Table 14-3). Most growth factors are *mitogens*, which means that they stimulate cells to pass through the restriction point and subsequently divide by mitosis.

Stimulatory Growth Factors Activate the Ras Pathway

If mammalian cells are placed in a culture medium containing nutrients and vitamins but lacking growth factors, they normally become arrested in G1 despite the presence of adequate nutrients. Growth and division can be triggered by adding small amounts of blood serum, which contains several stimulatory *growth factors*. Among them is **platelet-derived growth factor (PDGF)**, a protein produced by blood platelets that stimulates the proliferation of connective tissue cells and smooth muscle

cells. Another important growth factor, **epidermal growth factor (EGF)**, is widely distributed in many tissues and body fluids. EGF was initially isolated from the salivary glands of mice by Stanley Cohen, who received a Nobel Prize in 1987 for his pioneering investigations of growth factors.

Growth factors such as PDGF and EGF act by binding to plasma membrane receptors located on the surface of target cells. In Chapter 14, you learned that receptors for these growth factors exhibit tyrosine kinase activity. The binding of a growth factor to its receptor activates this tyrosine kinase activity, leading to phosphorylation of tyrosine residues located in the portion of the receptor molecule protruding into the cytosol. Phosphorylation of these tyrosines in turn triggers a complex cascade of events that culminates in the cell passing through the restriction point and entering into S phase. The *Ras pathway* introduced in Chapter 14 plays a central role in these events, as shown by studies involving cells that have stopped dividing because growth factor is not present. When mutant, hyperactive forms of the Ras protein are injected into such cells, the cells enter S phase and begin dividing, even in the absence of growth factor. Conversely, injecting cells with antibodies that inactivate the Ras protein prevents cells from entering S phase and dividing in response to growth factor stimulation.

How does the Ras pathway affect the cell cycle? As shown in **Figure 19-42**, the process involves several steps. **1** First, binding of a growth factor to its receptor at the plasma membrane leads to activation of Ras. **2** Next, activated Ras leads to phosphorylation and activation of a protein kinase called *Raf*, which sets in motion a cascade of phosphorylation events. Activated Raf phosphorylates serine and threonine residues in a protein kinase called *MEK*, which in turn phosphorylates threonine and tyrosine residues in a group of protein kinases called *MAP kinases* (*mitogen-activated protein kinases*; *MAPKs*). **3** The activated MAPKs enter the nucleus and phosphorylate several regulatory proteins that activate the transcription of specific genes. Among these proteins are *Jun* (a component of the AP-1 transcription factor) and members of the *Ets family* of transcription factors. These activated transcription factors turn on the transcription of “early genes” that code for the production of other transcription factors, including Myc, Fos, and Jun, which then activate the transcription of a family of “delayed genes.” One of these latter genes encodes the E2F transcription factor, whose role in controlling entry into S phase was described earlier in the chapter. **4** Also included in the delayed genes are several genes coding for either Cdk or cyclin molecules, whose production leads to the formation of Cdk-cyclin complexes that phosphorylate Rb and hence trigger passage from G1 into S phase.

Thus in summary, the Ras pathway is a multistep signaling cascade in which the binding of a growth factor to a receptor on the cell surface ultimately causes the cell to pass through the restriction point and into S phase, thereby starting the cell on the road to cell division. The importance of this pathway for the control of cell proliferation has been

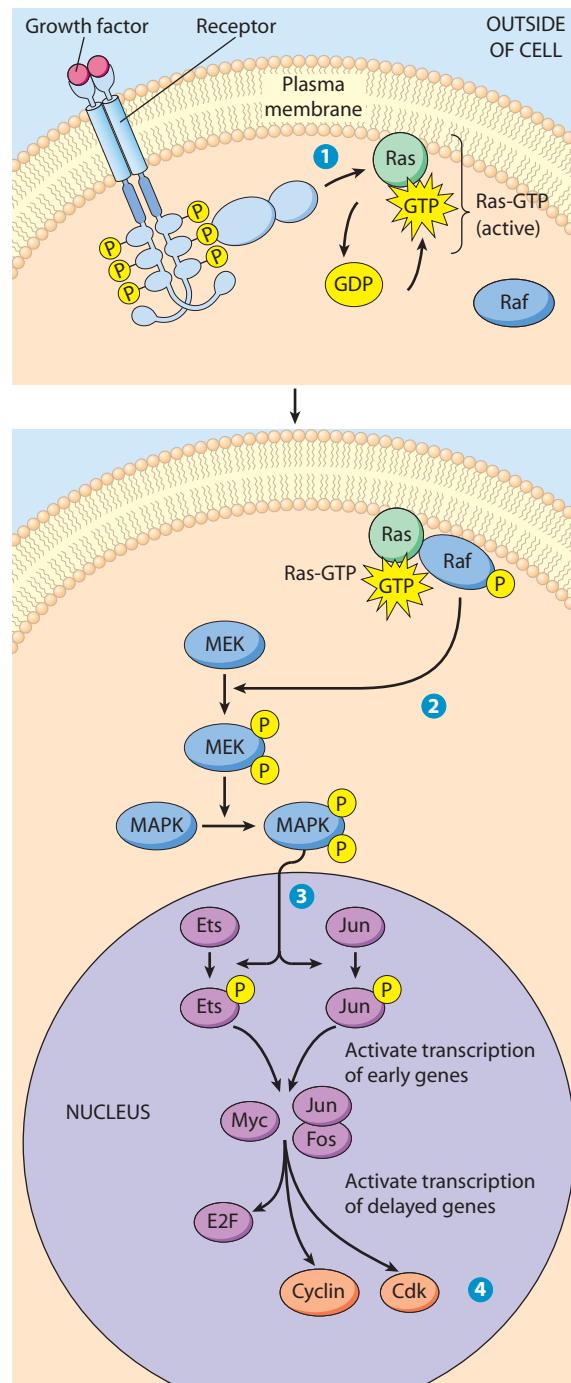

FIGURE 19-42 Regulation of the Cell Cycle via the Ras Pathway. Regulation of the cell cycle by Ras consists of four steps: **1** binding of a growth factor to its receptor, leading to activation of Ras protein; **2** activation of a cascade of cytoplasmic protein kinases (Raf, MEK, and MAPK); **3** activation or production of nuclear transcription factors (Ets, Jun, Fos, Myc, E2F); and **4** synthesis of cyclin and Cdk molecules. The resulting Cdk-cyclin complexes catalyze the phosphorylation of Rb and hence trigger passage from G1 into S phase (MAPK = Map kinases).

highlighted by the discovery that mutations affecting the Ras pathway appear frequently in cancer cells. For example, mutant Ras proteins that provide an ongoing stimulus for the cell to proliferate, independent of growth factor stimulation, are commonly encountered in pancreatic, colon,

lung, and bladder cancers; and they occur in about 25–30% of all human cancers overall. In Chapter 24, the role played by such Ras pathway mutations in the development of cancer will be described in detail.

Stimulatory Growth Factors Can Also Activate the PI3K-Akt Pathway

When a growth factor binds to a receptor that triggers the Ras pathway, the activated receptor may simultaneously trigger other pathways as well. One example that we examined in Chapter 14 in the context of insulin signaling (page 417) is the *PI 3-kinase-Akt pathway*. This pathway begins with receptor-induced activation of phosphatidylinositol 3-kinase (abbreviated as *PI 3-kinase* or *PI3K*), which catalyzes formation of *PIP₃* (phosphatidylinositol-3,4,5-trisphosphate), ultimately leading to phosphorylation and activation of *Akt*. Through its ability to catalyze the phosphorylation of several key target proteins, *Akt* suppresses apoptosis (see the next section of this chapter) and inhibits cell cycle arrest (Figure 19-43). One way in which the latter happens is through activation of a monomeric G protein called *Rheb*. Activation of *Rheb* leads to activation of *TOR*, a key regulator of cell growth mentioned earlier in this chapter. The net effect of the PI

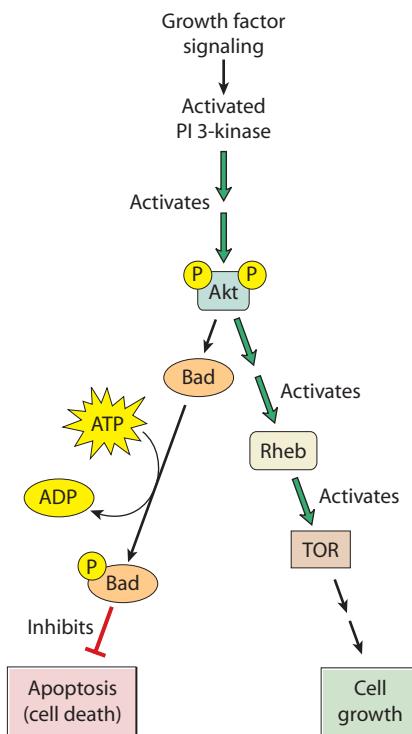

FIGURE 19-43 The PI 3-Kinase–Akt Signaling Pathway.

Growth factors that bind to receptor tyrosine kinases activate several pathways in addition to the Ras pathway illustrated in Figure 19-42. The pathway shown here leads to activation of the protein kinase Akt. Akt suppresses apoptosis, in part by phosphorylating and inactivating a protein called Bad that normally promotes apoptosis. Akt also inhibits cell cycle arrest by leading to activation of TOR. Thus, the net effect of PI 3-kinase–Akt signaling is to promote cell survival and proliferation. The PI 3-kinase–Akt pathway is inhibited by PTEN (see Figure 14-23).

3-kinase–Akt signaling pathway is therefore to promote cell survival and proliferation.

As in the case of the Ras pathway, mutations that disrupt the normal behavior of the PI 3-kinase–Akt pathway are associated with many cancers. In some cases, such mutations cause excessive activity of the Akt protein that leads to increased cell proliferation and survival. In other cases, hyperactivity of the PI 3-kinase–Akt pathway is caused by mutations that disable proteins that normally inhibit this pathway. One such protein is *PTEN*, a phosphatase that removes a phosphate group from *PIP₃* and thereby prevents the activation of Akt (see page 417). When mutations disrupt PTEN, the cell cannot degrade *PIP₃* efficiently, and its concentration rises. The accumulating *PIP₃* activates Akt in an uncontrolled fashion, even in the absence of growth factors, leading to enhanced cell proliferation and survival. Mutations that reduce PTEN activity are found in up to 50% of prostate cancers, 35% of uterine cancers, and to varying extents in ovarian, breast, liver, lung, kidney, thyroid, and lymphoid cancers.

Inhibitory Growth Factors Act Through Cdk Inhibitors

Although we usually think of growth factors as being growth-stimulating molecules, the function of some growth factors is actually to inhibit cell proliferation. One example is **transforming growth factor β** (*TGF β*), a protein that can exhibit either growth-stimulating or growth-inhibiting properties, depending on the target cell type. When acting as a growth inhibitor, the binding of *TGF β* to its cell surface receptor triggers a series of events in which the receptor catalyzes the phosphorylation of *Smad* proteins that move into the nucleus and regulate gene expression (see Figure 14-20). Once inside the nucleus, Smads activate the expression of genes coding for proteins that inhibit cell proliferation. Two key genes produce proteins called *p15* and *p21*, which are **Cdk inhibitors** that suppress the activity of Cdk-cyclin complexes and thereby block progression through the cell cycle. (The *p21* protein was already mentioned earlier in the chapter when we discussed the mechanism of *p53*-mediated cell cycle arrest.)

Growth-inhibiting signals that act on cells by triggering the production of Cdk inhibitors help protect normal tissues from excessive cell divisions that might otherwise produce more cells than are needed. In Chapter 24, we will see how defects in such pathways can lead to uncontrolled cell proliferation and the development of cancer.

Apoptosis

As you saw in previous sections of this chapter, organisms tightly regulate when their cells enter mitosis. When cells divide is often regulated by growth factors, which can stimulate or inhibit division, depending on the circumstances. At other times, however, organisms need to regulate whether cells stay alive. Damaged or diseased cells need to be killed, but this presents a challenge. Dismantling cells that are

destined for death must occur in such a way that the internal contents of the dead cell—which include digestive enzymes in organelles such as lysosomes—do not wreak havoc on other cells around them. Multicellular organisms accomplish this feat through an important kind of programmed cell death—**apoptosis**. Apoptosis is a key event in many biological processes. In embryos, apoptosis occurs in a variety of circumstances. Examples include removal of the webbing between the digits (fingers and toes) during the development of hands and feet and the “pruning” of neurons that occurs in human infants during the first few months of life as connections mature within the developing brain. In adult humans, apoptosis occurs continually; when cells become infected by pathogens or when white blood cells reach the end of their life span, they are eliminated through apoptosis. When cells that should die via apoptosis do not, the consequences can be dire. Mutations in some of the proteins that participate in apoptosis can lead to cancer. For example, melanoma frequently results from a mutation in Apaf-1, a protein we discuss later in this section.

Apoptosis is very different from another type of cell death, known as *necrosis*, which sometimes follows massive tissue injury. Whereas necrosis involves the swelling and rupture of the injured cells, apoptosis involves a specific series of events that lead to the dismantling of the internal contents of the cell (**Figure 19-44**). During the early phases of apoptosis, the cell’s DNA segregates near the

periphery of the nucleus, and the volume of the cytoplasm decreases (**1**). Next, the cell begins to produce small, bubble-like, cytoplasmic extensions (“blebs”), and the nucleus and organelles begin to fragment (**2**). The cell’s DNA is cleaved by an apoptosis-specific DNA endonuclease, or *DNase* (an enzyme that digests DNA), at regular intervals along the DNA. As a result, the DNA fragments, which are multiples of 200 base pairs in length, form a diagnostic “ladder” of fragments. (This precise size distribution of DNA reflects the susceptibility of DNA to cleavage between nucleosomes, structures you learned about in Chapter 18). Eventually the cell is dismantled into small pieces called *apoptotic bodies*. During apoptosis, inactivation of a phospholipid translocator, or flippase (see Chapter 7), results in accumulation of phosphatidylserine in the outer leaflet of the plasma membrane. The phosphatidylserine serves as an “eat-me” signal for the remnants of the affected cell to be engulfed by other nearby cells (typically macrophages) via phagocytosis (see Chapter 12; **3**). The macrophages act as scavengers to remove the resulting cellular debris.

That cells have a “death program” was first conclusively demonstrated in the nematode, *Caenorhabditis elegans*, where key genes that control apoptosis were first identified (**Box 19B**). Subsequent research showed that many other organisms, including mammals, use similar proteins during apoptosis. A key event in apoptosis is the

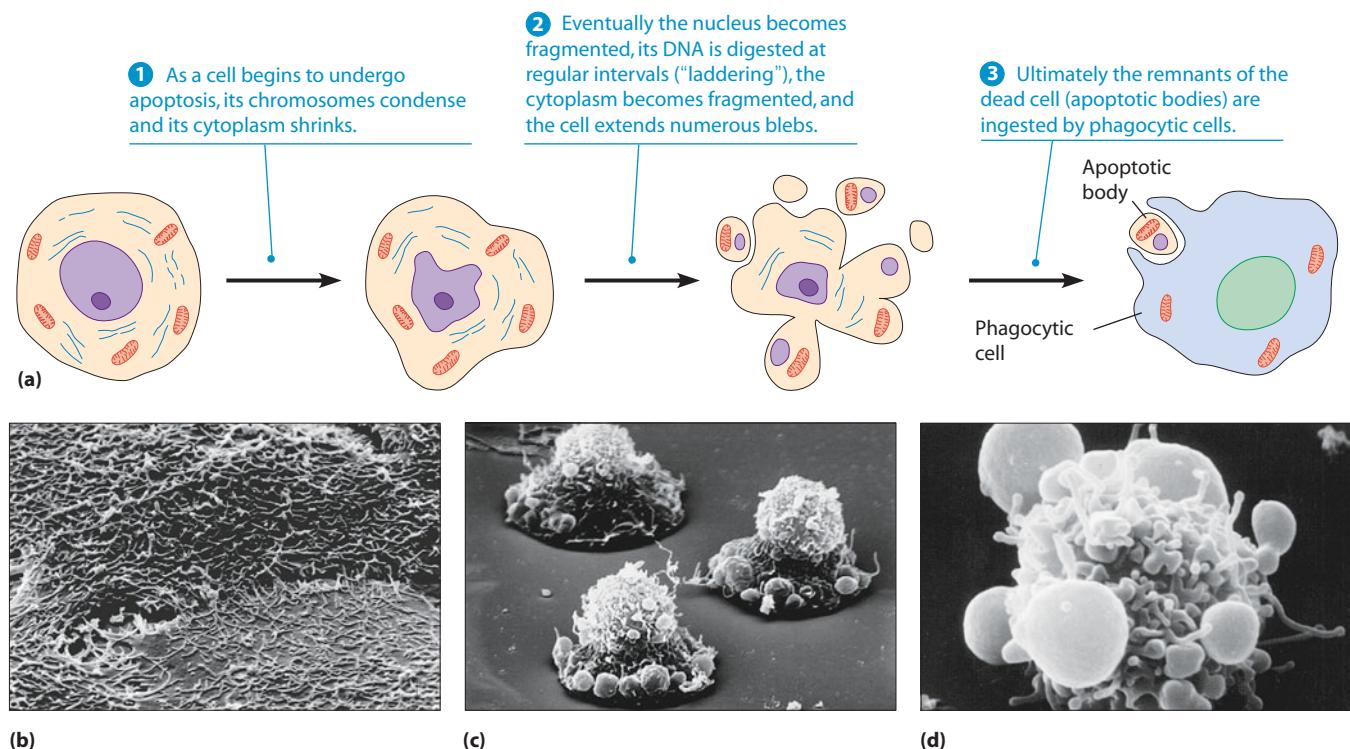

FIGURE 19-44 Major Steps in Apoptosis. (a) Cells in the process of apoptosis undergo a series of characteristic changes. Ultimately the remnants of the dead cell (apoptotic bodies) are ingested by phagocytic cells. (b–d) SEMs of epithelial cells undergoing apoptosis. (b) Epithelial cells in contact with one another in culture form flat sheets. (c) As apoptosis ensues, the cells round up, withdraw their connections with one another, and bleb. (d) A single dead cell with many apoptotic bodies.

Apoptosis in *Caenorhabditis elegans*

Key breakthroughs in the study of apoptosis came through analysis of the development of the nematode worm, *Caenorhabditis elegans*. *C. elegans* is uniquely suited to studying cell death. Its life cycle is very short, it is optically transparent, and its embryos are remarkably consistent in their development. In fact, they are so consistent that the lineage of every cell in the adult animal is known with complete precision. This means the sequence of cell divisions that results in each of the 1090 cells produced during development can be traced back to the single-celled fertilized egg! This feat was achieved largely through the work of John Sulston at the Medical Research Council in Cambridge, England. Sulston also showed that 131 cells undergo precisely timed apoptosis during normal embryonic development in *C. elegans*. Largely through the work of Robert Horvitz and colleagues at the Massachusetts Institute of Technology, mutants defective in various aspects of cell death, called *ced* mutants (for cell death abnormal), were identified. For example, Horvitz and colleagues identified several mutations that block phagocytosis of dead cells, so that their corpses persist, making them easy to see in the light microscope (Figure 19B-1). One of the first *ced* genes to be characterized at the molecular level was the gene *ced-3*, which encodes a member of the caspase family of proteins (see Figure 19-45). Another gene, *ced-9*, encodes the *C. elegans* version of *Bcl-2*, which plays a key role in regulating the leakage of molecules from mitochondria that can trigger apoptosis. Another gene, *ced-10*, encodes a member of the Rac family of proteins, which is required for phagocytosis of dead cells. In conjunction with work proceeding on cultured cells at about the same time, the work of Horvitz and

FIGURE 19B-1 Cell Death in *C. elegans*. Wild-type (top) and *ced-1* mutant (bottom) embryos (DIC microscopy). Although cell deaths can be seen in both embryos as small “buttons,” these cell corpses accumulate only in the *ced-1* embryo because phagocytosis of dead cells fails (arrows).

colleagues provided key insights into apoptosis. For this work—and his work on cell signaling in the vulva—Horvitz, along with Sulston and geneticist Sydney Brenner, shared the Nobel Prize in Physiology or Medicine in 2002.

activation of a series of enzymes called **caspases**. (Caspases get their name because they contain a cysteine at their active site, and they cleave proteins at sites that contain an *aspartic acid* residue followed by four amino acids that are specific to each caspase). Caspases are produced as inactive precursors known as **procaspases**, which are subsequently cleaved to create active enzymes, often by other caspases, in a proteolytic cascade. Once they are activated, caspases cleave other proteins. The apoptosis-specific DNase is a good example; it is bound to an inhibitory protein that is cleaved by a caspase.

Apoptosis Is Triggered by Death Signals or Withdrawal of Survival Factors

There are two main routes by which cells can activate caspases and enter the apoptotic pathway. In some cases, activation of caspases occurs directly. For example, when cells in the human body are infected by certain viruses, a population of *cytotoxic T lymphocytes* are activated and induce the infected cells to initiate apoptosis. How do lymphocytes induce cells to initiate the process of apoptosis? Typically, such activation is triggered when cells receive *cell death signals*. Two well-known death signals are *tumor necrosis factor* and *CD95/Fas*. Here, we will

focus on CD95, a protein on the surface of infected cells. Lymphocytes have a protein on their surfaces that binds to CD95, causing the CD95 within the infected cell to aggregate (Figure 19-45, ①). CD95 aggregation results in the attachment of adaptor proteins to the clustered CD95, which in turn recruits a procaspase (*procaspase-8*) to sites of receptor clustering. When the procaspase is activated (②), it acts as an initiator of the caspase cascade. A key action of such *initiator caspases* is the activation of an *executioner caspase*, known as *caspase-3* (③). Active caspase-3 is important for activating many steps in apoptosis.

In other cases, apoptosis is triggered indirectly. One of the best-studied cases of this second type of apoptosis involves **survival factors**. When such factors are withdrawn, a cell may enter apoptosis (④). Surprisingly, a key site of action of this second pathway is the mitochondrion. The connection between mitochondria and cell death may be surprising, but it is clear that, in addition to their role in energy production, mitochondria are important in apoptosis. If withdrawal of survival factors is the sentence of execution, then the executioners are mitochondria.

How do mitochondria hasten cell death? In a healthy cell that is not committed to apoptosis, there are several *anti-apoptotic* proteins in the outer mitochondrial membrane

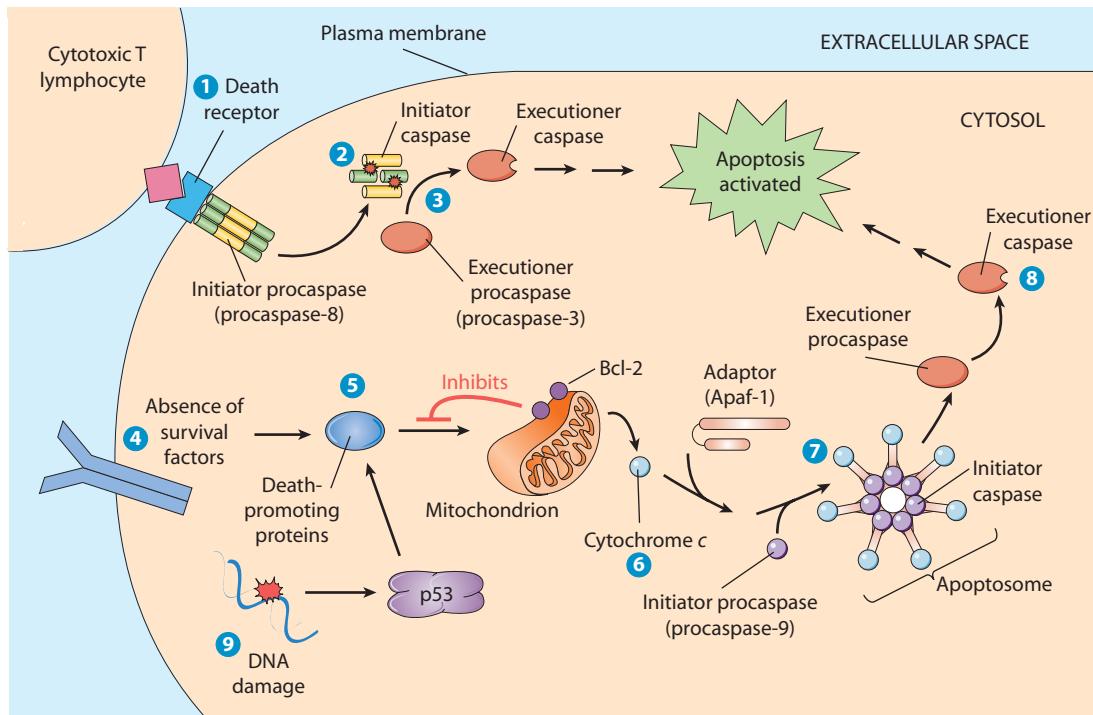

FIGURE 19-45 Induction of Apoptosis by Cell Death Signals or by Withdrawal of Survival Factors.

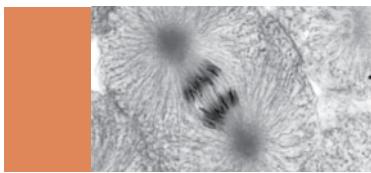

Cell death signals, such as ligands on the surface of a cytotoxic T lymphocyte, can lead to apoptosis. ① Ligand binds to a “death receptor” on the surface of a target cell. Binding causes clustering of receptors and recruitment of adaptor proteins in the target cell, resulting in clustering of initiator procaspase (procaspase-8) protein. ② Initiator caspases then become activated. ③ The initiator caspases in turn activate the executioner caspase, caspase-3, a key initiator of apoptosis. ④ When survival factors are no longer present, ⑤ death-promoting (pro-apoptotic) proteins accumulate, counterbalancing anti-apoptotic proteins (such as Bcl-2) at the mitochondrial outer membrane, ⑥ causing release of cytochrome *c*. ⑦ Cytochrome *c* forms a complex with other proteins, resulting in activation of an initiator caspase (caspase-9). ⑧ The initiator caspase in turn activates the executioner caspase, caspase-3, triggering apoptosis. ⑨ DNA damage can also lead to apoptosis through the activity of the p53 protein.

that prevent apoptosis, but only as long as a cell continues to be exposed to survival factors. These proteins are structurally related to a protein known as **Bcl-2**, the best understood of these anti-apoptotic proteins. Bcl-2 and other anti-apoptotic proteins exert their effects by counteracting other proteins that are themselves structurally similar to Bcl-2. These proteins, however, *promote* apoptosis, and so they are collectively referred to as *pro-apoptotic* proteins. Thus, pro- and anti-apoptotic proteins, influenced by cell signals, wage an ongoing battle; when the balance shifts toward pro-apoptotic proteins, a cell is more likely to undergo apoptosis (5). For example, stimulation of the Akt pathway, which you learned about earlier in this chapter, can lead to phosphorylation and inactivation of a pro-apoptotic protein called *Bad* (for Bcl-2-associated death promoter; Figure 19-43).

Surprisingly, mitochondria trigger apoptosis by releasing **cytochrome *c*** into the cytosol (Figure 19-45, 6). Although the details by which this happens are currently under debate, eventually the accumulation of pro-apoptotic protein at the surface of the mitochondrion leads to the formation of channels in the outer mitochondrial membrane, allowing cytochrome *c* to escape into the cytosol. Although cytochrome *c* is normally involved in electron transport (see

Chapter 10), it is important in triggering apoptosis in at least two ways. First, cytochrome *c* stimulates calcium release from adjacent mitochondria and from the endoplasmic reticulum, where it binds inositol-1,4,5-trisphosphate (IP_3) receptors. Second, it can activate an initiator procaspase associated with mitochondria, known as *procaspase-9*. It does this by recruiting a cytosolic adaptor protein (known as *Apaf-1*) that assembles procaspase-9 into a complex sometimes called an *apoptosome*; the apoptosome promotes the production of active caspase-9 (7). Like other initiator caspases, caspase-9 activates the executioner caspase, caspase-3 (8). Thus, in the end, both cell death mechanisms lead to the activation of a common caspase that sets apoptosis in motion.

There is another situation that can trigger the mitochondrial pathway to apoptosis. When a cell suffers so much damage that it is unable to repair itself, it may trigger its own demise. In particular, when a cell's DNA is damaged (for example, by radiation or ultraviolet light), it can enter apoptosis via the activity of *p53* (9). As we saw earlier in this chapter, *p53* acts through the protein Puma, which binds to and inhibits Bcl-2 (see Figure 19-40, step 2). In the end, just like withdrawal of survival factors, the *p53* pathway activates pro-apoptotic proteins to trigger apoptosis.

SUMMARY OF KEY POINTS

Overview of the Cell Cycle

- The eukaryotic cell cycle is divided into G1, S, G2, and M phases. Chromosomal DNA replication takes place during S phase, whereas cell division (mitosis and cytokinesis) occurs in M phase. Interphase (G1, S, and G2) is a time of cell growth and metabolism that typically occupies about 95% of the cycle.
- The length of the cell cycle varies greatly, ranging from cells that divide rapidly and continuously to cells that do not divide at all.

DNA Replication

- DNA is replicated by a semiconservative mechanism in which the two strands of the double helix unwind and each strand serves as a template for the synthesis of a complementary strand.
- Bacterial chromosome replication is typically initiated at a single point and moves in both directions around a circular DNA molecule. In contrast, eukaryotes initiate DNA replication at multiple replicons, and replication proceeds bidirectionally at each replicon. A licensing mechanism involving the binding of MCM proteins to replication origins allows eukaryotes to ensure that DNA is replicated only once prior to each mitosis.
- During replication, DNA polymerases synthesize DNA in the 5' → 3' direction. Synthesis is continuous along the leading strand but discontinuous along the lagging strand, generating small Okazaki fragments that are subsequently joined by DNA ligase.
- DNA replication is initiated by primase, which synthesizes short RNA primers that are later removed and replaced with DNA. During replication, the double helix is unwound through the combined action of DNA helicases, topoisomerases, and single-stranded DNA binding proteins. As replication proceeds, a proofreading mechanism based on the 3' → 5' exonuclease activity of DNA polymerase allows incorrectly base-paired nucleotides to be removed and replaced.
- The ends of linear chromosomal DNA molecules are synthesized by telomerase, an enzyme that uses an RNA template for creating short, repeated DNA sequences at the ends of each chromosome.

DNA Damage and Repair

- DNA damage arises both spontaneously and through the action of mutagenic chemicals and radiation.
- Some forms of DNA polymerase carry out translesion synthesis of new DNA across regions where the template DNA is damaged.
- Excision repair is used to correct DNA damage involving abnormal bases, whereas mismatch repair fixes improperly base-paired nucleotides. Nonhomologous end-joining and homologous recombination are used to repair double-strand DNA breaks.

Nuclear and Cell Division

- Mitosis is subdivided into prophase, prometaphase, metaphase, anaphase, and telophase. During prophase, replicated chromosomes condense into paired sister chromatids while centrosomes initiate assembly of the mitotic spindle. In prometaphase, the nuclear envelope breaks down and chromosomes then attach to spindle microtubules and move to the spindle equator, where they line up at metaphase. At anaphase, sister chromatids separate and the resulting daughter chromosomes move toward opposite spindle poles. During telophase the chromosomes decondense, and a nuclear envelope reassembles around each daughter nucleus.
- Chromosome movements are driven by three groups of motor proteins. Motor proteins located at the kinetochores and spindle poles move chromosomes toward the spindle poles, accompanied by disassembly of the microtubules at their plus and minus ends. Motor proteins that crosslink the polar microtubules move overlapping microtubules in opposite directions, thereby pushing the spindle poles apart. The final group of motor proteins move astral microtubules toward the plasma membrane, thereby pulling the spindle poles apart.
- Cytokinesis usually begins before mitosis is complete. In animal cells, an actomyosin filament network forms a cleavage furrow that constricts the cell at the midline and separates the cytoplasm into two daughter cells. In plant cells, a cell wall forms through the middle of the dividing cell.

Regulation of the Cell Cycle

- Progression through the eukaryotic cell cycle is regulated by Cdk-cyclin complexes.
- At the restriction point (Start in yeast), a Cdk-cyclin complex catalyzes the phosphorylation of the Rb protein to trigger passage into S phase.
- At the G2-M boundary, another Cdk-cyclin complex triggers entry into mitosis by catalyzing the phosphorylation of proteins that promote nuclear envelope breakdown, chromosome condensation, and spindle formation.
- At the metaphase-anaphase boundary, activation of the anaphase-promoting complex triggers a protein degradation pathway that initiates chromatid separation and targets mitotic cyclin for breakdown. The resulting loss of mitotic Cdk activity leads to events associated with the exit from mitosis, including cytokinesis, chromatin decondensation, and reassembly of the nuclear envelope.
- Checkpoint pathways monitor intracellular conditions and temporarily halt the cell cycle if conditions are not suitable for proceeding. The DNA replication checkpoint verifies that DNA synthesis has been completed before allowing the cell to exit from G2 and begin mitosis. DNA damage checkpoints involving the p53 protein halt the cell cycle at various points if

DNA damage is detected. Finally, the mitotic spindle checkpoint prevents chromosomes from moving to the spindle poles before all chromosomes are attached to the spindle.

Growth Factors and Cell Proliferation

- The cells of multicellular organisms do not normally proliferate unless they are stimulated by an appropriate growth factor.
- Many growth factors bind to receptors that activate the Ras pathway, which culminates in passage through the restriction point and into S phase. Growth factor receptors also activate the PI3-kinase–Akt pathway, which promotes cell survival and proliferation by phosphorylating and thereby activating target proteins that suppress apoptosis and inhibit cell cycle arrest.
- Some growth factors inhibit (rather than stimulate) cell proliferation by triggering the production of Cdk inhibitors.

MAKING CONNECTIONS

In this chapter, you have seen how DNA is replicated by a mechanism that unwinds the two strands of the DNA double helix and uses each strand as a template to guide the synthesis of a new complementary strand. The two sets of replicated DNA molecules are then parceled out to the two daughter cells during mitosis. Cell signaling, a topic you learned about in Chapter 14, regulates mitosis. The processes of mitosis and cytokinesis involve intricate regulation of the cytoskeleton, which you learned about in

Apoptosis

- Apoptosis is a form of cellular death triggered by activation of death receptors, withdrawal of survival factors, or as a result of DNA damage.
- Apoptosis involves the orderly dismantling of a dying cell's contents.
- Proteases called caspases are key mediators of apoptosis. Initiator caspases activate executioner caspases, which in turn activate other apoptosis proteins.
- Initiator caspases can be activated in several ways, including through the release of cytochrome *c* from mitochondria. Pro- and anti-apoptotic proteins at the mitochondrion regulate release of cytochrome *c*.

PROBLEM SET

More challenging problems are marked with a •.

19-1 Cell Cycle Phases. Indicate whether each of the following statements is true of the G1 phase of the cell cycle, S phase, G2 phase, or M phase. A given statement may be true of any, all, or none of the phases.

- (a) The amount of nuclear DNA in the cell doubles.
- (b) The nuclear envelope breaks into fragments.
- (c) Sister chromatids separate from each other.
- (d) Cells that will never divide again are likely to be arrested in this phase.
- (e) The primary cell wall of a plant cell forms.
- (f) Chromosomes are present as diffuse, extended chromatin.
- (g) This phase is part of interphase.
- (h) Mitotic cyclin is at its lowest level.
- (i) A Cdk protein is present in the cell.
- (j) A cell cycle checkpoint has been identified in this phase.

19-2 The Mitotic Index and the Cell Cycle. The mitotic index is a measure of the mitotic activity of a population of cells. It is calculated as the percentage of cells in mitosis at any one time. Assume that upon examining a sample of 1000 cells, you find 30 cells in prophase, 20 in prometaphase, 20 in metaphase, 10 in anaphase, 20 in telophase, and 900 in interphase. Of those in

Chapters 15 and 16. In Chapter 20 you will learn how a different type of cell division, meiosis, allows genetic information in replicated DNA molecules to be recombined during formation of the sperm and egg cells that make sexual reproduction possible. After learning about the replication and distribution of DNA molecules during mitosis in this chapter and meiosis in the following chapter, you will see in Chapters 21–23 how the information stored in DNA molecules is expressed and regulated.

interphase, 400 are found (by staining the cells with a DNA-specific stain) to have *X* amount of DNA, 200 to have 2*X*, and 300 cells to be somewhere in between. Autoradiographic analysis indicates that the G2 phase lasted 4 hours.

- (a) What is the mitotic index for this population of cells?
- (b) Specify the proportion of the cell cycle spent in each of the following phases: prophase, prometaphase, metaphase, anaphase, telophase, G1, S, and G2.
- (c) What is the total length of the cell cycle?
- (d) What is the actual amount of time (in hours) spent in each of the phases of part b?
- (e) To measure the G2 phase, radioactive thymidine (a DNA precursor) is added to the culture at some time *t*, and samples of the culture are analyzed autoradiographically for labeled nuclei at regular intervals thereafter. What specific observation would have to be made to assess the length of the G2 phase?
- (f) What proportion of the interphase cells would you expect to exhibit labeled nuclei in autoradiographs prepared shortly after exposure to the labeled thymidine? (Assume a labeling period just long enough to allow the thymidine to get into the cells and begin to be incorporated into DNA.)

19-3 Meselson and Stahl Revisited. Although the Watson–Crick structure for DNA suggested a semiconservative model for DNA replication, at least two other models are conceivable.

In a *conservative model*, the parental DNA double helix remains intact and a second, all-new copy is made. In a *dispersive model*, each strand of both daughter molecules contains a mixture of old and newly synthesized segments.

- (a) Starting with one parental double helix, sketch the progeny molecules for two rounds of replication according to each of these alternative models. Use one color for the original parent strands and another color for all the DNA synthesized thereafter (as is done in Figure 19-3 for the semiconservative model).
- (b) For each of the alternative models, indicate the distribution of DNA bands that Meselson and Stahl would have found in their cesium chloride gradients after one and two rounds of replication.

19-4 DNA Replication. Sketch a replication fork of bacterial DNA in which one strand is being replicated discontinuously and the other is being replicated continuously. List six different enzyme activities associated with the replication process, identify the function of each activity, and show where each would be located on the replication fork. In addition, identify the following features on your sketch: DNA template, RNA primer, Okazaki fragments, and single-stranded DNA binding protein.

• **19-5 More DNA Replication.** The following are observations from five experiments carried out to determine the mechanism of DNA replication in the hypothetical organism *Fungus mungus*. For each experiment, indicate whether the results support (S), refute (R), or have no bearing (NB) on the hypothesis that this fungus replicates its DNA by the same mechanism as that known for *E. coli*. Explain your reasoning in each case.

- (a) Neither of the two DNA polymerases of *F. mungus* appears to have an exonuclease activity.
- (b) Replicating DNA from *F. mungus* shows discontinuous synthesis on both strands of the replication fork.
- (c) Some of the DNA sequences from *F. mungus* are present in multiple copies per genome, whereas other sequences are unique.
- (d) Short fragments of *F. mungus* DNA isolated during replication contain both ribose and deoxyribose.
- (e) *F. mungus* cells are grown in the presence of the heavy isotopes ^{15}N and ^{13}C for several generations and then grown for one generation in normal (^{14}N , ^{12}C) medium; then DNA is isolated from these cells and denatured. The single strands yield a single band in a cesium chloride density gradient.

19-6 Still More DNA Replication. Suppose you are given a new temperature-sensitive bacterial mutant that grows normally at 37°C but cannot replicate its chromosomes properly at 42°C . To investigate the nature of the underlying defect, you incubate the cells at 42°C with radioactive substrates required for DNA synthesis. After one hour you find that the cell population has doubled its DNA content, suggesting that DNA replication can still occur at 42°C . Moreover, centrifugation reveals that all of this DNA has the same large molecular weight as does the original DNA present in the cells. When the DNA is denatured, however, you discover that 75% of the resulting single-stranded DNA has a molecular weight that is half that of the original double-stranded DNA, and the remaining 25% of the DNA has a much lower molecular weight. Based on the pre-

ceding results, what gene do you think is defective in these cells? Explain how such a defect would account for the experimental results that you observed.

19-7 The Minimal Chromosome. To enable it to be transmitted intact from one cell generation to the next, the linear DNA molecule of a eukaryotic chromosome must have appropriate nucleotide sequences making up three special kinds of regions: Origins of replication (at least one), a centromere, and two telomeres. What would happen if such a chromosomal DNA molecule somehow lost:

- (a) all of its origins of replication?
- (b) all of the DNA constituting its centromere?
- (c) one of its telomeres?

19-8 DNA Damage and Repair. Indicate whether each of the following statements is true of depurination (DP), deamination (DA), or pyrimidine dimer formation (DF). A given statement may be true of any, all, or none of these processes.

- (a) This process is caused by spontaneous hydrolysis of a glycosidic bond.
- (b) This process is induced by ultraviolet light.
- (c) This can happen to guanine but not to cytosine.
- (d) This can happen to thymine but not to adenine.
- (e) This can happen to thymine but not to cytosine.
- (f) Repair involves a DNA glycosylase.
- (g) Repair involves an endonuclease.
- (h) Repair involves DNA ligase.
- (i) Repair depends on the existence of separate copies of the genetic information in the two strands of the double helix.
- (j) Repair depends on cleavage of both strands of the double helix.

19-9 Nonstandard Purines and Pyrimidines. Shown in **Figure 19-46a** are three nonstandard nitrogenous bases that are formed by the deamination of naturally occurring bases in DNA.

- (a) Indicate which base in DNA must be deaminated to form each of these bases.

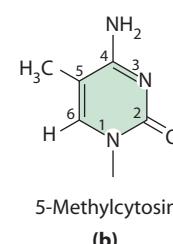

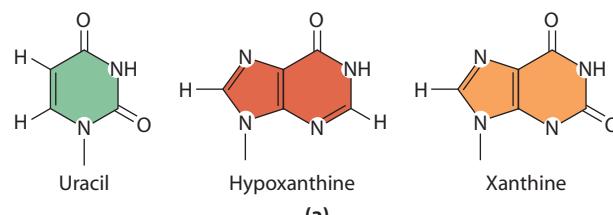

FIGURE 19-46 Structures of Several Nonstandard Purines and Pyrimidines. See Problem 19-9.

- (b) Why are there only three bases shown, when DNA contains four bases?
- (c) Why is it important that none of the bases shown in Figure 19-46a occurs naturally in DNA?
- (d) Figure 19-46b shows 5-methylcytosine, a pyrimidine that arises naturally in DNA when cellular enzymes methylate cytosine. Why is the presence of this base likely to increase the probability of a mutation?

• **19-10 Chromosome Movement in Mitosis.** It is possible to mark the microtubules of a spindle by photobleaching with a laser microbeam (**Figure 19-47**). When this is done, chromosomes move toward the bleached area during anaphase. Are the following statements consistent (C) or inconsistent (I) with this experimental result?

- (a) Microtubules move chromosomes solely by disassembling at the spindle poles.
- (b) Chromosomes move by disassembling microtubules at their kinetochore ends.
- (c) Chromosomes are moved along microtubules by a kinetochore motor protein that moves along the surface of the microtubule and “pulls” the chromosome with it.

19-11 Cytokinesis. Predict what will happen in each of the following situations, based on your knowledge of cytokinesis. In each case, explain your answer.

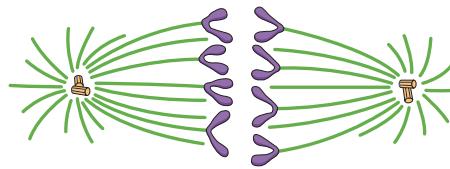

- (a) A fertilized sea urchin egg is injected with C3 transferase, a bacterial toxin that ADP ribosylates and inhibits Rho, 30 minutes prior to first cleavage.
- (b) A one-celled *C. elegans* zygote lacks *anillin*, a protein that is required to assemble myosin efficiently at the cell surface.

19-12 More on Cell Cycle Phases. For each of the following pairs of phases from the cell cycle, indicate how you could tell in which of the two phases a specific cell is located.

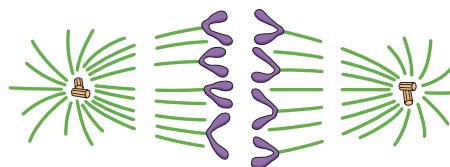

- | | |
|---------------|--------------|
| (a) G1 and G2 | (c) G2 and M |
| (b) G1 and S | (d) G1 and M |

• **19-13 Cell Cycle Regulation.** Recall that one approach to the study of cell cycle regulation has been to fuse cultured cells that are at different stages of the cell cycle and observe the effect of the fusion on the nuclei of the fused cells (heterokaryons). When cells in G1 are fused with cells in S, the nuclei from the G1 cells begin DNA replication earlier than they would have if they had not been fused. In fusions of cells in G2 and S, however, nuclei continue their previous activities, apparently uninfluenced by the fusion. Fusions between mitotic cells and interphase cells always lead to chromatin condensation in the nonmitotic nuclei. Based on these results, identify each of the following statements about cell cycle regulation as probably true (T), probably false (F), or not possible to conclude from the data (NP).

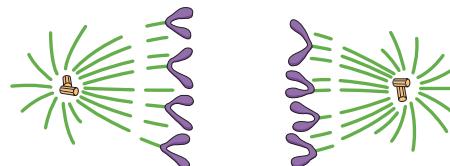

- (a) The activation of DNA synthesis may result from the stimulatory activity of one or more cytoplasmic factors.
- (b) The transition from S to G2 may result from the presence of a cytoplasmic factor that inhibits DNA synthesis.
- (c) The transition from G2 to mitosis may result from the presence in the G2 cytoplasm of one or more factors that induce chromatin condensation.
- (d) G1 is not an obligatory phase of all cell cycles.
- (e) The transition from mitosis to G1 appears to result from the disappearance or inactivation of a cytoplasmic factor present during M phase.

Microtubules are labeled with a fluorescent dye during anaphase.

A laser microbeam is used to mark two areas by bleaching the fluorescent dye.

The chromosomes are observed to move toward the bleached areas.

FIGURE 19-47 Use of Laser Photobleaching to Study Chromosome Movement During Mitosis. See Problem 19-10.

• **19-14 Role of Cyclin-Dependent Protein Kinases.** Based on your understanding of the regulation of the eukaryotic cell cycle, how could you explain each of the following experimental observations?

- (a) When mitotic Cdk-cyclin is injected into cells that have just emerged from S phase, chromosome condensation and nuclear envelope breakdown occur immediately, rather than after the normal G2 delay of several hours.
- (b) When an abnormal, indestructible form of mitotic cyclin is introduced into cells, they enter into mitosis but cannot emerge from it and reenter G1 phase.
- (c) Mutations that inactivate the main protein phosphatase used to catalyze protein dephosphorylations cause a long delay in the reconstruction of the nuclear envelope that normally takes place at the end of mitosis.

• **19-15 Apoptosis and Medicine.** A current focus of molecular medicine is to trigger or prevent apoptosis in specific cells. Several components of the apoptotic pathway are being targeted using this approach. For each of the following, state specifically how the treatment would be expected to stimulate or inhibit apoptosis.

- (a) Cells are treated with a small molecule called pifithrin- α , which was originally isolated for its ability to reversibly block p53-dependent transcriptional activation.
- (b) Exposing cells to recombinant TRAIL protein, a ligand for the tumor necrosis factor family of receptors.
- (c) Treatment of cells with organic compounds that enter the cell and bind with high affinity to the active site of caspase-3.

Sexual Reproduction, Meiosis, and Genetic Recombination

Mitotic cell division, which we discussed in the preceding chapter, is used for the proliferation of most eukaryotic cells, leading to the production of more organisms or more cells per organism. Since a mitotic cell division cycle involves one round of DNA replication followed by the segregation of identical chromatids into two daughter cells, mitotic division produces cells that are genetically identical, or very nearly so. This ability to perpetuate genetic traits faithfully allows mitotic division to form the basis of **asexual reproduction** in eukaryotes. During asexual reproduction, new individuals are generated by mitotic division of cells in a single parent organism, either unicellular or multicellular. Although the details vary among organisms, asexual reproduction is widespread in nature. Examples include mitotic division of unicellular organisms, budding of offspring from a multicellular parent's body, and regeneration of whole organisms from pieces of a parent organism. In plants, entire organisms can even be regenerated from single cells taken from an adult plant.

Asexual reproduction can be an efficient and evolutionarily successful mode of perpetuating a species. As long as environmental conditions remain essentially constant, the genetic predictability of asexual reproduction is perfectly suited for maintaining the survival of a population. But if the environment changes, a population that reproduces asexually may not be able to adapt to the new conditions. Under such conditions, organisms that reproduce sexually rather than asexually will usually have an advantage, as we now discuss.

Sexual Reproduction

In contrast to asexual reproduction, in which progeny are genetically identical to the single parent from which they arise, **sexual reproduction** allows genetic information from two parents to be mixed together, thereby producing

offspring that are genetically dissimilar, both from each other and from the parents. Moreover, the offspring are unpredictably dissimilar; that is, we cannot anticipate exactly which combination of genes a particular offspring will receive from its two parents. Since most plants and animals—and even many eukaryotic microorganisms—reproduce sexually, this type of reproduction must provide some distinct advantages.

Sexual Reproduction Produces Genetic Variety by Bringing Together Chromosomes from Two Different Parents

Sexual reproduction allows genetic traits found in different individuals to be combined in various ways in newly developing offspring, thereby generating enormous variety among the individuals that make up a population. Genetic variation ultimately depends on the occurrence of *mutations*, which are unpredictable alterations in DNA base sequence. Mutations are rare events, and beneficial mutations are even rarer. But when beneficial mutations do arise, it is clearly advantageous to preserve them in the population. It can be even more beneficial to bring mutations together in various combinations—and therein lies an advantage of sexual reproduction. Although mutations occur in both sexual and asexual species, only sexual reproduction can bring about a reshuffling of genetic information in each new offspring.

Because sexual reproduction combines genetic information from two different parents into a single offspring, at some point in its life cycle every sexually reproducing organism has cells that contain two copies of each type of chromosome, one inherited from each parent. The two members of each chromosome pair are called **homologous chromosomes**. Two homologous chromosomes carry the same lineup of genes, although for any given gene, the two versions may differ slightly in base sequence. Not surprisingly, homologous chromosomes

usually look alike when viewed with a microscope (see Figure 19-23). An exception to this rule is the **sex chromosomes**, which determine whether an individual is male or female. The two kinds of sex chromosomes, generally called X and Y chromosomes, differ significantly in genetic makeup and appearance. In mammals, for example, females have two X chromosomes of the same size, whereas males have one X chromosome and a Y chromosome that is much smaller. Nonetheless, parts of the X and Y chromosomes are actually homologous; and, during sexual reproduction, the X and Y chromosomes behave as homologues.

A cell or organism with two sets of chromosomes is said to be **diploid** (from the Greek word *diploos*, meaning “double”) and contains two copies of its genome. A cell or organism with a single set of chromosomes, and therefore a single copy of its genome, is **haploid** (from the Greek word *haploos*, meaning “single”). By convention, the haploid chromosome number for a species is designated n (or $1n$) and the diploid number $2n$. For example, in humans $n = 23$, which means that most human cells contain two sets of 23 chromosomes, yielding a diploid total of 46. The diploid state is an essential feature of the life cycle of sexually reproducing species. In a sense, a diploid cell contains an extra set of genes that is available for mutation and genetic innovation. Changes in a second copy of a gene usually will not threaten the survival of an organism, even if the mutation disrupts the original function of that particular gene copy. In addition, the diploid state provides some protection against chromosome damage; if one chromosome is accidentally broken, it can sometimes be repaired using the DNA sequence of the homologous chromosome as a template (page 626).

Diploid Cells May Be Homozygous or Heterozygous for Each Gene

To further explore the genetic consequences of the diploid state, let’s now focus on the behavior of an individual **gene locus** (plural: **loci**), which is the place on a chromosome that contains the DNA sequence for a particular gene. For simplicity, we will assume that the gene controls a single, clear-cut characteristic—or **character**, as geneticists usually say—in the organism. Let’s also assume that only one copy of this gene is present per haploid genome, so that a diploid organism will have two copies of the gene, which may be either identical or slightly different. The two versions of the gene are called **alleles**, and the combination of alleles determines how an organism will express the character controlled by the gene. In garden peas, for example, the alleles at one particular locus determine seed color, which may be green or yellow (Figure 20-1). An organism with two identical alleles for a given gene is said to be **homozygous** for that gene or character. Thus, a pea plant that inherited the same allele for yellow seed color from both of its parents is said to be homozygous for seed color. An organism with two different alleles for a gene is

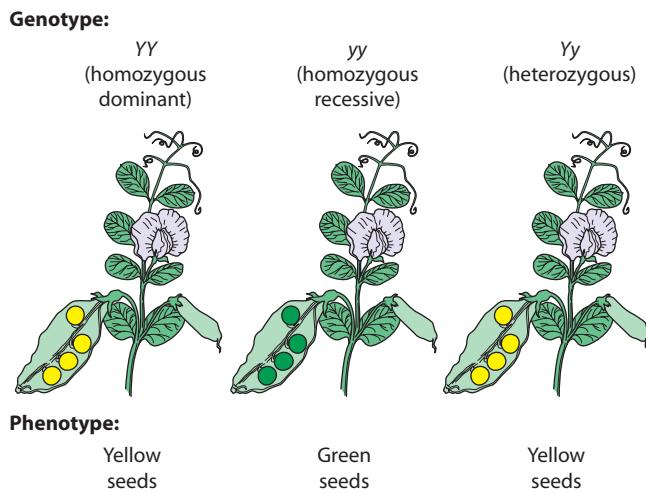

FIGURE 20-1 Genotype and Phenotype. In garden peas, seed color (phenotype) can be either yellow or green. The seed-color alleles are Y (yellow, dominant) or y (green, recessive). Because the pea plant is a diploid organism, its genetic makeup (genotype) for seed color may be homozygous dominant (YY), homozygous recessive (yy), or heterozygous (Yy).

said to be **heterozygous** for that gene or for the character it determines. A pea plant with one allele that specifies yellow seed color and a second allele that specifies green seed color is therefore heterozygous for seed color.

In a heterozygous individual, one of the two alleles is often **dominant** and the other **recessive**. These terms convey the idea that the dominant allele determines how the trait will appear in a heterozygous individual. (The word *trait* refers to a particular variant of a character, such as green or yellow seeds, where seed color is the character.) For seed color in peas, the yellow trait is dominant over green; this means that pea plants heterozygous for seed color have yellow seeds. A dominant allele is usually designated by an uppercase letter that stands for the trait, whereas a corresponding recessive allele is represented by the same letter in lowercase. In both cases, italics are used. Thus, alleles for seed color in peas are represented by Y for yellow and y for green because the yellow trait is dominant. As Figure 20-1 illustrates, a pea plant can be homozygous for the dominant allele (YY), homozygous for the recessive allele (yy), or heterozygous (Yy).

It is important to distinguish between the **genotype**, or genetic makeup of an organism, and its **phenotype**, or the physical expression of its genotype. The phenotype of an organism can usually be determined by inspection (e.g., by looking to see whether seeds are green or yellow). Genotype, on the other hand, can be *directly* determined only by studying an organism’s DNA. The genotype also can be deduced from indirect evidence, such as the organism’s phenotype and information about the phenotypes of its parents and/or offspring. Organisms exhibiting the same phenotype do not necessarily have identical genotypes. In the example of Figure 20-1, pea plants with

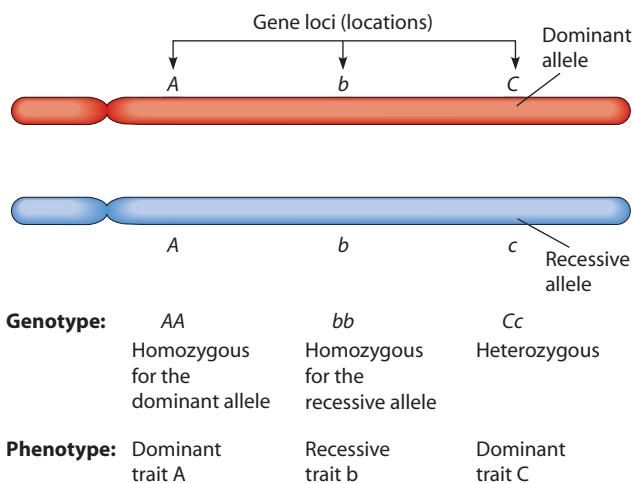

FIGURE 20-2 Some Genetic Terminology. This diagram shows a homologous pair of chromosomes from a diploid cell; the chromosomes are the same size and shape and carry genes for the same characters (characteristics), in the same order. The site of a gene on a chromosome is called a gene locus. The particular versions of a gene—alleles—found at comparable gene loci on homologous chromosomes may be identical (giving the organism a genotype that is homozygous for that gene) or different (making the genotype heterozygous). If one allele of a gene is dominant and the other recessive, the heterozygous organism exhibits a dominant phenotype with respect to the character in question. A recessive phenotypic trait is observed only if the genotype is homozygous for the recessive allele. Red and blue are used here and in most later figures to distinguish the different parental origins of the two chromosomes.

yellow seeds (phenotype) can be either YY or Yy (genotype). **Figure 20-2** summarizes the genetic terminology introduced so far.

Gametes Are Haploid Cells Specialized for Sexual Reproduction

The hallmark of sexual reproduction is that genetic information contributed by two parents is brought together in a single individual. Because the offspring of sexual reproduction are diploid, the contribution from each parent must be haploid. The haploid cells produced by each parent that fuse together to form the diploid offspring are called **gametes**, and the process that produces them is **gametogenesis**. Biologists distinguish between male and female individuals on the basis of the gametes they produce. Gametes produced by males, called **sperm** (or *spermatozoa*), are usually quite small and may be inherently motile. Female gametes, called **eggs** or **ova** (singular: **ovum**), are specialized for the storage of nutrients and tend to be quite large and nonmotile. For example, in sea urchins the volume of an egg cell is more than 10,000 times greater than that of a sperm cell; in birds and amphibians, which have massive yolk eggs, the size difference is even greater. But despite their differing sizes, sperm and egg bring equal amounts of chromosomal DNA to the offspring.

The union of sperm and egg during sexual reproduction is called **fertilization**. The resulting fertilized egg, or **zygote**, is diploid, having received one chromosome set from the sperm and a homologous set from the egg. In the life cycles of multicellular organisms, fertilization is followed by a series of mitotic divisions and progressive specialization of various groups of cells to form a multicellular embryo and eventually an adult.

In a few unusual situations, eggs can develop into offspring without the need for sperm—a phenomenon known as **parthenogenesis**. A striking case in point is the Komodo dragon, an inhabitant of the central islands of Indonesia. The Komodo dragon is the world's largest species of lizard, growing to an average length of 7–10 feet. When male Komodos are unavailable for sexual reproduction, female Komodos give birth to offspring through a self-fertilization process involving the fusion of a haploid egg cell with a haploid *polar body*—a “mini-egg” produced at the same time eggs are formed (see page 611). Consequently, the genes of each offspring derive solely from the mother, though the offspring are not exact duplicates of the mother because different combinations of alleles are present in the haploid cells that fuse together to create the embryo.

In some organisms, gametes cannot be categorized as being male or female. Certain fungi and unicellular eukaryotes, for example, produce gametes that are identical in appearance but differ slightly at the molecular level. Such gametes are said to differ in **mating type**. The union of two of these gametes requires that they be of different mating types, but the number of possible mating types in a species may be greater than two—in some cases, more than ten!

Meiosis

Since gametes are haploid, they cannot be produced from diploid cells by mitosis because mitosis creates daughter cells that are genetically identical to the original parent cell. In other words, if gametes were formed by mitotic division of diploid cells, both sperm and egg would have a diploid chromosome number, just like the parent diploid cells. The hypothetical zygote created by the fusion of such diploid gametes would be **tetraploid** (i.e., possess four homologous sets of chromosomes). Moreover, the chromosome number would continue to double for each succeeding generation—an impossible scenario. Thus, for the chromosome number to remain constant from generation to generation, a different type of cell division must occur during the formation of gametes. That special type of division, called **meiosis**, reduces the chromosome number from diploid to haploid.

Meiosis involves one round of chromosomal DNA replication followed by two successive nuclear divisions. This results in the formation of four daughter nuclei (usually in separate daughter cells) containing one

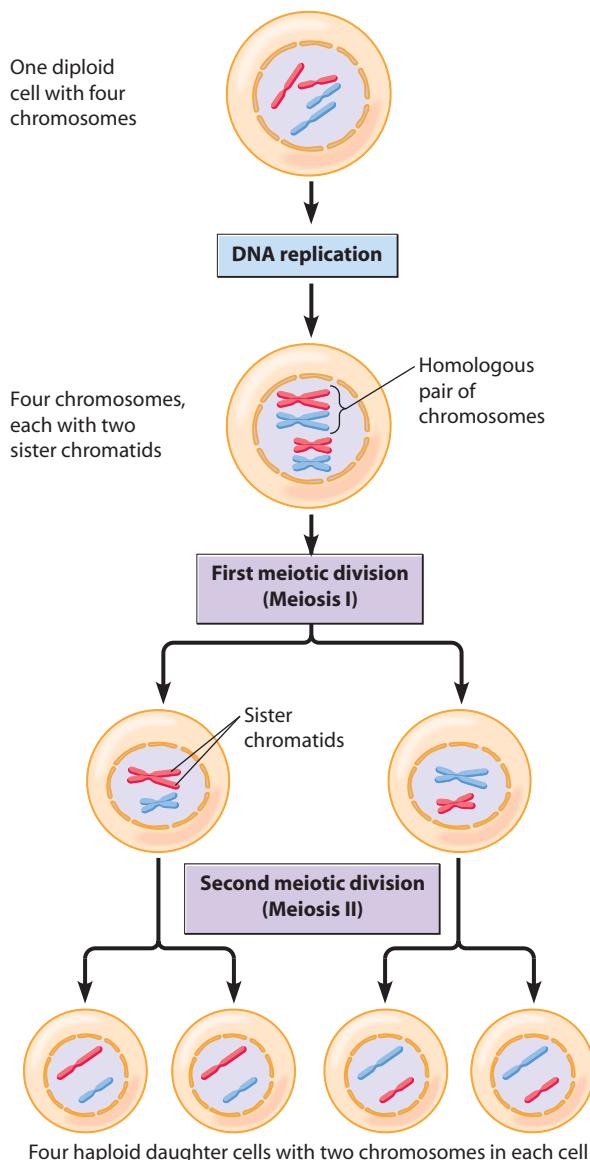

FIGURE 20-3 The Principle of Meiosis. Meiosis involves a single round of DNA replication (chromosome duplication) in a diploid cell followed by two successive cell division events. In this example, the diploid cell has only four chromosomes, which can be grouped into two homologous pairs. After DNA replication, each chromosome consists of two sister chromatids. In the first meiotic division (meiosis I), homologous chromosomes separate, but sister chromatids remain attached. In the second meiotic division (meiosis II), sister chromatids separate, resulting in four haploid daughter cells with two chromosomes each. Notice that each haploid cell has one chromosome from each homologous pair that was present in the diploid cell. For simplicity, the effects of crossing over and genetic recombination are not shown in this diagram.

 **ACTIVITIES** www.thecellplace.com Meiosis

haploid set of chromosomes per nucleus. **Figure 20-3** outlines the principle of meiosis starting with a diploid cell containing four chromosomes ($2n = 4$). A single round of DNA replication is followed by two cell divisions, meiosis I and meiosis II, leading to the formation of four haploid cells.

The Life Cycles of Sexual Organisms Have Diploid and Haploid Phases

Meiosis and fertilization are indispensable components of the life cycle of every sexually reproducing organism, because the doubling of chromosome number that takes place at fertilization is balanced by the halving that occurs during meiosis. As a result, the life cycle of sexually reproducing organisms is divided into two phases: a diploid ($2n$) phase and a haploid ($1n$) phase. The diploid phase begins at fertilization and extends until meiosis, whereas the haploid phase is initiated at meiosis and ends with fertilization.

Organisms vary greatly in the relative prominence of the haploid and diploid phases of their life cycles, as shown for some representative groups in **Figure 20-4**. Some fungi are examples of sexually reproducing organisms whose life cycles are primarily haploid but include a brief diploid phase that begins with gamete fusion (the fungal equivalent of fertilization) and ends with meiosis (Figure 20-4b). Meiosis usually takes place almost immediately after gamete fusion, so the diploid phase is very short. Accordingly, only a very small fraction of nuclei in such fungi are diploid at any one time. Fungal gametes develop, without meiosis, from cells that are already haploid.

Mosses and ferns are probably the best examples of organisms in which both the haploid and diploid phases are prominent features of the life cycle. Every species of these plants has two alternative, morphologically distinct, multicellular forms, one haploid and the other diploid (Figure 20-4c). For mosses, the haploid form of the organism is larger and more prominent, and the diploid form is smaller and more short-lived. For ferns, it is the other way around. In both cases, gametes develop from preexisting haploid cells.

Organisms that alternate between haploid and diploid multicellular forms in this way are said to display an **alternation of generations** in their life cycles. In addition to mosses and ferns, eukaryotic algae and other plants exhibit an alternation of diploid and haploid generations. In all such organisms, the products of meiosis are **haploid spores**, which, after germination, give rise by mitotic cell division to the haploid form of the plant or alga. The haploid form in turn produces the gametes by specialization of cells that are already haploid. The gametes, upon fertilization, give rise to the diploid form. Because the diploid form produces spores, it is called a **sporophyte** ("spore-producing plant"). The haploid form produces gametes and is therefore called a **gametophyte**. While all plants exhibit an alternation of generations, in most cases the sporophyte generation predominates. In flowering plants, for example, the gametophyte generation is an almost vestigial structure located in the flower (female gametophyte in the *carpel*, male gametophytes in the flower's *anthers*).

The best examples of life cycles dominated by the diploid phase are found in animals (Figure 20-4d). In such

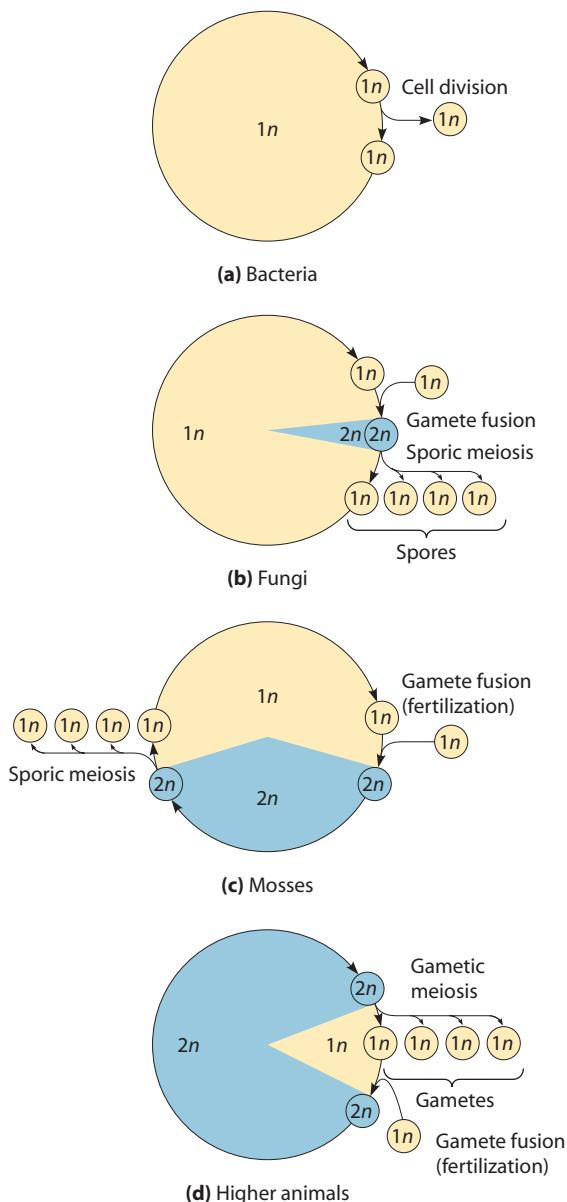

FIGURE 20-4 Types of Life Cycles. The relative prominence of the haploid ($1n$) and diploid ($2n$) phases of the life cycle differ greatly, depending on the organism. (a) Bacteria exist exclusively in the haploid state. (b) Many fungi exemplify a life form that is predominantly haploid but has a brief diploid phase. Because the products of meiosis in fungi are haploid spores, this type of meiosis is called *sporic meiosis*. The spores give rise to haploid cells, some of which later become gametes (without meiosis). (c) Mosses (and ferns as well) alternate between haploid and diploid forms, both of which are significant components in the life cycles of these organisms. Sporic meiosis produces haploid spores, which in this case grow into haploid plants. Eventually, some of the haploid plant's cells differentiate into gametes. (In seed plants, such as conifers and flowering plants, the haploid forms of the organism are vestigial, each consisting of only a small number of cells.) (d) Higher animals are the best examples of organisms that are predominantly diploid, with only the gametes representing the haploid phase of the life cycle. Animals are said to have a *gametic meiosis*, since the immediate products of meiosis are haploid gametes.

organisms, including humans, meiosis gives rise not to spores but to gametes directly, so the haploid phase of the life cycle is represented only by the gametes. Meiosis in such species is called *gametic meiosis* to distinguish it from the *sporic meiosis* observed in spore-producing organisms exhibiting an alternation of generations. Meiosis is thus gametic in animals and sporic in plants.

Meiosis Converts One Diploid Cell into Four Haploid Cells

Wherever it occurs in an organism's life cycle, meiosis is always preceded by chromosome duplication in a diploid cell and involves two successive divisions that convert the diploid nucleus into four haploid nuclei. **Figure 20-5** illustrates the various phases of meiosis; refer to it as you read the following discussion.

The first meiotic division, or **meiosis I**, is sometimes referred to as the *reduction division* of meiosis because it is the event that reduces the chromosome number from diploid to haploid. Early during meiosis I, the two chromosomes of each homologous pair come together during prophase to exchange some of their genetic information (using a mechanism to be discussed shortly). This pairing of homologous chromosomes, called **synapsis**, is unique to meiosis; at all other times, including mitosis, the chromosomes of a homologous pair behave independently.

The two chromosomes of each homologous pair bind together so tightly during the first meiotic prophase that they behave as a single unit called a **bivalent** (or *tetrad*, which emphasizes that each of the two homologous chromosomes consists of two sister chromatids, yielding a total of four chromatids). After aligning at the spindle equator, each bivalent splits apart in such a way that its two homologous chromosomes move to opposite spindle poles. Because each pole receives only one member of each homologous pair, the daughter nuclei produced by meiosis I are considered to be haploid (even though the individual chromosomes in these nuclei are composed of two sister chromatids). During the second meiotic division (meiosis II), which closely resembles a mitotic division, the two sister chromatids of each chromosome separate into two daughter cells. Hence, the events unique to meiosis happen during the first meiotic division: the synapsis of homologous chromosomes and their subsequent segregation into different daughter nuclei.

Meiotic cell divisions involve the same basic stages as mitosis, although cell biologists do not usually distinguish prometaphase as a separate phase. Thus, the meiotic phases are *prophase*, *metaphase*, *anaphase*, and *telophase*. We will see shortly that prophase I is much longer and more complicated than mitotic prophase, whereas prophase II tends to be quite short. Another important difference from mitosis is that a normal interphase does not intervene between the two meiotic divisions. If an interphase does take place, it is usually very short and—most

importantly—does *not* include DNA replication, because each chromosome already consists of a pair of replicated sister chromatids that had been generated prior to the first meiotic division. The purpose of the second meiotic division, like that of a typical mitotic division, is to parcel these sister chromatids into two daughter nuclei.

Meiosis I Produces Two Haploid Cells That Have Chromosomes Composed of Sister Chromatids

The first meiotic division segregates homologous chromosomes into different daughter cells. This feature of meiosis has special genetic significance because it represents the point in an organism's life cycle when the two alleles for each gene part company. And it is this separation of alleles that makes possible the eventual remixing of different pairs of alleles at fertilization. Also of great significance during the first meiotic division are events involving the physical exchange of parts of DNA molecules. Such an exchange of DNA segments between two different sources is called **genetic recombination** by molecular biologists. As we will discuss shortly, this type of DNA exchange between homologous chromosomes takes place when the chromosomes are synapsed during prophase I.

Prophase I: Homologous Chromosomes Become Paired and Exchange DNA. Prophase I is a particularly long and complex phase. Based on light microscopic observations, early cell biologists divided prophase I into five stages called *leptotene*, *zygotene*, *pachytene*, *diplotene*, and *diakinesis* (**Figure 20-6**, p. 608).

The **leptotene** stage begins with the condensation of chromatin fibers into long, threadlike structures, similar to what occurs at the beginning of mitosis. At **zygotene**, continued condensation makes individual chromosomes distinguishable, and homologous chromosomes become closely paired with each other via the process of synapsis, forming bivalents. Keep in mind that each bivalent has four chromatids, two derived from each chromosome. Bivalent formation is of considerable genetic significance because the close proximity between homologous chromosomes allows DNA segments to be exchanged by a process called **crossing over**. It is this physical exchange of genetic information between corresponding regions of homologous chromosomes that accounts for genetic recombination. You will learn more about the molecular nature of crossing over later in this chapter. Crossing over occurs during the **pachytene** stage, which is marked by a dramatic compacting process that reduces each chromosome to less than a quarter of its previous length.

At the **diplotene** stage, the homologous chromosomes of each bivalent begin to separate from each other, particularly near the centromere. However, the two chromosomes of each homologous pair remain attached by connections known as **chiasmata** (singular: **chiasma**). Such connections are situated in regions where homolo-

gous chromosomes have exchanged DNA segments and hence provide visual evidence that crossing over has occurred between two chromatids, one derived from each chromosome.

In some organisms—female mammals, for instance—the chromosomes decondense during diplotene, transcription resumes, and the cells “take a break” from meiosis for a prolonged period of growth, sometimes lasting for years. (We will consider this situation at the end of our discussion of meiosis.) With the onset of **diakinesis**, the final stage of prophase I, the chromosomes recondense to their maximally compacted state. Now the centromeres of the homologous chromosomes separate further, and the chiasmata eventually become the only remaining attachments between the homologues. At this stage, the nucleoli disappear, the spindle forms, and the nuclear envelope breaks down, marking the end of prophase I.

With the advent of modern tools, especially the electron microscope, cell biologists have been able to refine our picture of what happens during prophase I. They have found that what holds homologous chromosomes in tight apposition during synapsis is the **synaptonemal complex**, an elaborate protein structure resembling a zipper (**Figure 20-7**, p. 609). The *lateral elements* of the synaptonemal complex start to attach to individual chromosomes during leptotene, but the *central element*, which actually joins homologous chromosomes together, does not form until zygotene (see **Figure 20-7b**). How do the members of each pair of homologous chromosomes find each other so they can be joined by a synaptonemal complex? During early zygotene, the ends (telomeres) of each chromosome become clustered on one side of the nucleus and attach to the nuclear envelope, with the body of each chromosome looping out into the nucleus. To picture this, imagine holding all the ends of four ropes (two long and two short) together. If you give the ropes a strong shake, they will settle into four loops, arranged according to length. This type of chromosome configuration, called a *bouquet*, is thought to promote chromosome alignment.

The alignment of similar-sized chromosomes facilitates formation of synaptonemal complexes, which become fully developed during pachytene. Formation of synaptonemal complexes is closely associated with the process of crossing over in higher eukaryotes, and some electron micrographs reveal additional protein complexes, called **recombination nodules**, that may mediate the crossing over process. The synaptonemal complexes then disassemble during diplotene, allowing the homologous chromosomes to separate (except where they are joined by chiasmata).

Metaphase I: Bivalents Align at the Spindle Equator. During metaphase I, the bivalents attach via their kinetochores to spindle microtubules and migrate to the spindle equator. The presence of *paired* homologous chromosomes (i.e., bivalents) at the spindle equator during metaphase I is a crucial difference between meiosis I and a

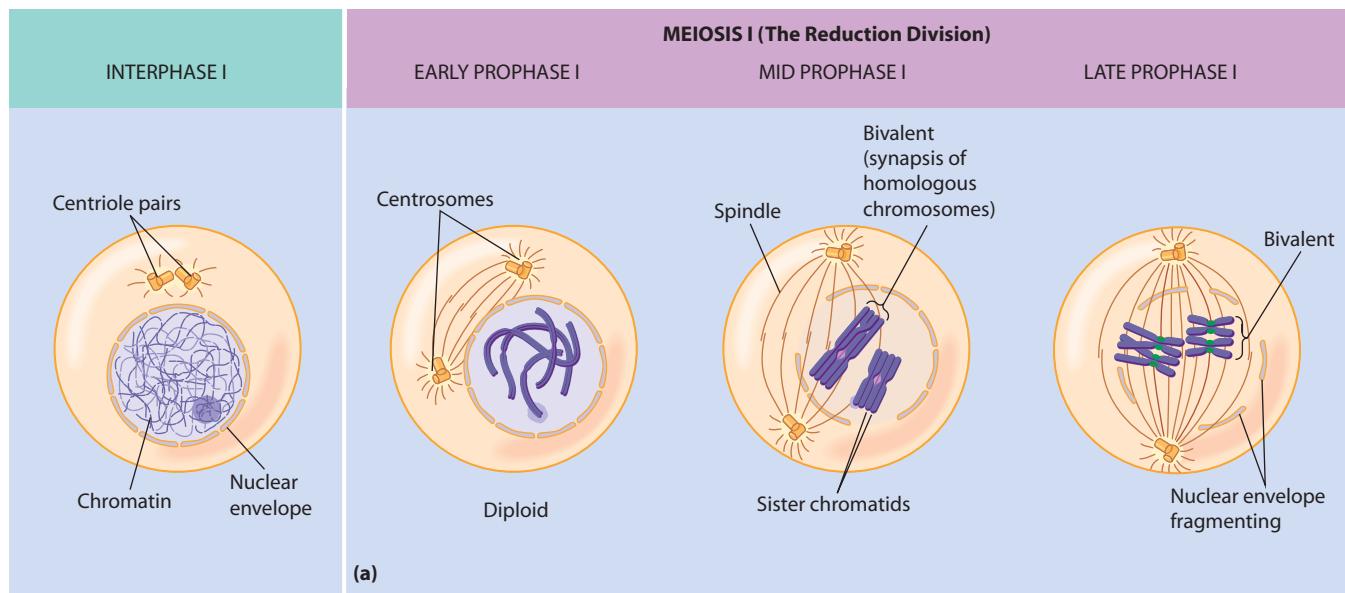

FIGURE 20-5 Meiosis in an Animal Cell. Meiosis consists of two successive divisions, called meiosis I and II, with no intervening DNA synthesis or chromosome duplication. (a) During prophase I, the chromosomes (duplicated during the previous S phase) condense and the two centrosomes migrate to opposite poles of the cell. Each chromosome (four in this example) consists of two sister chromatids. Homologous chromosomes pair to form bivalents. (b) Bivalents become aligned at the spindle equator (metaphase I). (c) Homologous chromosomes separate during anaphase I, but sister chromatids remain attached at the centromere. (d) Telophase and cytokinesis follow. Although not illustrated here, there may then be a short interphase (interphase II). In meiosis II, (e) chromosomes recondense (prophase II), (f) chromosomes align at the spindle equator (metaphase II), and (g) sister chromatids at last separate (anaphase II). (h) After telophase II and cytokinesis, the result is four haploid daughter cells, each containing one chromosome of each homologous pair. Prophase I is a complicated process shown in more detail in Figure 20-6. Meiosis in plants is similar, except for the absence of centrioles and the mechanism of cytokinesis, which involves formation of a cell plate (described in Chapter 19).

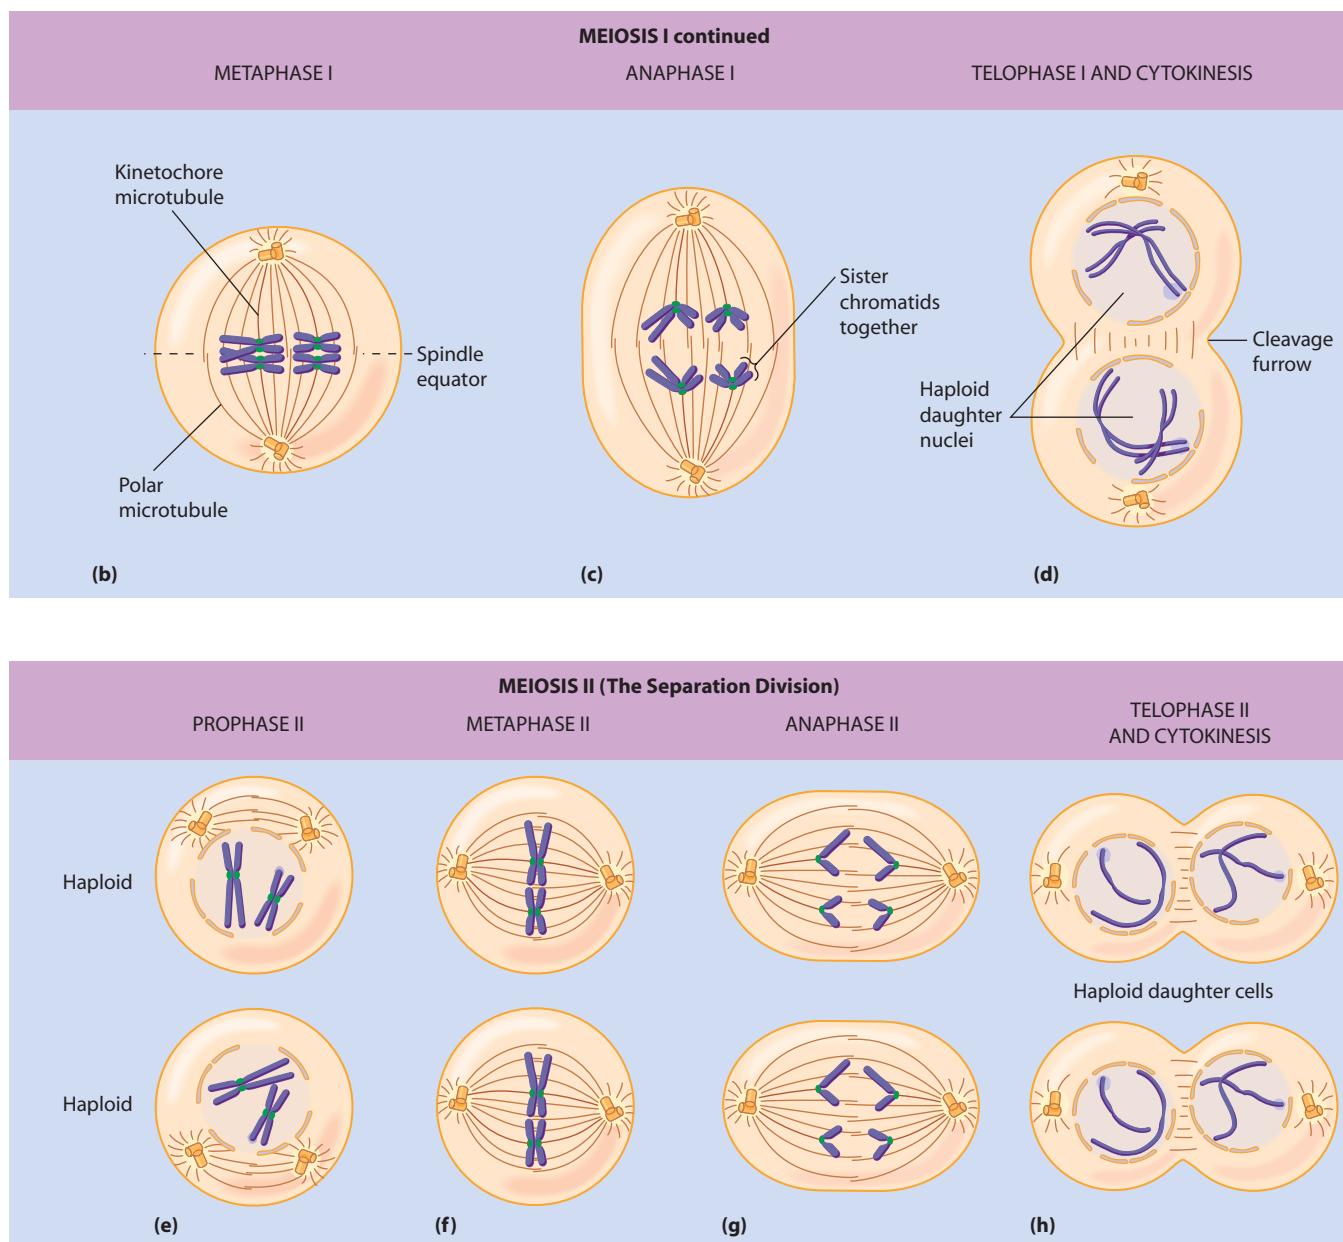

typical mitotic division, where such pairing is not observed (Figure 20-8, p. 610). Because each bivalent contains four chromatids (two sister chromatids from each chromosome), four kinetochores are also present. The kinetochores of sister chromatids lie side by side—in many species appearing as a single mass—and face the same pole of the cell. Such an arrangement allows the kinetochores derived from the sister chromatids of one homologous chromosome to attach to microtubules emanating from one spindle pole and the kinetochores derived from the sister chromatids of the other homologous chromosome to attach to microtubules emanating from the opposite spindle pole. This orientation sets the stage for separation of the homologous chromosomes during anaphase. The bivalents are randomly oriented at this point, in the sense that, for each bivalent, either the maternal or paternal homologue may face a given pole of the cell. As a result, each spindle pole (and hence each daughter cell) will receive a random mixture of maternal and paternal chromosomes when the two members of each chromosome pair move toward opposite spindle poles during anaphase.

At this stage, homologous chromosomes are held together solely by chiasmata. If for some reason prophase I had occurred without crossing over, and hence without chiasma formation, the chromosomes might not pair properly at the spindle equator, and

homologous chromosomes might not separate properly during anaphase I. This is exactly what happens during meiosis in mutant yeast cells that exhibit deficiencies in genetic recombination.

Anaphase I: Homologous Chromosomes Move to Opposite Spindle Poles. At the beginning of anaphase I, the members of each pair of homologous chromosomes separate from each other and start migrating toward opposite spindle poles, pulled by their respective kinetochore microtubules. Again, note the fundamental difference between meiosis and mitosis (Figure 20-8). During mitotic anaphase, *sister chromatids separate* and move to opposite spindle poles, whereas in anaphase I of meiosis, *homologous chromosomes separate* and move to opposite spindle poles while sister chromatids remain together. Because the two members of each pair of homologous chromosomes move to opposite spindle poles during anaphase I, each pole receives a haploid set of chromosomes.

How can we explain the fact that sister chromatids separate from each other during mitosis but not during meiosis I? In Chapter 19, we saw that mitotic anaphase is associated with activation of the enzyme separase by the anaphase-promoting complex (see Figure 19-38); the activated separase in turn cleaves the cohesins that hold sister chromatids together, thereby allowing sister chromatids to separate. To prevent chromatid separation from taking

place during anaphase I of meiosis, a protein called *shugoshin* (Japanese for “guardian spirit”) protects the cohesins located at the chromosomal centromere from being degraded by separase.

Telophase I and Cytokinesis: Two Haploid Cells Are Produced. The onset of telophase I is marked by the arrival of a haploid set of chromosomes at each spindle pole. Which member of a homologous pair ends up at which pole is determined entirely by how the chromosomes happened to be oriented at the spindle equator during metaphase I. After the chromosomes have arrived at the spindle poles, nuclear envelopes sometimes form around the chromosomes before cytokinesis ensues, generating two haploid cells whose chromosomes consist of sister chromatids. In most cases, the chromosomes do not decondense before meiosis II begins.

Meiosis II Resembles a Mitotic Division

After meiosis I has been completed, a brief interphase may intervene before meiosis II begins. However, this interphase is not accompanied by DNA replication because each chromosome already consists of a pair of replicated, sister chromatids that were generated by DNA synthesis during the interphase preceding meiosis I. So *DNA is replicated only once in conjunction with meiosis, and that is prior to the first meiotic division*. The purpose of meiosis II, like that of a typical mitotic division, is to parcel the sister chromatids created by this initial round of DNA replication into two newly forming cells. As a result, meiosis II is sometimes referred to as the *separation division* of meiosis.

Prophase II is very brief. If detectable at all, it is much like a mitotic prophase. Metaphase II also resembles the equivalent stage in mitosis, except that only half as many

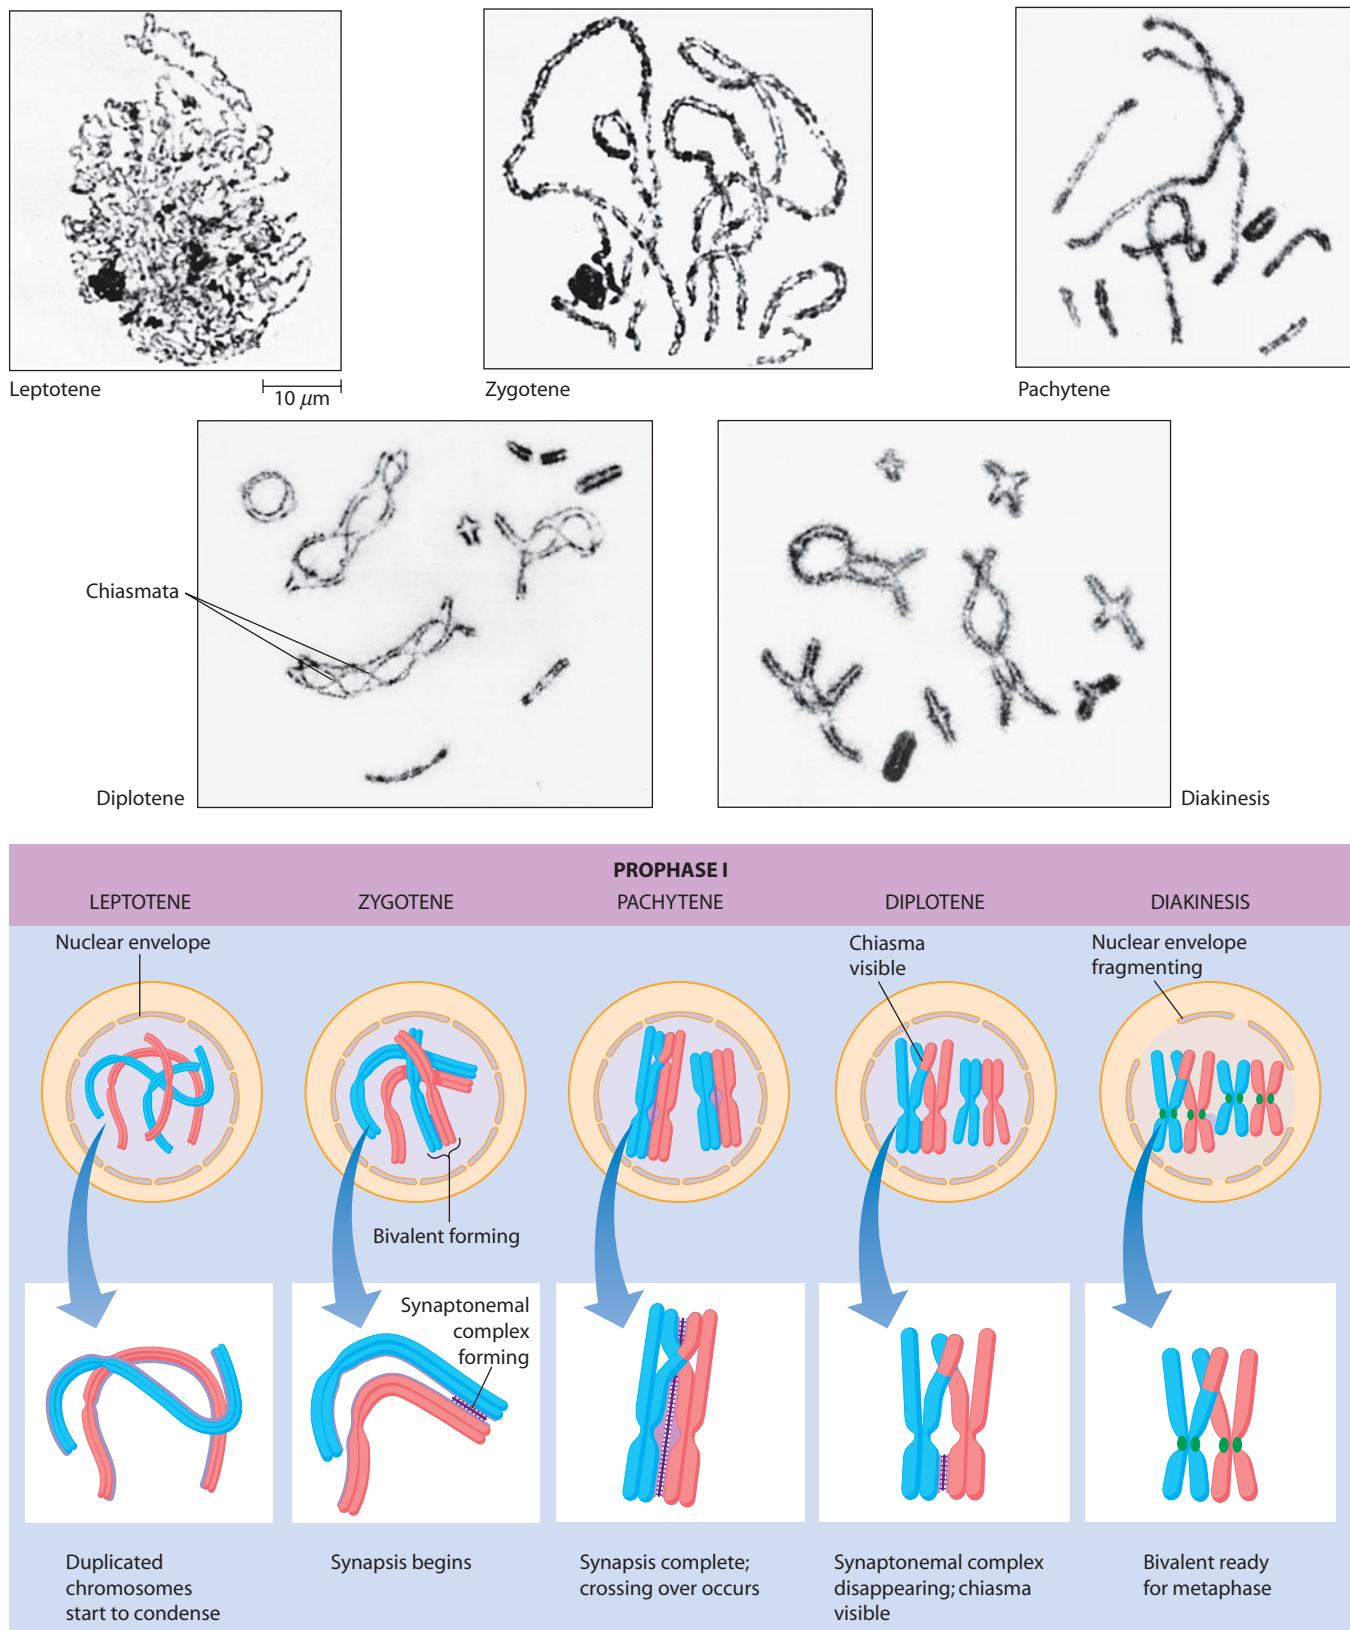

FIGURE 20-6 Meiotic Prophase I. Based on changes in chromosome behavior and appearance, prophase I is subdivided into the five stages shown in these photographs and schematic diagram. The diagram depicts the cell nucleus at each stage for a diploid cell containing four chromosomes (two homologous pairs). The lower part of the diagram focuses on a single homologous pair in greater detail, revealing the formation and subsequent disappearance of the synaptonemal complex, a protein structure that holds homologous chromosomes in close lateral apposition during pachytene. Red and blue distinguish the paternal and maternal chromosomes of each homologous pair; the synaptonemal complex is shown in shades of purple.

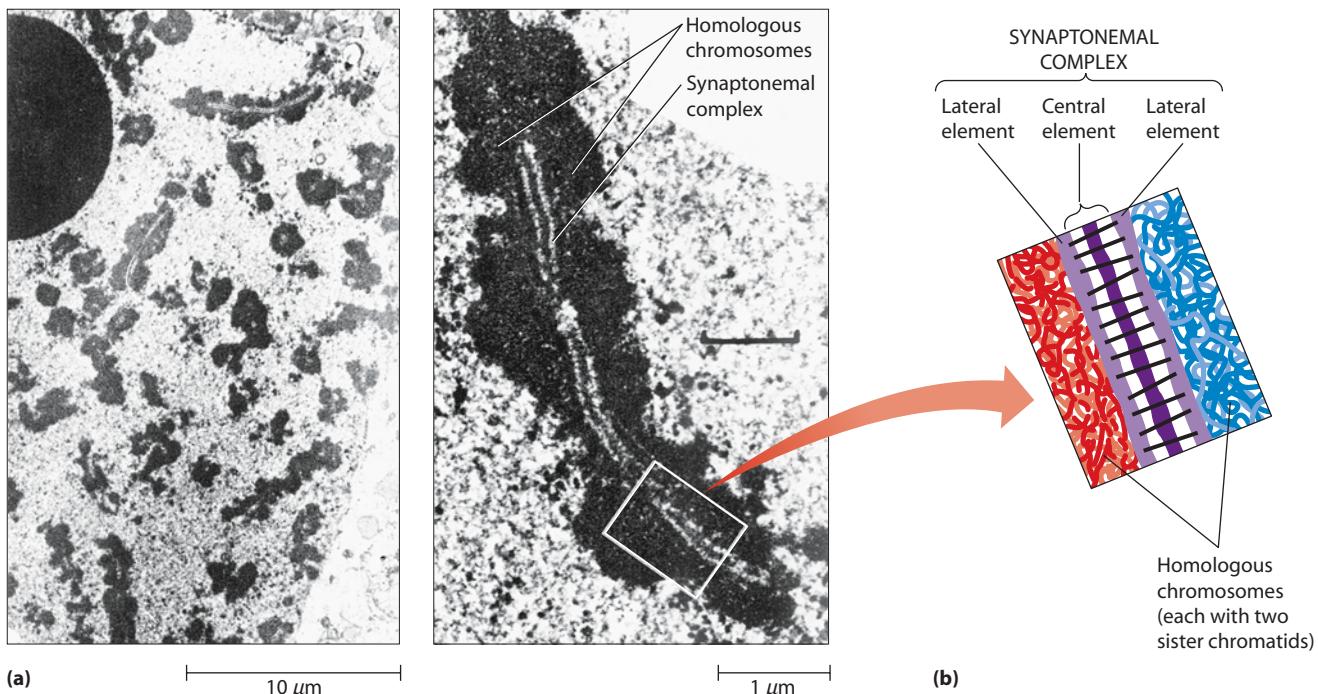

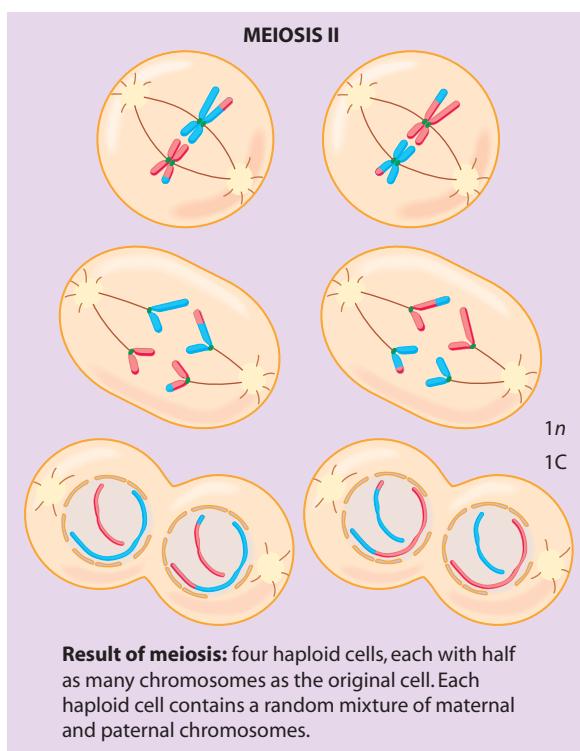

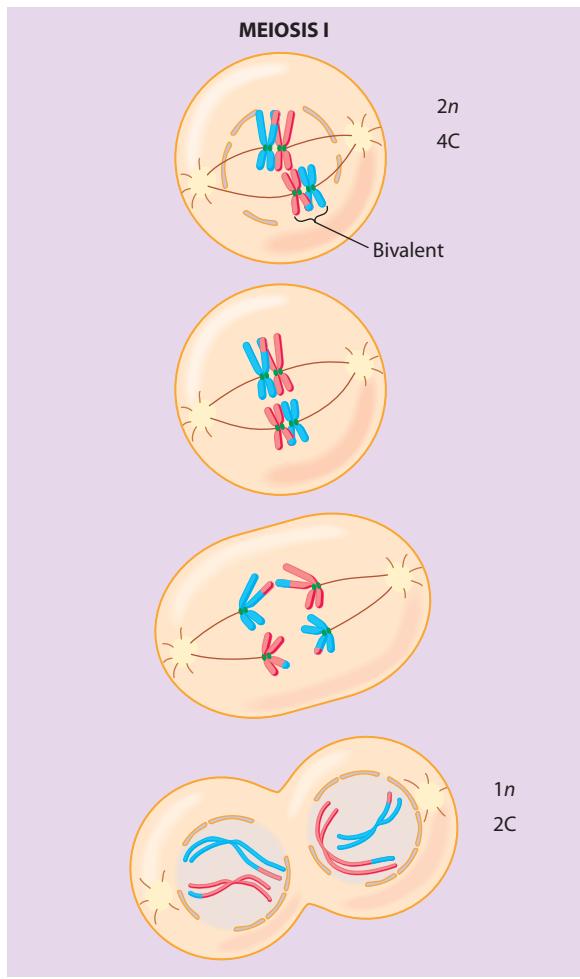

FIGURE 20-7 The Synaptonemal Complex. (a) These electron micrographs show, at two magnifications, synaptonemal complexes in the nuclei of cells from a lily. The cells are at the pachytene stage of prophase I. (b) The diagram identifies the complex's *lateral elements* (light purple), which seem to form on the chromosomes during leptotene, and its *central* (or *axial*) element (dark purple), which starts to appear during zygotene and “zips” the homologous chromosomes together. At pachytene, the homologues are held tightly together all along their lengths.

chromosomes are present at the spindle equator. The kinetochores of sister chromatids now face in opposite directions, allowing the sister chromatids to separate and move (as new daughter chromosomes) to opposite spindle poles during anaphase II. The remaining phases of the second meiotic division resemble the comparable stages of mitosis. The final result is the formation of four daughter cells, each containing a haploid set of chromosomes. Because the two members of each homologous chromosome pair were randomly distributed to the two cells produced by meiosis I, each of the haploid daughter cells produced by meiosis II contains a random mixture of maternal and paternal chromosomes. Moreover, each of these chromosomes is composed of a mixture of maternal and paternal DNA sequences created by crossing over during prophase I.

While each of the cells produced by meiosis normally contains a complete, haploid set of chromosomes, a rare malfunction called **nondisjunction** can produce cells that either lack a particular chromosome or contain an extra chromosome, a condition we termed *aneuploidy* in Chapter 19. Nondisjunction refers to the failure of homologous chromosomes (during anaphase I) or sister chromatids (during anaphase II) to separate from each other at the metaphase-anaphase transition. Instead, both chromosomes or chromatids remain together and move into one of the two daughter cells, thereby generating one cell containing both copies of the chromosome and one

cell containing neither copy. The resulting gametes have an incorrect number of chromosomes and tend to produce defective embryos that die before birth. However, a few such gametes can participate in the formation of embryos that do survive. For example, if an abnormal human sperm containing two copies of chromosome 21 fertilizes a normal egg containing one copy of chromosome 21, the resulting embryo, possessing three copies of chromosome 21, can develop fully and lead to the birth of a live child. But this child will exhibit a series of developmental abnormalities—including short stature, broad hands, folds over the eyes, and low intelligence—that together constitute *Down syndrome*.

At this point, you may want to study Figure 20-8 in its entirety to review the similarities and differences between meiosis and mitosis. In this diagram, the amount of DNA present at various stages is indicated using the **C value**, which corresponds to the amount of DNA present in a single (haploid) set of chromosomes. In a diploid cell prior to S phase, the chromosome number is $2n$ and the DNA content is 2C because two sets of chromosomes are present. When DNA undergoes replication during S phase, the DNA content is doubled to 4C because each chromosome now consists of two chromatids. In meiosis I, segregation of homologous chromosomes into different daughter cells reduces the chromosome number from $2n$ to $1n$ and the DNA content from 4C to 2C. Sister chromatid separation during meiosis II then reduces the DNA

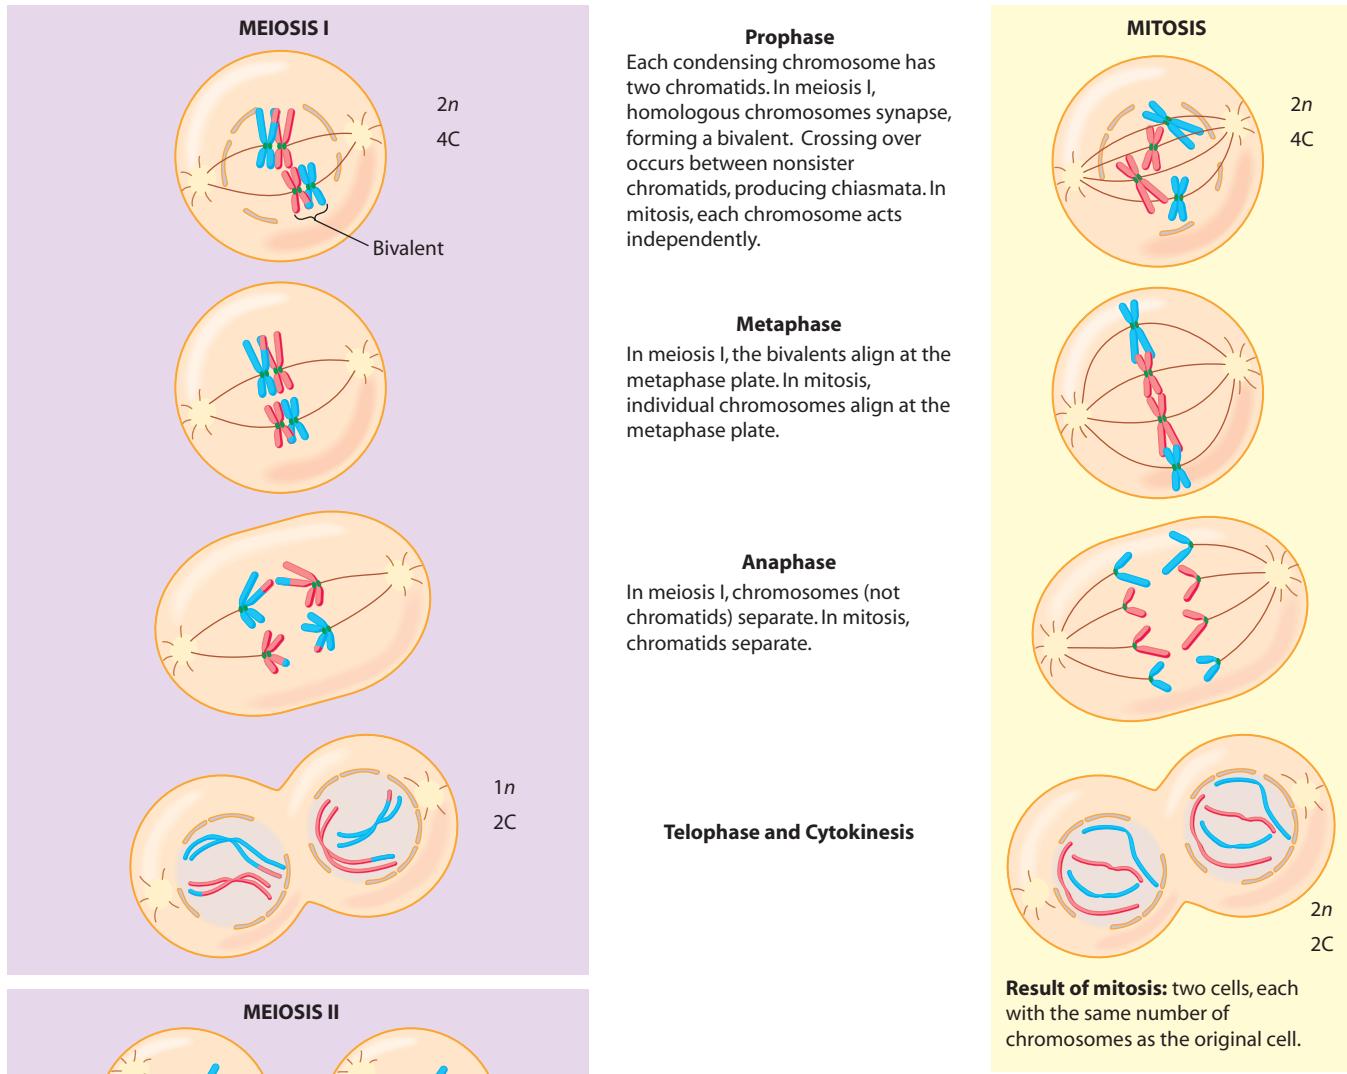

Prophase
Each condensing chromosome has two chromatids. In meiosis I, homologous chromosomes synapse, forming a bivalent. Crossing over occurs between nonsister chromatids, producing chiasmata. In mitosis, each chromosome acts independently.

Metaphase
In meiosis I, the bivalents align at the metaphase plate. In mitosis, individual chromosomes align at the metaphase plate.

Anaphase
In meiosis I, chromosomes (not chromatids) separate. In mitosis, chromatids separate.

Telophase and Cytokinesis

Result of mitosis: two cells, each with the same number of chromosomes as the original cell.

In meiosis II,
sister
chromatids
separate.

FIGURE 20-8 Meiosis and Mitosis Compared. Meiosis and mitosis are both preceded by DNA replication, resulting in two sister chromatids per chromosome at prophase. Meiosis, which occurs only in sex cells, includes two nuclear (and cell) divisions, halving the chromosome number to the haploid level. Moreover, during the elaborate prophase of the first meiotic division, homologous chromosomes synapse, and crossing over occurs between nonsister chromatids. Mitosis involves only a single division, producing two diploid nuclei (and usually, cells), each with the same number of chromosomes as the original cell. In mitosis, the homologous chromosomes behave independently; at no point do they come together in pairs. The meaning of the C values in this figure (4C, 2C, 1C) is described on page 609.

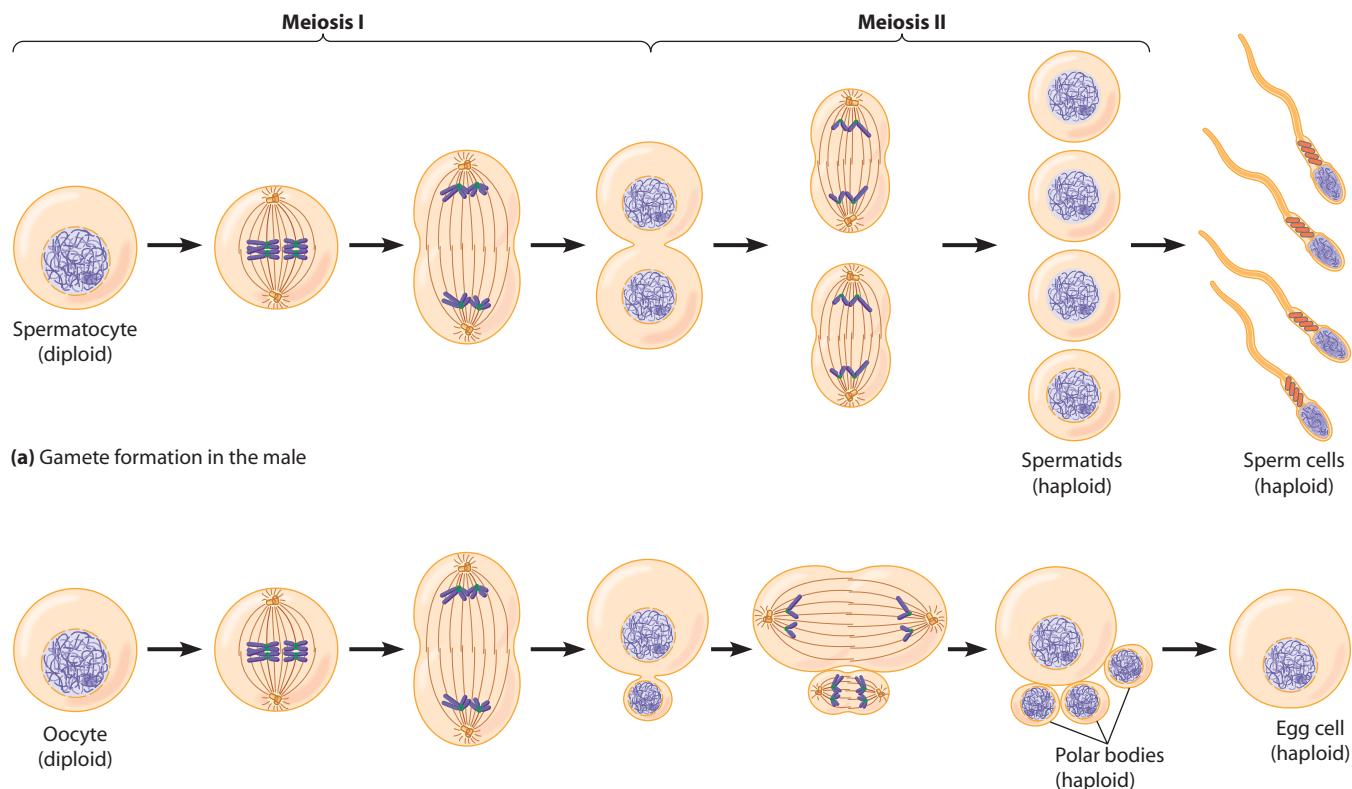

FIGURE 20-9 Gamete Formation. (a) In the male, all four haploid products of meiosis are retained and differentiate into sperm. (b) In the female, both meiotic divisions are asymmetric, forming one large egg cell and three (in some cases, only two) small cells called polar bodies that do not give rise to functional gametes. Although not indicated here, the mature egg cell usually grows much larger than the oocyte it arose from.

www.thecellplace.com Meiosis I in sperm formation

content from $2C$ to $1C$, while the chromosome number remains at $1n$. In contrast, a normal mitosis reduces the DNA content from $4C$ to $2C$ (by sister chromatid separation) while the chromosome number remains at $2n$.

Sperm and Egg Cells Are Generated by Meiosis Accompanied by Cell Differentiation

Meiosis lies at the heart of gametogenesis, which as we saw earlier is the process of forming haploid gametes from diploid precursor cells. But male and female gametes differ significantly in structure, which means that gametogenesis must consist of more than just meiosis. **Figure 20-9** is a schematic depiction of gametogenesis in animals. In males, meiosis converts a diploid *spermatocyte* into four haploid *spermatids* of similar size (Figure 20-9a). After meiosis has been completed, the spermatids then differentiate into sperm cells by discarding most of their cytoplasm and developing flagella and other specialized structures.

In females, meiosis converts a diploid *oocyte* into four haploid cells, but only one of the four survives and gives rise to a functional egg cell (Figure 20-9b). This outcome is generated by two meiotic divisions that divide the cyto-

plasm of the oocyte unequally, with one of the four daughter cells receiving the bulk of the cytoplasm of the original diploid oocyte. The other three, smaller cells, called **polar bodies**, usually degenerate (although recall that the Komodo dragon can use a polar body to “fertilize” an egg). The advantage of having only one of the four haploid products of meiosis develop into a functional egg cell is that the cytoplasm that would otherwise have been distributed among four cells is instead concentrated into one egg cell, maximizing the content of stored nutrients in each egg.

An important difference between sperm and egg formation concerns the stage at which the cells acquire the specialized characteristics that make them functionally mature gametes. During sperm cell development, meiosis creates haploid spermatids that must then discard most of their cytoplasm and develop flagella before they are functionally mature. In contrast, developing egg cells acquire their specialized features *during* the process of meiosis. Many of the specialized features of the egg cell are acquired during prophase I, when meiosis is temporarily halted to allow time for extensive cell growth. During this *growth phase*, the cell also develops various types of external coatings designed to protect the egg from

chemical and physical injury. The amount of growth that takes place during this phase can be quite extensive. A human egg cell, for example, has a diameter of about 100 μm , giving it a volume more than a hundred times as large as that of the diploid oocyte from which it arose. And consider the gigantic size of a bird egg!

After the growth phase has been completed, developing oocytes remain arrested in prophase I until resumption of meiosis is initiated by an appropriate stimulus. In amphibians, resumption of meiosis is triggered by the steroid hormone progesterone, whose presence leads to an increase in the activity of the protein kinase, MPF. In Chapter 19, we showed that MPF is a Cdk-cyclin complex that controls mitotic cell division by triggering passage from G2 into M phase. MPF also controls meiosis by triggering the transition from prophase I to metaphase I. Progesterone exerts its control over MPF by stimulating the production of Mos, a protein kinase that activates a series of other protein kinases, which in turn leads to the activation of MPF.

In response to the activation of MPF, the first meiotic division is completed. In some organisms, the second meiotic division then proceeds rapidly to completion; in others, it halts at an intermediate stage and is not completed until after fertilization. In vertebrate eggs, for example, the second meiotic division is generally arrested at metaphase II until fertilization takes place. Metaphase II arrest is triggered by *cystostatic factor* (CSF), a biochemical activity present in the cytoplasm of mature eggs. CSF works by inhibiting the anaphase-promoting complex, whose activity is normally required for the transition from metaphase to anaphase (page 585). After an egg is fertilized, CSF undergoes inactivation. In the absence of CSF activity, the anaphase-promoting complex is free to trigger the transition from metaphase to anaphase, thereby allowing meiosis to be completed.

By the time meiosis is completed, the egg cell is fully mature and may even have been fertilized. The mature egg is a highly differentiated cell that is specialized for the task of producing a new organism in much the same sense that a muscle cell is specialized to contract or a red blood cell is specialized to transport oxygen. This inherent specialization of the egg is vividly demonstrated by the observation that even in the absence of fertilization by a sperm cell, many kinds of animal eggs can be stimulated to develop into a complete embryo by artificial treatments as simple as a pinprick. Hence, everything needed for programming the early stages of development must already be present in the egg.

Normally, of course, this developmental sequence is activated by interactions between sperm and egg, which trigger important biochemical changes in the egg. For example, in addition to the rapid formation of a physical barrier to the entry of additional sperm by the fertilized egg (page 405), fertilization simultaneously initiates a burst of metabolic activity in preparation for embryonic development. Although not described here, fertilization in plants involves similarly complex cellular and biochemical events.

Meiosis Generates Genetic Diversity

As we have pointed out, one of the main functions of meiosis is to preserve the chromosome number in sexually reproducing organisms. If it were not for meiosis, gametes would have as many chromosomes as other cells in the body, and the chromosome number would double each time gametes fused to form a new organism.

Equally important, however, is the role meiosis plays in generating genetic diversity in sexually reproducing populations. Meiosis is the point in the flow of genetic information where various combinations of chromosomes (and the alleles they carry) are assembled in gametes for potential passage to offspring. Although every gamete is haploid, and hence possesses one member of each pair of homologous chromosomes, the particular combination of paternal and maternal chromosomes in any given gamete is random. This randomness is generated by the random orientation of bivalents at metaphase I, where the paternal and maternal homologues of each pair can face either pole, independent of the orientations of the other bivalents. In human gametes, which contain 23 chromosomes, the end result is more than 8 million different combinations of maternal and paternal chromosomes!

Moreover, the crossing over that takes place between homologous chromosomes during prophase I generates additional genetic diversity among the gametes. By allowing the exchange of DNA segments between homologous chromosomes, crossing over generates more combinations of alleles than the random assortment of maternal and paternal chromosomes would create by itself. We will return to crossing over (recombination) later in the chapter. First, however, we turn to the historic experiments that revealed the genetic consequences of chromosome segregation and random assortment during meiosis. These experiments were carried out by Gregor Mendel before chromosomes were even known to exist.

Genetic Variability: Segregation and Assortment of Alleles

Most students of biology have heard of Gregor Mendel and the classic genetics experiments he conducted in a monastery garden. Mendel's findings, first published in 1865, laid the foundation for what we now know as *Mendelian genetics*. Working with the common garden pea, Mendel chose seven readily identifiable characters of pea plants and selected in each case two varieties of plants that displayed different forms of the character. For example, seed color was one character Mendel chose because he had one strain of peas with yellow seeds and another with green seeds (see Figure 20-1). He first established that each of the plant strains was **true-breeding** upon self-fertilization, which means that plants grown from his yellow seeds produced only yellow seeds and

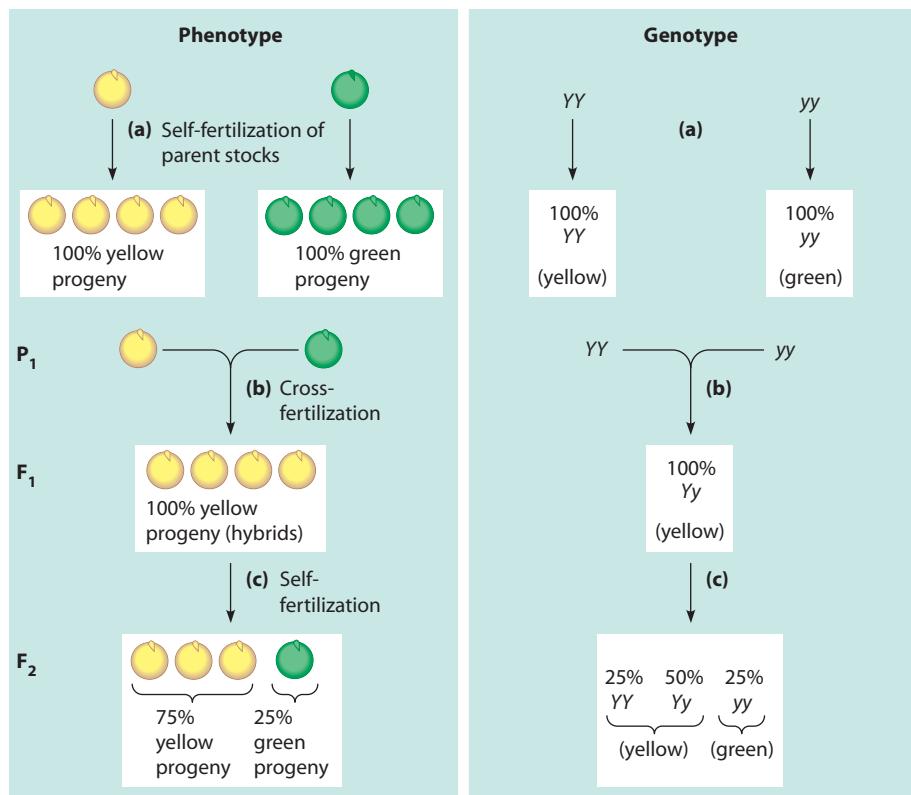

FIGURE 20-10 Genetic Analysis of Seed Color in Pea Plants. Genetic crosses were performed starting with two true-breeding strains of pea plants, one having yellow seeds and one having green seeds. The yellow-seed trait is dominant (allele Y); the green-seed trait is recessive (allele y). The resulting phenotypes of the progeny are shown on the left and their genotypes on the right. (The genotypes were deduced later.) (a) The parent stocks are homozygous for either the dominant (YY) or recessive (yy) trait and breed true upon self-fertilization. (b) When crossed, the parent stocks yield F_1 plants (hybrids) that are all heterozygous (Yy) and therefore show the dominant trait. (c) Upon self-fertilization, the F_1 plants produce yellow and green seeds in the F_2 generation in a ratio of 3:1. See Figures 20-11 and 20-12 for further analyses.

plants grown from his green seeds produced only green seeds (Figure 20-10a). Once this had been established, Mendel was ready to investigate the principles that govern the inheritance of such traits.

Information Specifying Recessive Traits Can Be Present Without Being Displayed

In his first set of experiments, Mendel cross-fertilized the true-breeding parental plants (the **P_1 generation**) to produce **hybrid** strains. The outcome of this experiment must have seemed mystifying at first: In every case, the resulting offspring—called the **F_1 generation**—exhibited one or the other of the parental traits, but never both. In other words, one parental trait was always dominant and the other was always recessive. In the case of seed color, for example, all the F_1 plants had yellow seeds (Figure 20-10b), indicating that yellow seed color is dominant.

During the next summer, Mendel allowed all the F_1 hybrids to self-fertilize. For each of the seven characters under study, he made the same surprising observation: The recessive trait that had seemingly disappeared in the F_1 generation reappeared among the progeny in the next generation, the **F_2 generation**. Moreover, for each of the seven characters, the ratio of dominant to recessive phenotypes in the progeny was always about 3:1. In the case of seed color, for example, plants grown from the yellow F_1 seeds produced about 75% yellow seeds and 25% green (Figure 20-10c).

This outcome was quite different from the behavior of the true-breeding yellow seeds of the parent strain, which had produced only yellow seeds when self-fertilized. Clearly, there was an important difference between the yellow seeds of the P_1 stock and the yellow seeds of the F_1 generation. They looked alike, but the former bred true whereas the latter did not.

Next, Mendel investigated the F_2 plants through self-fertilization (Figure 20-11). The F_2 plants exhibiting the recessive trait (green, in the case of seed color) always bred true (Figure 20-11c), suggesting they were genetically identical to the green-seeded P_1 strain that Mendel had begun with. F_2 plants with the dominant trait yielded a more complex pattern. One-third bred true for the dominant trait (Figure 20-11a) and therefore seemed identical to the P_1 plants with the dominant (yellow-seed) trait. The other two-thirds of the yellow-seeded F_2 plants produced progeny with both dominant and recessive phenotypes, in a 3:1 ratio (Figure 20-11b)—the same ratio that had arisen from the F_1 self-fertilization.

These results led Mendel to conclude that genetic information specifying the recessive trait must be present in the F_1 hybrid plants and seeds, even though the trait is not displayed. This conclusion was consistent with results from another set of experiments, in which F_1 hybrids were crossed with the original parent strains, a technique called **backcrossing** (Figure 20-12). Backcrossing F_1 hybrids to the dominant parent strain always produced progeny exhibiting the dominant trait (Figure 20-12a), whereas

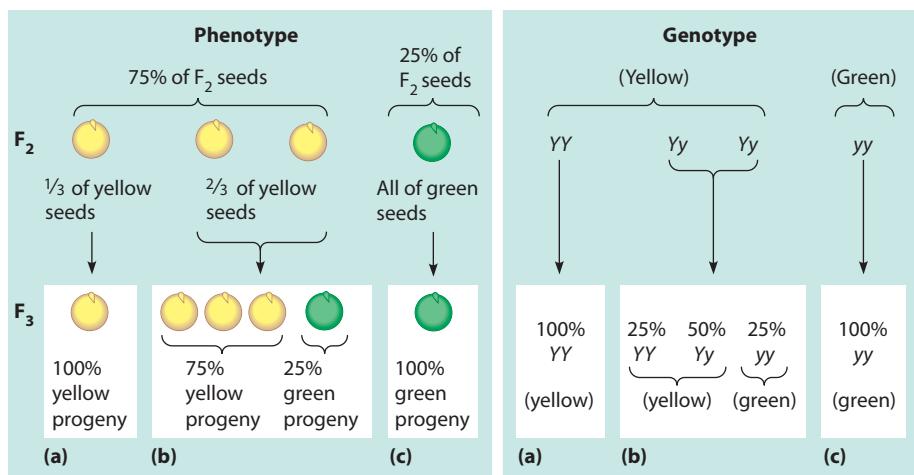

FIGURE 20-11 Analysis of F₂ Pea Plants by Self-Fertilization. The F₂ plants of Figure 20-10 were analyzed through self-fertilization. The phenotypic results are shown on the left and the genotypes (deduced later) on the right. (a) One-third of the yellow F₂ progeny of Figure 20-10 (25% of the total F₂ progeny) breed true for yellow seed color upon self-fertilization because they are genetically YY. (b) Two-thirds of the yellow F₂ progeny (50% of the total F₂ progeny) yield yellow and green seeds upon self-fertilization, in a ratio of 3:1 (just as the F₂ plants of Figure 20-10 did upon self-fertilization). (c) All the green F₂ seeds (25% of the total F₂ progeny) breed true for green seed color upon self-fertilization because they are genetically yy.

backcrossing to the recessive parent yielded a mixture of plants exhibiting dominant and recessive traits in a ratio of 1:1 (Figure 20-12b). Moreover, the dominant progeny from the latter cross behaved just like the F₁ hybrids: Upon self-fertilization, they gave rise to a 3:1 mixture of

phenotypes (Figure 20-12c), and upon backcrossing to the recessive parent, they yielded a 1:1 ratio of dominant to recessive progeny (Figure 20-12d). (An alternative way of diagramming crosses, called the *Punnett square*, is shown in Problem 20-7 at the end of the chapter.)

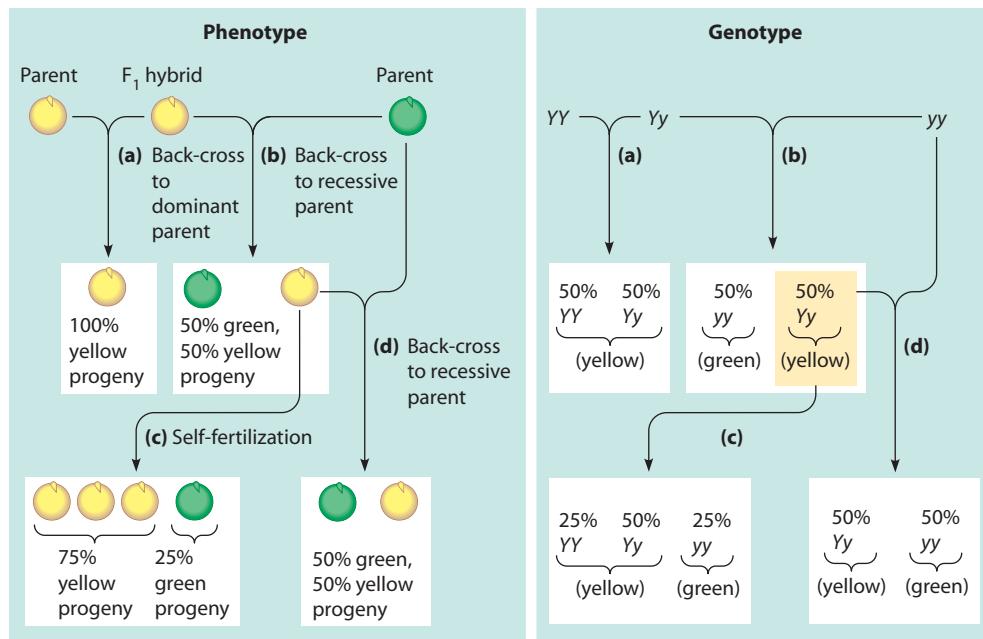

FIGURE 20-12 Analysis of F₁ Hybrids by Backcrossing. The F₁ hybrids of Figure 20-10 were analyzed by backcrossing to the parent (P₁) strains. The phenotypic results are shown on the left and the genotypes (deduced later) on the right. (a) Upon backcrossing of the F₁ hybrid (Yy) to the dominant parent (YY), all the progeny have yellow seeds because the genotype is either YY or Yy. (b) Backcrossing to the recessive parent (yy) yields yellow (Yy) or green (yy) seeds in equal proportions. (c) These yellow-seeded progeny will give rise, upon self-fertilization, to a 3:1 mixture of yellow and green seeds (just as with the F₁ hybrids in Figure 20-10). (d) Backcrossing of the yellow-seeded progeny to the homozygous recessive parent again yields a 1:1 mixture of yellow and green seeds, as in the backcross of part b.

The Law of Segregation States That the Alleles of Each Gene Separate from Each Other During Gamete Formation

After a decade of careful work documenting the preceding patterns of inheritance, Mendel formulated several principles—now known as **Mendel's laws of inheritance**—that explained the results he had observed. The first of these principles was that phenotypic traits are determined by discrete “factors” that are present in most organisms as pairs of “determinants.” Today, we call these “factors” *genes* and “determinants” *alleles* (alternative forms of genes). Mendel's conclusion seems almost self-evident to us, but it was an important assertion in his day. At that time, most scientists favored a *blending theory of inheritance*, a theory that viewed traits such as yellow and green seed color rather like cans of paint that are poured together to yield intermediate results. Other investigators had described the nonblending nature of inheritance before Mendel but without the accompanying data and mathematical analysis that were Mendel's special contribution. Mendel's breakthrough is especially impressive when we recall that he formulated his theory before anyone had seen chromosomes.

Of special importance to the development of genetics was Mendel's conclusion regarding the way genes are parceled out during gamete formation. According to his **law of segregation**, *the two alleles of a gene are distinct entities that segregate, or separate from each other, during the formation of gametes*. In other words, the two alleles retain their identities even when both are present in a hybrid organism, and they are then parceled out into separate gametes so they can emerge unchanged in later generations.

The Law of Independent Assortment States That the Alleles of Each Gene Separate Independently of the Alleles of Other Genes

In addition to the crosses already described, each focusing on a single pair of alleles, Mendel studied *multifactor* crosses between plants that differed in *several* characters. Besides differing in seed color, for example, the plants he crossed might differ in seed shape and flower position. As in his single-factor crosses, he used parent plants that were true-breeding (homozygous) for the characters he was testing and generated F₁ hybrids heterozygous for each character. He then self-fertilized these hybrids and determined how frequently the dominant and recessive forms of the various characters appeared among the progeny.

Mendel found that all possible combinations of traits appeared in the F₂ progeny, and he concluded that all possible combinations of the different alleles must therefore have been present among the F₁ gametes. Furthermore, based on the proportions of the various phenotypes detected in the F₂ generation, Mendel deduced that all possible combinations of alleles occurred in the gametes with equal frequency. In other words, *the two alleles of*

each gene segregate independently of the alleles of other genes. This is the **law of independent assortment**, another cornerstone of genetics. Later, it would be shown that this law applies only to genes on different chromosomes or very far apart on the same chromosome.

Early Microscopic Evidence Suggested That Chromosomes Might Carry Genetic Information

Mendel's findings lay dormant in the scientific literature until 1900, when his paper was rediscovered almost simultaneously by three other European biologists. In the meantime, much had been learned about the cellular basis of inheritance. By 1875, for example, microscopists had identified chromosomes with the help of stains produced by the developing aniline dye industry. At about the same time, fertilization was shown to involve the fusion of sperm and egg nuclei, suggesting that the nucleus carries genetic information.

The first proposal that chromosomes might be the bearers of this genetic information was made in 1883. Within ten years, chromosomes had been studied in dividing cells and had been seen to split longitudinally into two apparently identical daughter chromosomes. This led to the realization that the number of chromosomes per cell remains constant during the development of an organism. With the invention of better optical systems, more detailed analysis of chromosomes became possible. Mitotic cell division was shown to involve the movement of identical daughter chromosomes to opposite poles, thereby ensuring that daughter cells would have exactly the same complement of chromosomes as their parent cell.

Against this backdrop came the rediscovery of Mendel's paper, followed almost immediately by three crucial studies that established chromosomes as the carriers of Mendel's factors. The investigators were Edward Montgomery, Theodor Boveri, and Walter Sutton. Montgomery's contribution was to recognize the existence of homologous chromosomes. From careful observations of insect chromosomes, he concluded that the chromosomes of most cells could be grouped into pairs, with one member of the pair of maternal origin and the other of paternal origin. He also noted that the two chromosomes of each type come together during synapsis in the “reduction division” (now called meiosis I) of gamete formation, a process that had been reported a decade or so earlier.

Boveri then added the crucial observation that each chromosome plays a unique genetic role. This idea came from studies in which sea urchin eggs were fertilized in the presence of a large excess of sperm, causing some eggs to be fertilized by two sperm. The presence of two sperm nuclei in a single egg leads to the formation of an abnormal mitotic spindle that does not distribute the chromosomes equally to the newly forming embryonic cells. The resulting embryos exhibit various types of developmental defects, depending on which particular chromosomes they

are missing. Boveri therefore concluded that each chromosome plays a unique role in development.

Sutton, meanwhile, was studying meiosis in the grasshopper. In 1902, he made the important observation that the orientation of each pair of homologous chromosomes (bivalent) at the spindle equator during metaphase I is purely a matter of chance. Any homologous pair, in other words, may lie with the maternal or paternal chromosome toward either pole, regardless of the positions of other pairs. Many different combinations of maternal and paternal chromosomes are therefore possible in the gametes produced by any given individual (note the similarity to Mendel's observation that all possible combinations of different alleles are present among the F_1 generation of gametes).

Chromosome Behavior Explains the Laws of Segregation and Independent Assortment

During 1902–1903, Sutton put the preceding observations together into a coherent theory describing the role of chromosomes in inheritance. This *chromosomal theory of inheritance* can be summarized as five main points:

1. Nuclei of all cells except those of the *germ line* (sperm and eggs) contain two sets of homologous chromosomes, one set of maternal origin and the other of paternal origin.
2. Chromosomes retain their individuality and are genetically continuous throughout an organism's life cycle.
3. The two sets of homologous chromosomes in a diploid cell are functionally equivalent, each carrying a similar set of genes.
4. Maternal and paternal homologues synapse during meiosis and then move to opposite poles of the division spindle, thereby becoming segregated into different cells.
5. The maternal and paternal members of different homologous pairs segregate independently during meiosis.

The chromosomal theory of inheritance provided a physical basis for understanding how Mendel's genetic factors could be carried, transmitted, and segregated. For example, the presence of two sets of homologous chromosomes in each cell parallels Mendel's suggestion of two determinants for each phenotypic trait. Likewise, the segregation of homologous chromosomes during the meiotic divisions of gamete formation provides an explanation for Mendel's law of segregation, and the random orientation of homologous pairs at metaphase I accounts for his law of independent assortment.

Figure 20-13 and **20-14** illustrate the chromosomal basis of Mendel's laws, using examples from his pea plants. The basis for the law of segregation is shown in Figure

20-13 for the alleles governing seed color in a heterozygous pea plant with genotype Yy . (Peas have seven pairs of chromosomes, but only the pair bearing the alleles for seed color is shown.) During meiosis the two homologous chromosomes, each with two sister chromatids, synapse during prophase I, align together at the spindle equator at metaphase I, and then segregate into separate daughter cells. The second meiotic division then separates sister chromatids so that each haploid cell ends up with only one allele for seed color, either Y or y .

The basis for the law of independent assortment is illustrated in Figure 20-14 for the chromosomes carrying the genes for seed color (alleles Y and y) and seed shape

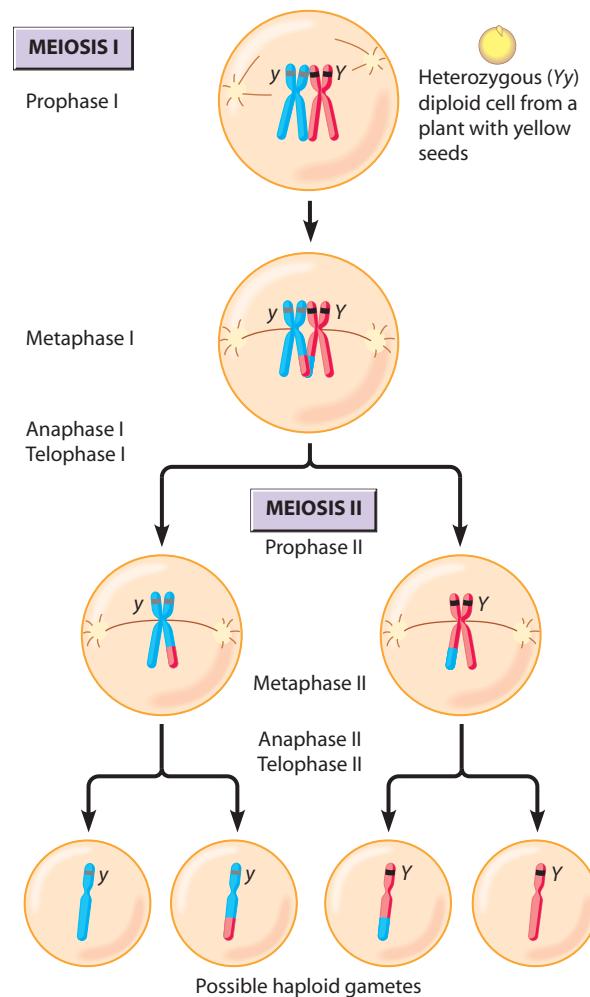

FIGURE 20-13 The Meiotic Basis for Mendel's Law of Segregation. Segregation of seed-color alleles during meiosis is illustrated for the case of a pea plant heterozygous for this character. Peas have seven pairs of chromosomes, but only the homologous pair bearing the seed-color alleles is shown here. During the first meiotic division (meiosis I), homologous chromosomes (each consisting of two sister chromatids) pair during prophase I, allowing crossing over to take place. The homologous chromosomes then align as a pair at the spindle equator during metaphase I and segregate into separate cells at anaphase I and telophase I. In meiosis II, sister chromatids segregate to different daughter cells. The result is four haploid daughter cells, each having one allele for seed color.

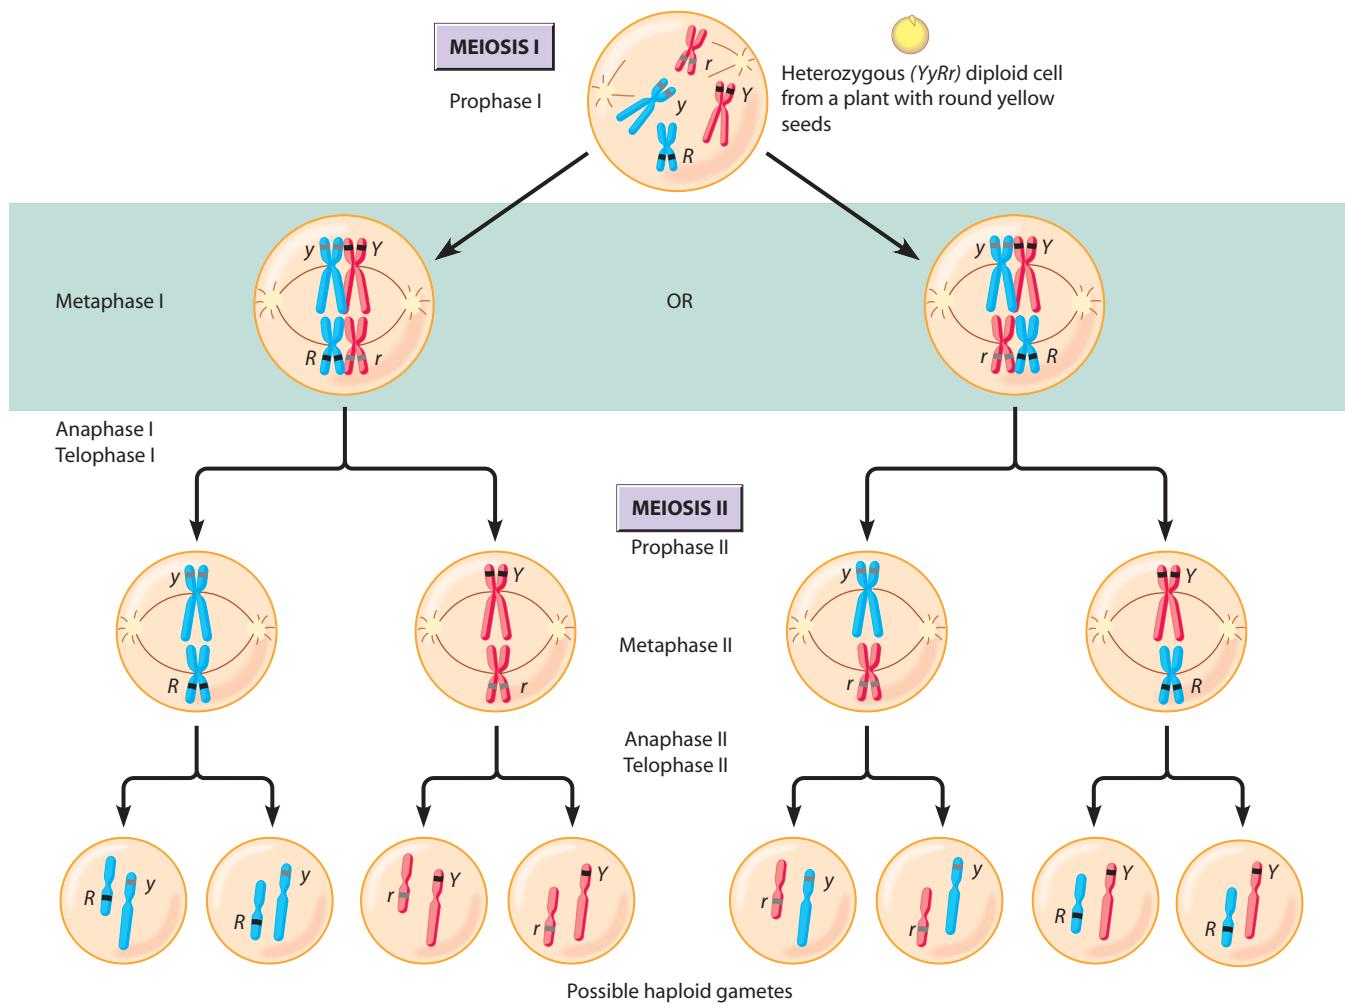

FIGURE 20-14 The Meiotic Basis for Mendel’s Law of Independent Assortment. Independent assortment of the alleles of two genes on different chromosomes is illustrated by meiosis in a pea plant heterozygous for seed color (Yy) and seed shape (Rr). Pea plants have seven pairs of chromosomes, but only the two pairs bearing the seed-color alleles and the seed-shape alleles are shown. During meiosis, segregation of the seed-color alleles occurs independently of segregation of the seed-shape alleles. The basis of this independent assortment is found at metaphase I, when the homologous pairs (bivalents) align at the spindle equator. Because each bivalent can face in either direction, there are two alternative situations: Either the paternal homologues (blue) can both face the same pole of the cell, with the maternal homologues (red) facing the other pole, or they can face different poles. The arrangement at metaphase I determines which homologues subsequently go to which daughter cells. Since the alternative arrangements occur with equal probability, all the possible combinations of the alleles therefore occur with equal probability in the gametes. For simplicity, chiasmata and crossing over are not shown in this diagram.

(alleles R and r , where R stands for round seeds, a dominant trait, and r for wrinkled seeds, a recessive trait). The explanation for independent assortment is that there are two possible, equally likely arrangements of the chromosome pairs at metaphase I. Of the $YyRr$ cells that undergo meiosis, half will produce gametes like the four at the bottom left of the figure, and half will produce gametes like the four at the bottom right. Therefore, the $YyRr$ plant will produce equal numbers of gametes of the eight types.

As we will discuss shortly, the law of independent assortment holds only for genes on *different* chromosomes (or for genes located far apart on the same chromosome). It is remarkable that Mendel happened to choose seven independently assorting characters in an organism that

has only seven pairs of chromosomes. Mendel was also fortunate that each of the seven characters he chose to study turned out to be controlled by a single gene (pair of alleles). Perhaps he concentrated on pea strains that, in preliminary experiments, gave him the most consistent and comprehensible results.

The DNA Molecules of Homologous Chromosomes Have Similar Base Sequences

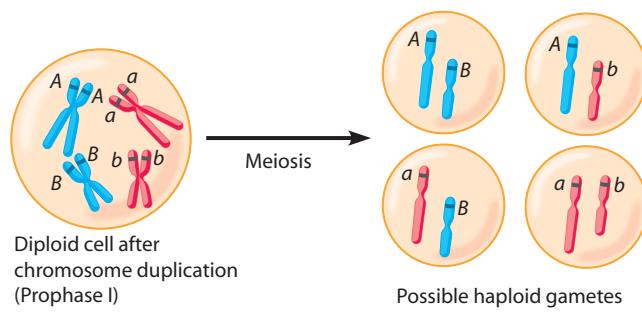

One of the five main points in the chromosomal theory of inheritance is the idea that homologous chromosomes are functionally equivalent, each carrying a similar set of genes. What does this mean in terms of our current understanding

of the molecular organization of chromosomes? Simply put, it means that homologous chromosomes have DNA molecules whose base sequences are almost, but not entirely, identical. Thus, homologous chromosomes typically carry the same genes in exactly the same order. However, minor differences in base sequence along the chromosomal DNA molecule can create different alleles of the same gene. Such differences arise by mutation, and the different alleles for a gene that we find in a population—whether of pea plants or people—arise from mutations that have gradually occurred in an ancestral gene. Alleles are usually “expressed” by transcription into RNA and translation into proteins, and it is the behavior of these proteins that ultimately creates an organism’s phenotype. As we will see in Chapter 21, a change as small as a single DNA base pair can create an allele that codes for an altered protein that is different enough to cause an observable change in an organism’s phenotype—in fact, such a DNA alteration can be lethal.

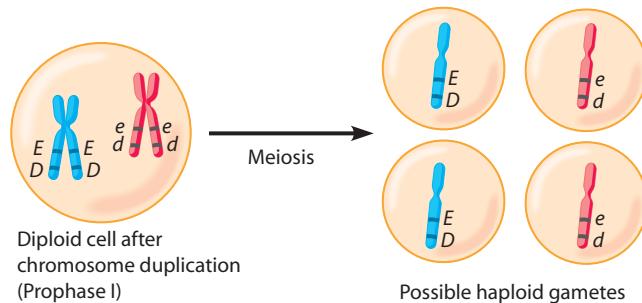

The underlying similarity in the base sequences of their DNA molecules—*DNA homology*—is thought to explain the ability of homologous chromosomes to undergo synapsis (close pairing) during meiosis and is essential for normal crossing over. One popular model for synapsis holds that the correct alignment of homologous chromosomes is brought about before completion of the synaptonemal complex by base-pairing interactions between matching regions of DNA in the two chromosomes. Support for this idea has come from studies showing that the chromosomes of some organisms possess special DNA sequences, called *pairing sites*, that promote synapsis between chromosomes when the same pairing site is present in two chromosomes. Protein components of the synaptonemal complex also play a role in facilitating the pairing between matching regions in the DNA of homologous chromosomes. After the synaptonemal complex is fully formed, DNA recombination is completed at these (and perhaps other) sites.

Genetic Variability: Recombination and Crossing Over

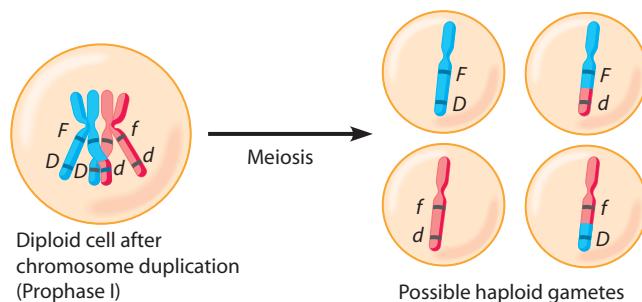

Segregation and independent assortment of homologous chromosomes during the first meiotic division lead to random assortment of the alleles carried by different chromosomes, as was shown in Figure 20-14 for seed shape and color in pea plants. **Figure 20-15a** summarizes the outcome of meiosis for a generalized version of the same situation. Here we have a diploid organism heterozygous for two genes on nonhomologous chromosomes, with the allele pairs called *Aa* and *Bb*. Meiosis in such an organism will produce gametes in which allele *A* is just as likely to occur with allele *B* as it is with allele *b*, and *B* is just as likely to occur with *A* as it is with *a*. But what happens if two genes, *D* and *E*, reside on the same chromosome? In that case, alleles *D* and *E* will routinely be linked together in the same gamete, as will alleles *d* and *e* (Figure 20-15b).

(a) Unlinked genes assort independently

(b) Linked genes end up together in the absence of crossing over

(c) Linked genes do not end up together when crossing over occurs

FIGURE 20-15 Segregation and Assortment of Linked and Unlinked Genes. In this figure, *A* and *a* are alleles of one gene, *B* and *b* are alleles of another gene, and so forth. (a) Alleles of genes on different chromosomes segregate and assort independently during meiosis; allele *A* is as likely to occur in a gamete with allele *B* as it is with allele *b*. (b) Alleles of genes on the same chromosome remain linked during meiosis in the absence of crossing over; in this case, allele *D* will occur routinely in the same gamete with allele *E* but not with allele *e*. (c) Alleles of genes on the same chromosome can become interchanged when crossing over takes place, so that allele *D* occurs not only with allele *F* but also with allele *f* and so forth.

But even for genes on the same chromosome, some scrambling of alleles can take place because of the phenomenon of crossing over, which leads to genetic recombination. Genetic recombination involves the exchange of genetic material between homologous chromosomes during prophase I of meiosis when the homologues are synapsed, creating chromosomes exhibiting new combina-

tions of alleles (Figure 20-15c). Recombination was originally discovered in studies with the fruit fly *Drosophila melanogaster*, conducted by Thomas Hunt Morgan and his colleagues beginning around 1910. We will therefore turn to Morgan's work to investigate recombination, beginning with his discovery of linkage groups.

Chromosomes Contain Groups of Linked Genes That Are Usually Inherited Together

The fruit flies used by Morgan and his colleagues had certain advantages over Mendel's pea plants as objects of genetic study, not the least of which was the fly's relatively brief generation time (about two weeks versus several months for pea plants). Unlike Mendel's peas, however, the fruit flies did not come with a ready-made variety of phenotypes and genotypes. Whereas Mendel was able to purchase seed stocks of different true-breeding varieties, the only type of fruit fly initially available to Morgan was what has come to be known as the **wild type**, or "normal" organism. Morgan and his colleagues therefore had to generate variants—that is, mutants—for their genetic experiments.

Morgan and his coworkers began by breeding large numbers of flies and then selecting mutant individuals having phenotypic modifications that were heritable. Later, X-irradiation was used to enhance the mutation rate, but in their early work Morgan's group depended entirely on spontaneous mutations. Within five years, they were able to identify about 85 different mutants, each carrying a mutation in a different gene. Each of these mutants could be propagated as a laboratory stock and used for matings as needed.

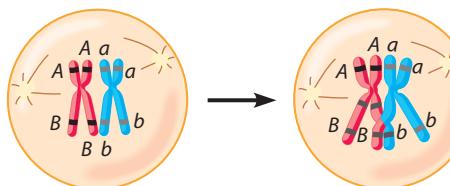

One of the first discoveries made by Morgan and his colleagues as they began analyzing their mutants was that, unlike the genes Mendel had studied in peas, the mutant

fruit fly genes did not all assort independently. Instead, some genes behaved as if they were linked together, and for such genes, the new combinations of alleles predicted by Mendel were infrequent or even nonexistent. In fact, it was soon recognized that fruit fly genes can be classified into four **linkage groups**, each group consisting of a collection of **linked genes** that are usually inherited together. Morgan quickly realized that the number of linkage groups was the same as the number of different chromosomes in the organism (the haploid chromosome number for *Drosophila* is four). The conclusion he drew was profound: Each chromosome is the physical basis for a specific linkage group. Mendel had not observed linkage, because the genes he studied either resided on different chromosomes or were far apart on the same chromosome and therefore behaved as if they were not linked to each other.

Homologous Chromosomes Exchange Segments During Crossing Over

Although the genes they discovered could all be organized into linkage groups, Morgan and his colleagues found that linkage within such groups was incomplete. Most of the time, genes known to be linked (and therefore on the same chromosome) assorted together, as would be expected. Sometimes, however, two or more such traits would appear in the offspring in nonparental combinations. This phenomenon of less-than-complete linkage was called **recombination** because the different alleles appeared in new and unexpected associations in the offspring.

To explain such recombinant offspring, Morgan proposed that homologous chromosomes can exchange segments, presumably by some sort of breakage-and-fusion event, as illustrated in **Figure 20-16a**. By this process, which Morgan termed *crossing over*, a particular

(a) Crossing over. Two homologous chromosomes, one bearing alleles A and B and the other alleles *a* and *b*, are paired at prophase I. Two nonsister chromatids undergo crossing over, causing portions of each to exchange places. The result is two recombinant chromatids, with alleles A and *b* on one chromatid and *a* and B on the other.

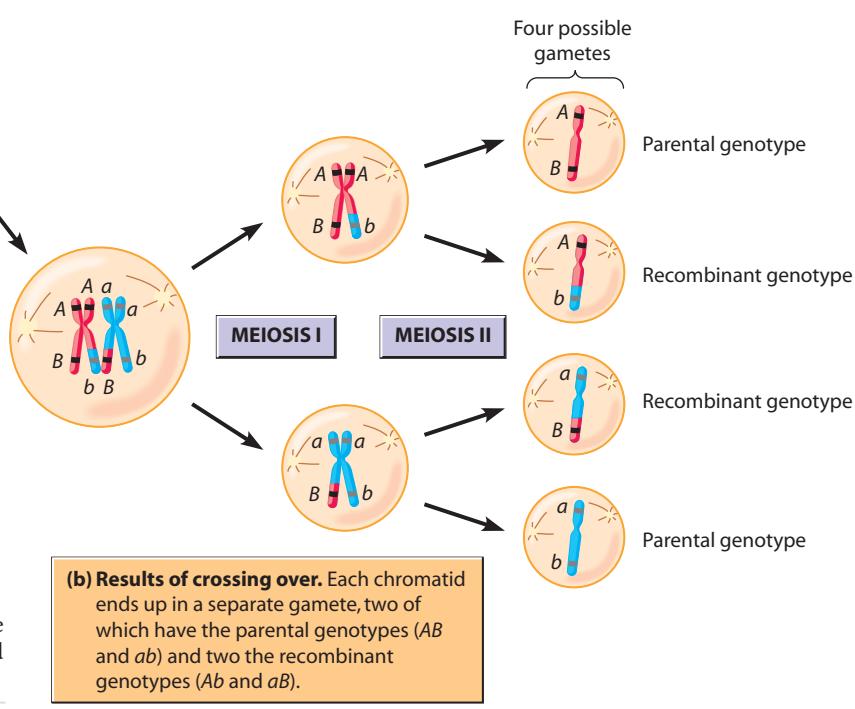

FIGURE 20-16 Crossing Over and Genetic Recombination. After a single crossover event, the results of meiosis include two parental gametes and two recombinant gametes.

allele or group of alleles initially present on one member of a homologous pair of chromosomes could be transferred to the other chromosome in a reciprocal manner.

In the example of Figure 20-16a, two homologous chromosomes, one with alleles *A* and *B* and the other with alleles *a* and *b*, lie side by side at synapsis. Portions of an *AB* chromatid and a nonsister *ab* chromatid then exchange DNA segments, thereby producing two recombinant chromatids—one with alleles *A* and *b* and the other with alleles *a* and *B*. Each of the four chromatids ends up in a different gamete at the end of the second meiotic division, so the products of meiosis will include two *parental* gametes and two *recombinant* gametes, assuming a single crossover event (Figure 20-16b).

We now know that crossing over takes place during the pachytene stage of meiotic prophase I (see Figure 20-6), when sister chromatids are packed tightly together and it is difficult to observe what is happening. As the chromatids begin to separate at diplotene, each of the four chromatids in a bivalent can be identified as belonging to one or the other of the two homologues. Wherever crossing over has taken place between nonsister chromatids, the two homologues remain attached to each other, forming a chiasma.

At the first meiotic metaphase, homologous chromosomes are almost always held together by at least one chiasma; if not, they may not segregate properly. Many bivalents contain multiple chiasmata. Human bivalents, for example, typically have two or three chiasmata because multiple crossover events routinely occur between paired homologues. To be genetically significant, crossing over must involve nonsister chromatids. In some species, exchanges between sister chromatids are also observed, but such exchanges have no genetic consequences because sister chromatids are genetically identical.

Gene Locations Can Be Mapped by Measuring Recombination Frequencies

Eventually, it became clear to Morgan and others that the frequency of recombinant progeny differed for different pairs of genes within each linkage group. This observation suggested that the frequency of recombination between two genes might be a measure of how far the genes are located from each other since genes located near each other on a given chromosome would be less likely to become separated by a crossover event than would genes that are far apart. This insight led Alfred Sturtevant, an undergraduate student in Morgan's lab, to suggest in 1911 that recombination data could be used to determine where genes are located along the chromosomes of *Drosophila*. In other words, a chromosome had come to be viewed as a linear string of genes whose positions can be determined on the basis of recombination frequencies.

Determining the sequential order and spacing of genes on a chromosome based on recombinant frequencies is called **genetic mapping**. In the construction of such maps,

the recombinant frequency is the map distance expressed in *map units (centimorgans)*. If, for example, the alleles in Figure 20-16b appear among the progeny in their parental combination (*AB* and *ab*) 85% of the time and in the recombinant combinations (*Ab* and *aB*) 15% of the time, we conclude that the two genes are linked (are on the same chromosome) and are 15 map units apart. This approach has been used to map the chromosomes of many species of plants and animals, as well as bacteria and viruses. However, because bacteria and viruses do not reproduce sexually, the methods used to generate recombinants are somewhat different.

Genetic Recombination in Bacteria and Viruses

Because it requires crossing over between homologous chromosomes, you might expect genetic recombination to be restricted to sexually reproducing organisms. Sexual reproduction provides an opportunity for crossing over once every generation when homologous chromosomes become closely juxtaposed during the meiotic divisions that produce gametes. In contrast, bacteria and viruses have haploid genomes and reproduce asexually, with no obvious mechanism for regularly bringing together genomes from two different parents.

Nonetheless, viruses and bacteria are still capable of genetic recombination. In fact, recombination data permitted the extensive mapping of viral and bacterial genomes well before the advent of modern DNA technology. To understand how recombination takes place despite a haploid genome, we need to examine the mechanisms that allow two haploid genomes, or portions of genomes, to be brought together within the same cell.

Co-infection of Bacterial Cells with Related Bacteriophages Can Lead to Genetic Recombination

Much of our early understanding of genes and recombination at the molecular level, as well as the vocabulary we use to express that information, came from experiments involving bacteriophages, particularly T-even phages and phage λ (see Box 18A, page 508). Although phages are haploid and do not reproduce sexually, genetic recombination between related phages can take place when individual bacterial cells are simultaneously infected by different versions of the same phage. **Figure 20-17** illustrates an experiment in which bacterial cells are co-infected by two related types of T4 phage. As the phages replicate in the bacterial cell, their DNA molecules occasionally become juxtaposed in ways that allow DNA segments to be exchanged between homologous regions. The resulting recombinant phage arises at a frequency that depends on the distance between the genes under study, just as in diploid organisms: The farther apart the genes, the greater the likelihood of recombination between them.

In phage recombination, crossing over involves relatively short, naked DNA molecules, rather than chromatids. The simplicity of this situation has facilitated research on the molecular mechanism of recombination and the proteins that catalyze the process. Phage recombination involves the precise alignment of homologous DNA molecules at the region of crossing over—a requirement that presumably holds for the recombination of eukaryotic and prokaryotic DNA as well.

Transformation and Transduction Involve Recombination with Free DNA or DNA Brought into Bacterial Cells by Bacteriophages

In bacteria, several mechanisms exist for recombining genetic information. One such mechanism has already been mentioned in Chapter 18, where we discussed the experiments with rough and smooth strains of pneumococcal bacteria that led Oswald Avery to conclude that

bacterial cells can be transformed from one genetic type to another by exposing them to purified DNA. This ability of a bacterial cell to take up DNA molecules and to incorporate some of that DNA into its own genome is called **transformation** (Figure 20-18a). Although initially described as a laboratory technique for artificially introducing DNA into bacterial cells, transformation is now recognized as a natural mechanism by which some (though by no means all) kinds of bacteria acquire genetic information when they have access to DNA from other cells.

A second mechanism for genetic recombination in bacteria, called **transduction**, involves DNA that has been brought into a bacterial cell by a bacteriophage. Most phages contain only their own DNA, but occasionally a phage will incorporate some bacterial host cell DNA sequences into its progeny particles. Such a phage particle can then infect another bacterium, acting like a syringe carrying DNA from one bacterial cell to the next (Figure 20-18b). Phages capable of carrying host cell DNA from one cell to another are called *transducing phages*.

The transducing phage known as P1, which infects *E. coli*, has been especially useful for gene mapping. The amount of DNA that will fit into a phage particle is small compared with the size of the bacterial genome. Two bacterial genes—or more generally, genetic markers (specific DNA sequences)—must therefore be close together for both to be simultaneously carried into a bacterial cell by a single phage particle. This is the basis of *cotransductional mapping*, in which the proximity of one marker to another is determined by measuring how frequently the markers accompany each other in a transducing phage particle. The closer two markers are, the more likely they are to be cotransduced into a bacterial cell. Studies using the transducing phage P1 have revealed that markers cannot be cotransduced if they are separated in the bacterial DNA by more than about 10^5 base pairs. This finding agrees with the observation that the P1 phage has a genome of about that size.

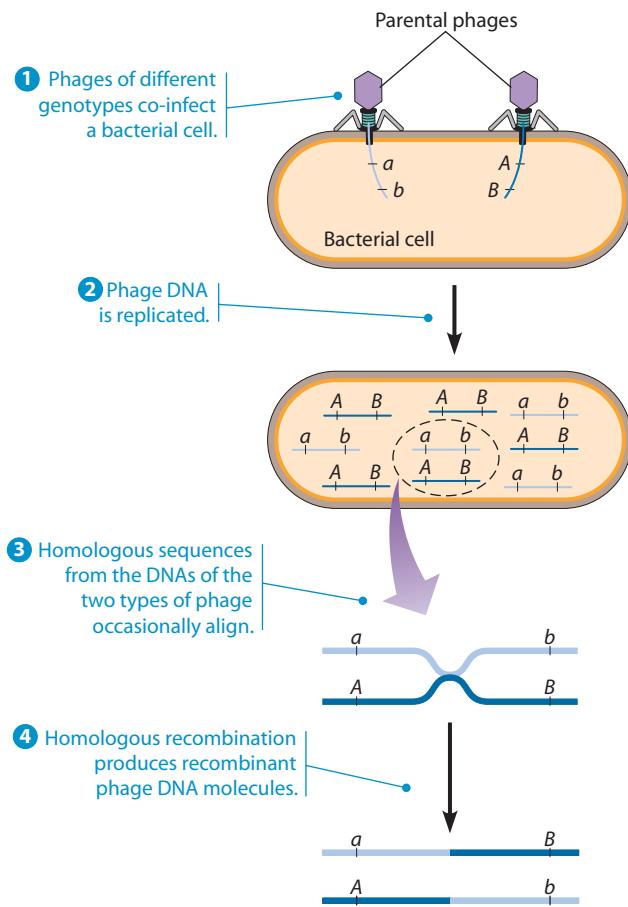

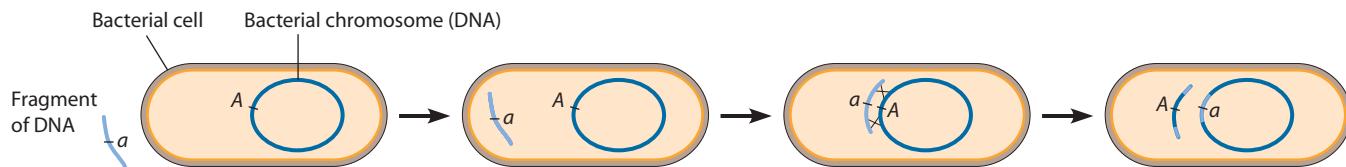

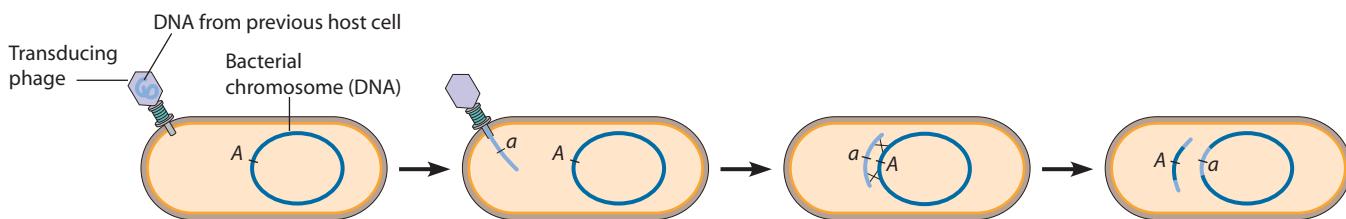

FIGURE 20-17 Genetic Recombination of Bacteriophages. Two phage populations with different genotypes co-infect a bacterial cell, thereby ensuring the simultaneous presence of both phage genomes in the same cell. One phage carries the mutant alleles *a* and *b*, while the other has alleles *A* and *B*. As the phage DNAs replicate, they occasionally become aligned and crossing over takes place, generating recombinant phage DNA molecules exhibiting *aB* and *Ab* genotypes. The frequency of occurrence of these recombinant genotypes provides a measure of the distance between genes.

Conjugation Is a Modified Sexual Activity That Facilitates Genetic Recombination in Bacteria

In addition to transformation and transduction, some bacteria also transfer DNA from one cell to another by **conjugation**. As the name suggests, conjugation resembles a mating in that one bacterium is clearly identifiable as the donor (often called a “male”) and another as the recipient (“female”). Although conjugation resembles a sexual process, this mode of DNA transfer is not an inherent part of the bacterial life cycle, and it usually involves only a portion of the genome; therefore conjugation does not qualify as true sexual reproduction. The existence of conjugation was postulated in 1946 by Joshua Lederberg and Edward L. Tatum, who were the first to show that genetic recombination occurs in bacteria. They also established that physical contact between two cells is necessary for conjugation to take place. We now understand that conjugation involves

(a) Transformation. Transformation involves uptake by the bacterial cell of exogenous DNA, which occasionally becomes integrated into the bacterial genome by two crossover events (indicated by X's). The exogenous DNA will be detectable in progeny cells only if integrated into the bacterial chromosome, because the fragment of DNA initially taken up does not normally have the capacity to replicate itself autonomously in the cell. (The main exception is an intact plasmid.)

(b) Transduction. Transduction involves the introduction of exogenous DNA into a bacterial cell by a phage. Once injected into the host cell, the DNA can become integrated into the bacterial genome in the same manner as in transformation. In both cases, linear fragments of DNA that end up outside the bacterial chromosome are eventually degraded by nucleases.

FIGURE 20-18 Transformation and Transduction in Bacterial Cells. Transformation and transduction are mechanisms by which bacteria incorporate external genetic information derived either from free DNA or from DNA brought into bacterial cells by bacteriophages. In this figure, the letters *A* and *a* represent alleles of the same gene.

the directional transfer of DNA from the donor bacterium to the recipient bacterium. Let's look at some details of how the process works.

The F Factor. The presence of a DNA sequence called the **F factor** (F for fertility) enables an *E. coli* cell to act as a donor during conjugation. The F factor can take the form of either an independent, replicating plasmid (page 530) or a segment of DNA within the bacterial chromosome. Donor bacteria containing the F factor in its plasmid form are designated F^+ , whereas recipient cells, which usually lack the F factor completely, are designated F^- . Donor cells develop long, hairlike projections called **sex pili** (singular: **pilus**) that emerge from the cell surface (Figure 20-19a). The end of each sex pilus contains molecules that selectively bind to the surface of recipient cells, thereby leading to the formation of a transient cytoplasmic **mating bridge** through which DNA is transferred from donor cell to recipient cell (Figure 20-19b).

When a donor cell contains an F factor in its plasmid form, a copy of the plasmid is quickly transferred to the recipient cell during conjugation, converting the recipient cell from F^- to F^+ (Figure 20-20a). Transfer always begins at a point on the plasmid called its **origin of transfer**, represented in the figure by an arrowhead. During transfer of an F factor to an F^- cell, the donor cell does not lose its F^+ status because the F factor is replicated in close association with the transfer process, allowing a copy of the F plasmid to remain behind in the donor cell. As a result, mixing an F^+ population of bacteria with F^-

cells will eventually lead to a population of cells that is entirely F^+ . "Maleness" is in a sense infectious, and the F factor is responsible for this behavior.

Hfr Cells and Bacterial Chromosome Transfer. Thus far, we have seen that donor and recipient cells are defined by the presence or absence of the F factor, which is in turn transmitted by conjugation. But how do recombinant bacteria arise by this means? The answer is that the F factor—while usually present as a plasmid—can sometimes become integrated into the bacterial chromosome, as shown in Figure 20-20b. (Integration results from crossing over between short DNA sequences in the chromosome and similar sequences in the F factor.) Chromosomal integration of the F factor converts an F^+ donor cell into an **Hfr cell**, which is capable of producing a high frequency of recombination in further matings because it can now transfer genomic DNA during conjugation.

When an Hfr bacterium is mated to an F^- recipient, DNA is transferred into the recipient cell (Figure 20-20c). But instead of transferring just the F factor itself, the Hfr cell transfers at least part (and occasionally all) of its chromosomal DNA, retaining a copy, as in F^+ DNA transfer. Transfer begins at the origin of transfer within the integrated F factor and proceeds in a direction dictated by the orientation of the F factor within the chromosome. Note that the chromosomal DNA is transferred in a linear form, with a small part of the F factor at the leading end and the remainder at the trailing end. Because the F factor is split in this way, only recipient cells that receive a complete

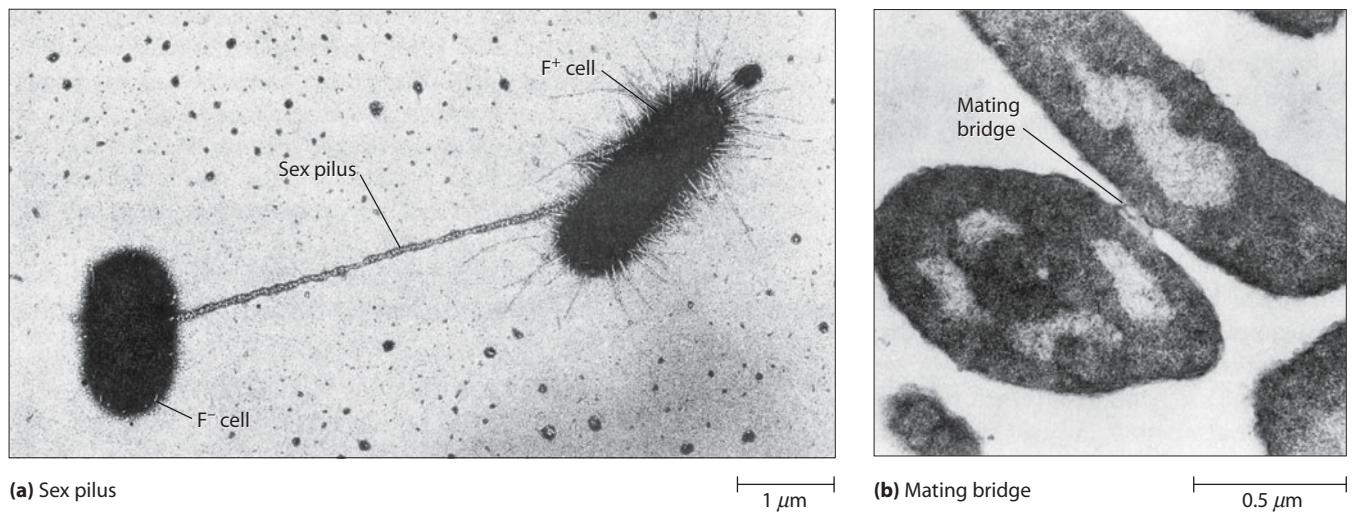

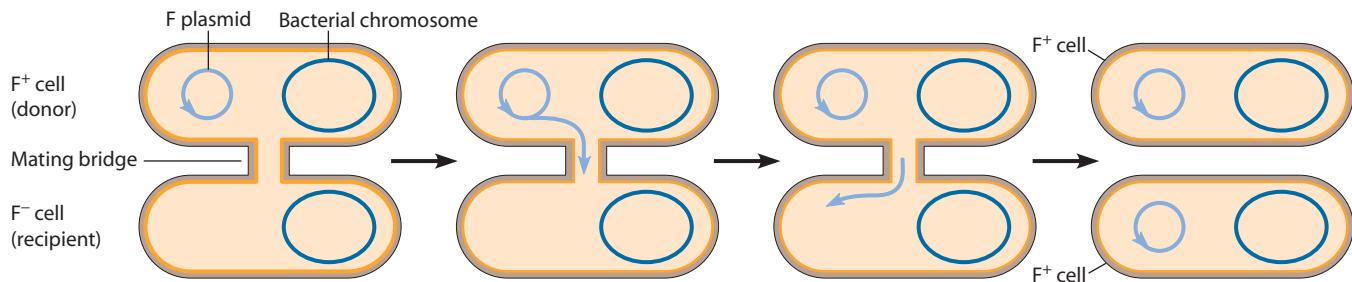

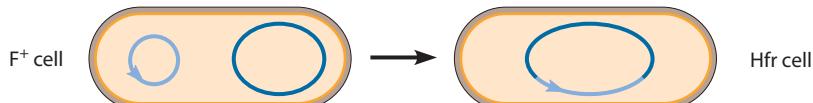

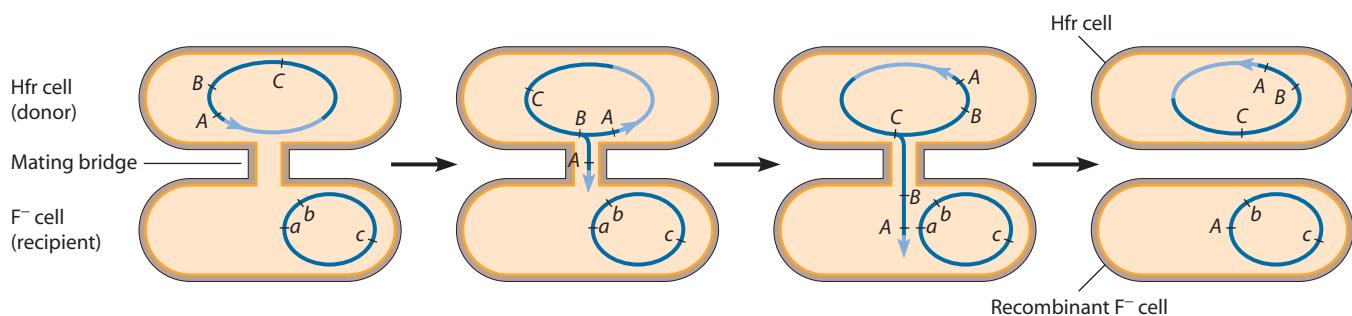

FIGURE 20-19 The Cellular Apparatus for Bacterial Conjugation. (a) The donor bacterial cell on the right, an F^+ cell, has many slender appendages, called pili, on its surface. Some of these pili are sex pili, including the very long pilus leading to the other cell, an F^- cell. Made of protein encoded by a gene on the F factor, sex pili enable a donor cell to attach to a recipient cell. (b) Subsequently, a cytoplasmic mating bridge forms, through which DNA is passed from the donor cell to the recipient cell (TEMs).

(a) Conjugation between F^+ and F^- cells. The transfer of a copy of the F factor plasmid from an F^+ donor bacterium to an F^- recipient converts the F^- cell into an F^+ cell. Plasmid transfer occurs through a mating bridge and begins at the F factor's origin of transfer, indicated by the arrowhead.

(b) Conversion of an F^+ cell into an Hfr cell. Integration of the F factor into the bacterial chromosome converts an F^+ cell into an Hfr cell.

(c) Conjugation between an Hfr cell and an F^- cell. Transferring a copy of the Hfr genome into an F^- cell begins with the origin of transfer on the integrated F factor. Cells rarely remain in contact long enough for the entire bacterial chromosome to be transferred. Once inside the F^- cell, parts of the Hfr DNA recombine with the DNA of the F^- cell. Uppercase letters represent alleles carried by the Hfr; lowercase letters represent corresponding alleles in the F^- cell. In the last step, allele A from the Hfr is recombined into the F^- cell's DNA in place of its a allele.

FIGURE 20-20 DNA Transfer by Bacterial Conjugation. (a) The presence of the F factor plasmid enables an *E. coli* cell to act as a plasmid donor during conjugation. (b) Chromosomal integration of the F factor creates an Hfr cell that can (c) transfer genomic DNA during conjugation.

bacterial chromosome from the Hfr donor actually become Hfr cells themselves. Transfer of the whole chromosome is extremely rare, however, because it takes about 90 minutes. Usually, mating contact is spontaneously disrupted before transfer is complete, leaving the recipient cell with only a portion of the Hfr chromosome, as shown in Figure 20-20c. As a result, genes located close to the origin of transfer on the Hfr chromosome are the most likely to be transmitted to the recipient cell.

Once a portion of the Hfr chromosome has been introduced into a recipient cell by conjugation, it can recombine with regions of the recipient cell's chromosomal DNA that are homologous (similar) in sequence. The recombinant bacterial chromosomes generated by this process contain some genetic information derived from the donor cell and some from the recipient. Only donor DNA sequences that are successfully integrated by this recombination mechanism survive in the recipient cell and its progeny. Donor DNA that is not integrated during recombination, as well as DNA removed from the recipient chromosome during the recombination process, is eventually degraded by nucleases.

The correlation between the position of a gene within the bacterial chromosome and its likelihood of transfer can be used to map genes with respect to the origin of transfer and therefore with respect to one another. For example, if gene A of an Hfr cell is transferred in conjugation 95% of the time, gene B 70% of the time, and gene C 55% of the time, then the sequence of genes is A-B-C, with gene A closest to the origin of transfer. Moreover, since the daughter cells of the recipient bacterium are recombinants, they can be used for genetic analysis. Typically, a cross is made between Hfr and F⁻ strains that differ in two or more genetic properties. After conjugation has taken place, the cells are plated on a nutrient medium on which recombinants can grow but "parent" strains cannot, thereby allowing the recombinants to be detected and recombinant frequencies to be calculated.

Molecular Mechanism of Homologous Recombination

We have now described five different situations in which genetic information can be exchanged between homologous DNA molecules: (1) prophase I of meiosis associated with gametogenesis in eukaryotes, (2) co-infection of bacteria with related bacteriophages, (3) transformation of bacteria with DNA, (4) transduction of bacteria by transducing phages, and (5) bacterial conjugation. Despite their obvious differences, all five situations share a fundamental feature: Each involves **homologous recombination** in which genetic information is exchanged between DNA molecules exhibiting extensive sequence similarity. We are now ready to discuss the molecular mechanisms underlying this type of recombination. Since the principles involved appear to be quite similar in prokaryotes and eukaryotes, we will use examples from both types of organisms.

DNA Breakage and Exchange Underlies Homologous Recombination

Shortly after it was first discovered that genetic information is exchanged between chromosomes during meiosis, two theories were proposed to explain how this might occur. The *breakage-and-exchange model* postulated that breaks occur in the DNA molecules of two adjoining chromosomes, followed by exchange and rejoicing of the broken segments. In contrast, the *copy-choice model* proposed that genetic recombination occurs while DNA is being replicated. According to the latter view, DNA replication begins by copying a DNA molecule located in one chromosome and then switches at some point to copying the DNA located in the homologous chromosome. The net result would be a new DNA molecule containing information derived from both chromosomes. One of the more obvious predictions made by the copy-choice model is that DNA replication and genetic recombination should happen at the same time. When subsequent studies revealed that DNA replication takes place during S phase while recombination typically occurs during prophase I, the copy-choice idea had to be rejected as a general model of meiotic recombination.

The first experimental evidence providing support for the breakage-and-exchange model was obtained in 1961 by Matthew Meselson and Jean Weigle, who employed phages of the same genetic type labeled with either the heavy (¹⁵N) or light (¹⁴N) isotope of nitrogen. Simultaneous infection of bacterial cells with these two labeled strains of the same phage resulted in the production of recombinant phage particles containing genes derived from both phages. When the DNA from these recombinant phages was examined, it was found to contain a mixture of ¹⁵N and ¹⁴N (Figure 20-21). Since these experiments were performed under conditions that prevented any new DNA from being synthesized, the recombinant DNA molecules must have been produced by breaking and rejoicing DNA molecules derived from the two original phages.

Subsequent experiments involving bacteria whose chromosomes had been labeled with either ¹⁵N or ¹⁴N revealed that DNA containing a mixture of both isotopes is also produced during genetic recombination between bacterial chromosomes. Moreover, when such recombinant DNA molecules are heated to dissociate them into single strands, a mixture of ¹⁵N and ¹⁴N is detected in each DNA strand; hence, the DNA double helix must be broken and rejoined during recombination.

A similar conclusion emerged from experiments performed shortly thereafter on eukaryotic cells by J. Herbert Taylor. In these studies, cells were briefly exposed to ³H-thymidine during the S phase preceding the last mitosis prior to meiosis, producing chromatids containing one radioactive DNA strand per double helix. During the following S phase, DNA replication in the absence of ³H-thymidine generated chromosomes containing one

DNA replication in the ABSENCE of ^{3}H -thymidine

Last mitosis before meiosis

Prophase I

Breakage and exchange

Recombinant chromatids

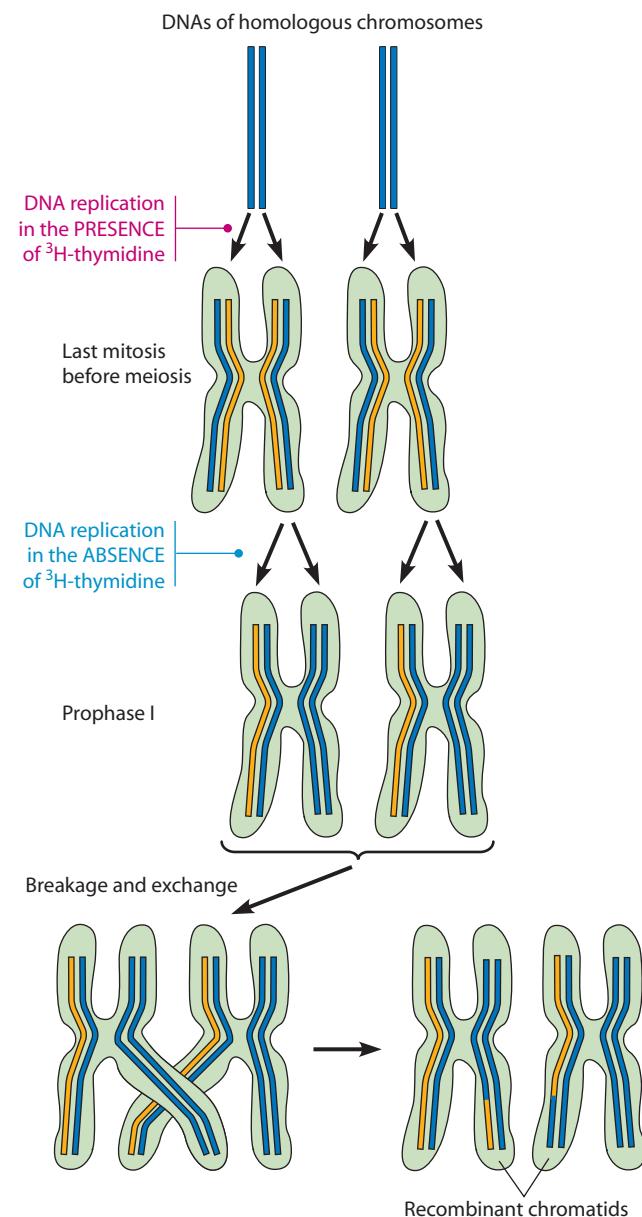

FIGURE 20-22 Experimental Demonstration of Breakage and Exchange During Eukaryotic Recombination.

In this experiment, DNA was radioactively labeled by briefly exposing eukaryotic cells to ^{3}H -thymidine before the last mitosis prior to meiosis. When autoradiography was employed to examine the chromatids during meiosis, some were found to contain a mixture of labeled (orange) and unlabeled (dark blue) segments as predicted by the breakage-and-exchange model.

labeled chromatid and one unlabeled chromatid (Figure 20-22). But during the subsequent meiosis, individual chromatids exhibited a mixture of radioactive and nonradioactive segments, as would be predicted by the breakage-and-exchange model. Moreover, the frequency of such exchanges was directly proportional to the frequency with which the genes located in these regions underwent genetic recombination. Such observations provided strong support for the notion that genetic recombination in eukaryotic cells, as in prokaryotes, involves DNA breakage and exchange. These experiments also showed that most DNA exchanges arise between homologous chromosomes rather than between the two sister chromatids of a given chromosome. This selectivity is important because it ensures that genes are exchanged between paternal and maternal chromosomes.

Homologous Recombination Can Lead to Gene Conversion

The conclusion that homologous recombination is based on DNA breakage and exchange does not in itself provide much information concerning the underlying molecular mechanisms. One of the simplest breakage-and-exchange models that might be envisioned would involve the cleavage of two homologous, double-stranded

DNA molecules at comparable locations, followed by exchange and rejoining of the cut ends. This model implies that genetic recombination should be completely reciprocal; that is, any genes exchanged from one chromosome should appear in the other chromosome and vice versa. For example, consider a hypothetical situation involving two genes designated *P* and *Q*. If one chromosome contains forms of these genes called *P*1 and *Q*1, and the other chromosome has alternative forms designated *P*2 and *Q*2, reciprocal exchange would be expected to

generate one chromosome with genes *P*₁ and *Q*₂ and a second chromosome with genes *P*₂ and *Q*₁.

Although this reciprocal pattern is usually observed, recombination has been found to be nonreciprocal in some situations. For example, recombination might generate one chromosome with genes *P*₁ and *Q*₂ and a second chromosome with genes *P*₂ and *Q*₂. In this particular example, the *Q*₁ gene expected on the second chromosome appears to have been converted to a *Q*₂ gene. For this reason, nonreciprocal recombination is often referred to as **gene conversion**. Gene conversion is most commonly observed when the recombining genes are located very close to one another. Because recombination between closely spaced genes is a rare event, gene conversion is most readily detectable in organisms that reproduce rapidly and generate large numbers of offspring, such as yeast and the common bread mold, *Neurospora*. More recently, however, gene conversion has been recognized in humans. For example, alteration of a gene by gene conversion underlies one form of *congenital adrenal hypoplasia*.

Homologous Recombination Is Initiated by Single-Strand DNA Exchanges (Holliday Junctions)

The preceding observations suggest that homologous recombination is more complicated than can be explained by a simple breakage-and-exchange model in which crossing over is accomplished by cleaving two double-stranded DNA molecules and then exchanging and rejoining the cut ends. Robin Holliday was the first to propose the alternative idea that recombination is based on the exchange of single DNA strands between two double-stranded DNA molecules. A current model of how such single-strand exchanges could lead to genetic recombination is illustrated in **Figure 20-23**. According to this model, the initial step (1) in recombination is the cleavage of one or both strands of the DNA double helix. In either case, a single broken DNA strand derived from one DNA molecule “invades” a complementary region of a homologous DNA double helix, displacing one of the two strands (2). Localized DNA synthesis and repair (3 and 4) ultimately generate a crossed structure, called a **Holliday junction**, in which a single strand from each DNA double helix has crossed over and joined the opposite double helix. Electron microscopy has provided direct support for the existence of Holliday junctions, revealing the presence of DNA double helices joined by single-strand crossovers at sites of genetic recombination (Figure 20-23, inset).

Once a Holliday junction has been formed, unwinding and rewinding of the DNA double helices causes the crossover point to move back and forth along the chromosomal DNA (5). This phenomenon, called *branch migration*, can rapidly increase the length of single-stranded DNA that is exchanged between two DNA

molecules. After branch migration has occurred, the Holliday junction is cleaved and the broken DNA strands are rejoined to produce two separate DNA molecules. A Holliday junction can be cleaved and rejoined in either of two ways. If it is cleaved in one plane, the two DNA molecules that are produced will exhibit crossing over; that is, the chromosomal DNA beyond the point where recombination occurred will have been completely exchanged between the two chromosomes (6a). If the Holliday junction is cut in the other plane, crossing over does not occur, but the DNA molecules exhibit a noncomplementary region near the site where the Holliday junction had formed (6b).

What is the fate of such noncomplementary regions? If they remain intact, an ensuing mitotic division will separate the mismatched DNA strands; each strand will then serve as a template for the synthesis of a new complementary strand. The net result will be two new DNA molecules with differing base sequences and hence two cells containing slightly different gene sequences in the affected region. This is the situation occasionally observed in *Neurospora*, where two genetically different cells can arise during the mitosis following meiosis. Alternatively, a noncomplementary DNA region may be corrected by excision and repair. The net effect of DNA repair would be to convert genes from one form to another—in other words, gene conversion.

A key enzyme involved in homologous recombination was first identified using bacterial extracts that catalyze the formation of Holliday junctions. Such extracts contain a protein, called *RecA*, whose presence is required for recombination. Mutant bacteria that produce a defective *RecA* protein cannot carry out genetic recombination, nor are extracts prepared from such cells capable of creating Holliday junctions from homologous DNA molecules. The *RecA* protein catalyzes a *strand invasion* reaction in which a single-stranded DNA segment displaces one of the two strands of a DNA double helix; in other words, it catalyzes step 2 in Figure 20-23. Eukaryotes contain a comparable protein called *Rad51*. In catalyzing the strand invasion reaction, *RecA* or *Rad51* first coats the single-stranded DNA region; the coated, single-stranded DNA then interacts with a DNA double helix, moving along the target DNA until it reaches a complementary sequence it can pair with.

Besides being involved in genetic recombination, strand invasion plays a role in certain types of DNA repair. As mentioned in Chapter 19, double-strand breaks in DNA are often repaired by a process that takes advantage of the fact that if one chromosome incurs a double-strand break, the intact DNA molecule of the homologous chromosomal DNA can serve as a template for guiding the repair of the broken chromosome. In such cases, single DNA strands from the broken DNA molecule invade the intact DNA molecule and find a complementary region to serve as a template for repairing the broken DNA, just as occurs in step 2 of Figure 20-23.

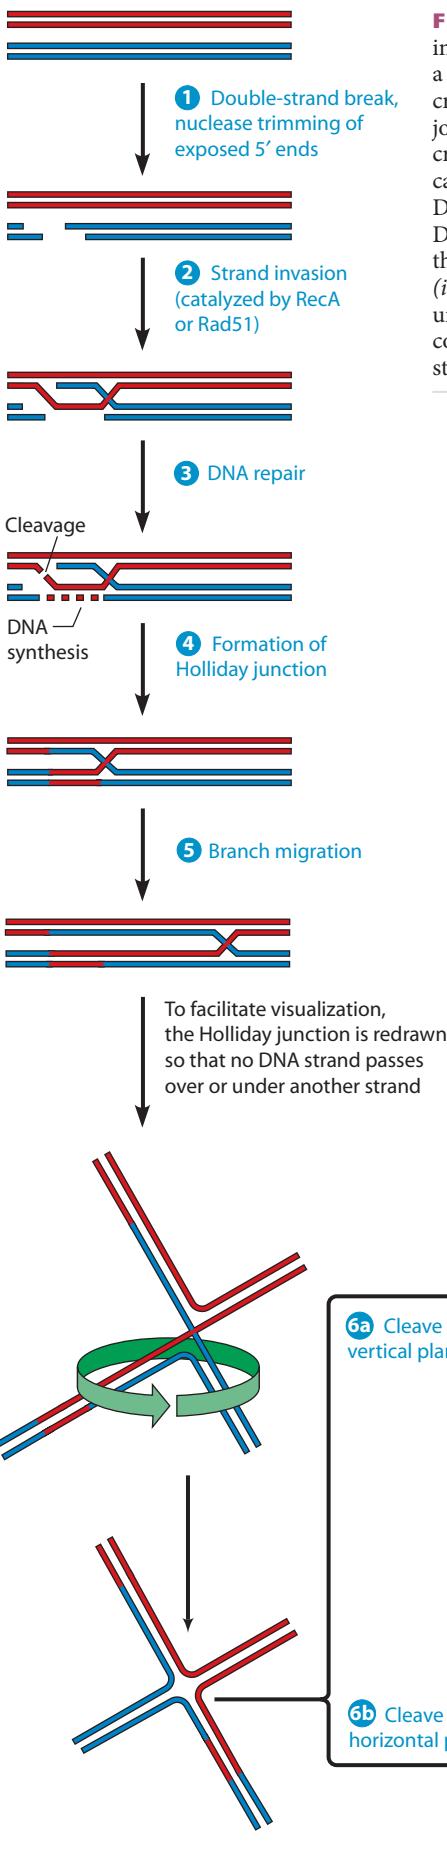

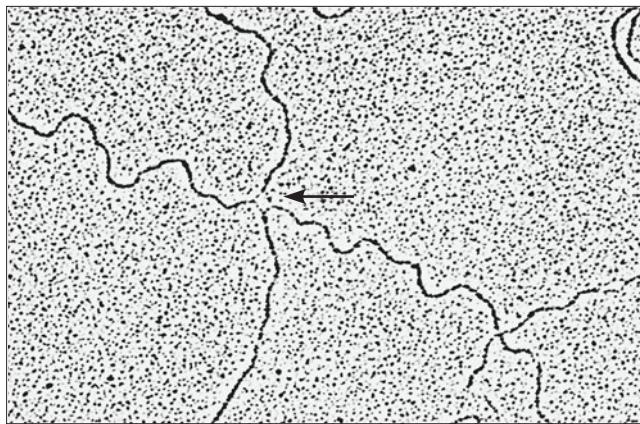

FIGURE 20-23 Molecular Model for Homologous Recombination. In this model, the initial step in recombination occurs when **1** a broken strand in one DNA molecule **2** invades a complementary region of a homologous DNA double helix. In steps **3** and **4**, one of the crossover points is repaired through cleavage and DNA synthesis, yielding two DNA molecules joined by a single Holliday junction in which a single strand from each DNA double helix has crossed over and joined the opposite double helix. After **5** DNA unwinding and rewinding causes the crossover point to move (branch migration), cleavage in one plane **6a** creates two DNA molecules that exhibit crossing over, whereas cleavage in the other plane **6b** generates DNA molecules that do not exhibit crossing over but contain a noncomplementary region near the site where the Holliday junction had formed. In the transmission electron micrograph (*inset*), the arrow points to a region where two bacteriophage DNA molecules in the process of undergoing homologous recombination are joined by a Holliday junction. (This photograph corresponds to the configuration shown at the bottom left of the drawing, immediately prior to steps **6a** and **6b**).

The Synaptonemal Complex Facilitates Homologous Recombination During Meiosis

Earlier in the chapter, we learned that during prophase I of meiosis, homologous chromosomes are joined together by a zipperlike, protein-containing structure called the synaptonemal complex. Several observations suggest that this structure plays an important role in genetic recombination. First, the synaptonemal complex appears at the time when recombination takes place. Second, its location between the opposed homologous chromosomes corresponds to the region where crossing over occurs. And finally, synaptonemal complexes are absent from organisms—such as male fruit flies—that fail to carry out meiotic recombination.

Presumably, the synaptonemal complex facilitates recombination by maintaining a close pairing between adjacent homologous chromosomes along their entire length. But if the synaptonemal complex facilitates recombination, how do cells ensure that such structures form only between homologous chromosomes? Evidence suggests the existence of a process called *homology searching*, in which a single-strand break in one DNA molecule produces a free strand that “invades” another DNA double helix and checks for the presence of complementary sequences (Figure 20-23, step ②). If extensive homology is not found, the free DNA strand invades another DNA molecule and checks for complementarity, repeating the process until a homologous DNA molecule is detected. Only then does a synaptonemal complex develop, bringing the homologous chromosomes together throughout their length to facilitate the recombination process.

Recombinant DNA Technology and Gene Cloning

In nature, genetic recombination usually takes place between two DNA molecules derived from organisms of the same species. In animals and plants, for example, an individual’s two parents are the original sources of the DNA that recombines during meiosis. A naturally arising recombinant DNA molecule usually differs from the parental DNA molecules only in the combination of alleles it contains; the fundamental identities and sequences of its genes remain the same.

In the laboratory, such limitations do not exist. Since the development of **recombinant DNA technology** in the 1970s, scientists have had at their disposal a collection of techniques for making recombinant DNA in the laboratory. Any segment of DNA can now be excised from any genome and spliced together with any other piece of DNA. Initially derived from basic research on the molecular biology of bacteria, these techniques have enabled researchers to isolate and study genes from any source with greater ease and precision than was earlier thought possible.

A central feature of recombinant DNA technology is the ability to produce specific pieces of DNA in large

enough quantities for research and other uses. This process of generating many copies of specific DNA fragments is called **DNA cloning**. (In biology, a *clone* is a population of organisms that is derived from a single ancestor and hence is genetically homogeneous, and a *cell clone* is a population of cells derived from the division of a single cell. By analogy, a *DNA clone* is a population of DNA molecules that are derived from the replication of a single molecule and hence are identical to one another.)

DNA cloning is accomplished by splicing the DNA of interest to the DNA of a genetic element, called a **cloning vector**, that can replicate autonomously when introduced into a cell grown in culture—in most cases, a bacterium such as *E. coli*. The cloning vector can be a plasmid or the DNA of a virus, usually a bacteriophage; in either case, the vector’s DNA “passenger” is copied every time it replicates. In this way, it is possible to generate large quantities of specific genes or other DNA segments—and of their protein products as well, if the passenger genes are transcribed and translated in proliferating cells that carry the vector.

To appreciate the importance of recombinant DNA technology, we need to grasp the magnitude of the problem that biologists faced as they tried to study the genomes of eukaryotic organisms. Much of our early understanding of information flow in cells came from studies with bacteria and viruses, whose genomes were mapped and analyzed in great detail using genetic methods that were not easily applied to eukaryotes. Until a few decades ago, investigators despaired of ever being able to understand and manipulate eukaryotic genomes to the same extent because the typical eukaryote has at least 10,000 times as much DNA as the best-studied phages—truly an awesome haystack in which to find a gene-sized needle. But the advent of recombinant DNA technology made it possible to isolate individual eukaryotic genes in quantities large enough to permit them to be thoroughly studied, ushering in a new era in biology.

The Discovery of Restriction Enzymes Paved the Way for Recombinant DNA Technology

Much of what we call recombinant DNA technology was made possible by the discovery of *restriction enzymes* (see Box 18B, page 520). The ability of restriction enzymes to cleave DNA molecules at specific sequences called *restriction sites* makes them powerful tools for cutting large DNA molecules into smaller fragments that can be recombined in various ways. Restriction enzymes that make staggered cuts in DNA are especially useful because they generate single-stranded *sticky ends* (also called *cohesive ends*) that provide a simple means for joining DNA fragments obtained from different sources. In essence, any two DNA fragments generated by the same restriction enzyme can be joined together by complementary base pairing between their single-stranded, sticky ends.

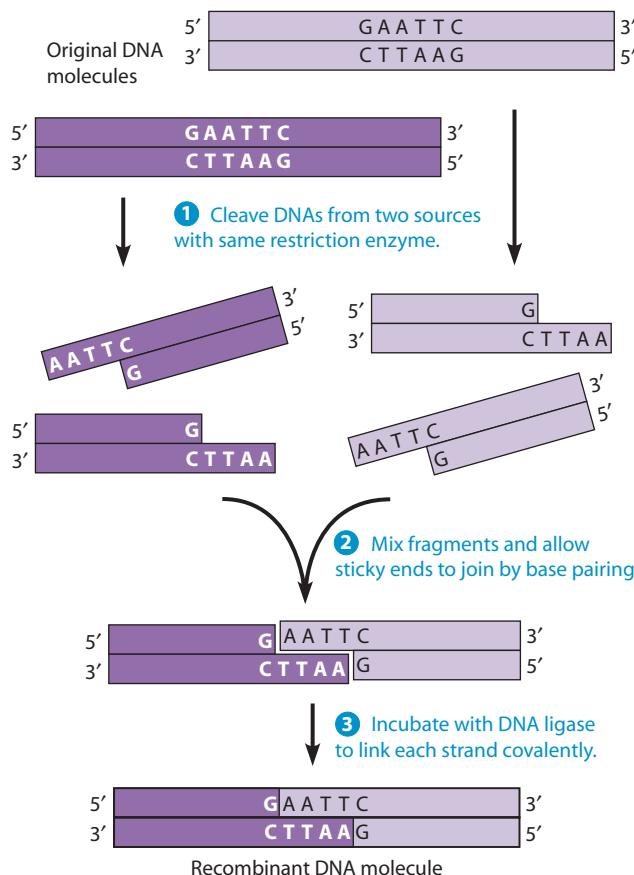

FIGURE 20-24 Creating Recombinant DNA Molecules. A restriction enzyme that generates sticky ends (in this case *EcoRI*) is used to cleave DNA molecules from two different sources. The complementary ends of the resulting fragments join by base pairing to create recombinant molecules containing segments from both of the original sources.

Figure 20-24 illustrates how this general approach works. DNA molecules from two sources are first treated with a restriction enzyme known to generate fragments with sticky ends (1), and the fragments are then mixed together under conditions that favor base pairing between these sticky ends (2). Once joined in this way, the DNA fragments are covalently sealed together by DNA ligase (3), an enzyme normally involved in DNA replication and repair (see Chapter 19). The final product is a **recombinant DNA molecule** containing DNA sequences derived from two different sources.

The combined use of restriction enzymes and DNA ligase allows any two (or more) pieces of DNA to be spliced together, regardless of their origins. A piece of human DNA, for example, can be joined to bacterial or phage DNA just as easily as it can be linked to another piece of human DNA. In other words, it is possible to form recombinant DNA molecules that never existed in nature, without regard for the natural barriers that otherwise limit recombination to genomes of the same or closely related species. Therein lies the power of (and, for some, the concern about) recombinant DNA technology.

DNA Cloning Techniques Permit Individual Gene Sequences to Be Produced in Large Quantities

The power of restriction enzymes is that they make it easy to insert a desired piece of DNA—usually a segment containing a specific gene—into a cloning vector that can replicate itself when introduced into bacterial cells. Suppose, for example, you wanted to isolate a gene that codes for a medically useful product, such as insulin needed for the treatment of diabetics or blood clotting factors needed by patients with hemophilia. By using restriction enzymes to insert a cDNA encoding such a protein (see the next section) into a cloning vector in bacterial cells and then identifying bacteria that contain the DNA of interest, it is possible to grow large masses of such cells and thereby obtain large quantities of the desired DNA (and its protein product).

Although the specific details vary, the following five steps are typically involved in this process of DNA cloning: (1) insertion of DNA into a cloning vector; (2) introduction of the recombinant vector into cultured cells, usually bacteria; (3) amplification of the recombinant vector in the bacteria; (4) selection of cells containing recombinant DNA; and (5) identification of clones containing the DNA of interest. **Figure 20-25** provides an overview of these events using a bacterial cloning vector. You should refer to this figure as we consider each step in turn.

1. Insertion of DNA into a Cloning Vector. The first step in cloning a desired piece of DNA is to insert it into an appropriate cloning vector, usually a bacteriophage or a plasmid. Most vectors used for DNA cloning are themselves recombinant DNA molecules, designed specifically for this purpose. For example, when bacteriophage 1 DNA is used as a cloning vector, the phage DNA has had some of its nonessential genes removed to make room in the phage head for spliced-in DNA. Plasmids used as cloning vectors usually have a variety of restriction sites and often carry genes that confer antibiotic resistance on their host cells. The antibiotic-resistance genes facilitate the selection stage (4), while the presence of multiple kinds of restriction sites allows the plasmid to incorporate DNA fragments prepared with a variety of restriction enzymes.

Figure 20-26 illustrates the structure of *pUC19* (“puck-19”), a plasmid cloning vector developed in the mid-1980s. This plasmid, as well as a series of versatile vectors subsequently derived from it, carries a gene that confers resistance to the antibiotic ampicillin (*amp*^R). Bacteria containing such plasmids can therefore be identified by their ability to grow in the presence of ampicillin. The *pUC19* plasmid also has 11 different restriction sites clustered in a region of the plasmid containing the *lacZ* gene, which codes for the enzyme β -galactosidase. Integration of foreign DNA at any of these restriction sites will disrupt the *lacZ* gene, thereby blocking the production of β -galactosidase. As we will see shortly, this

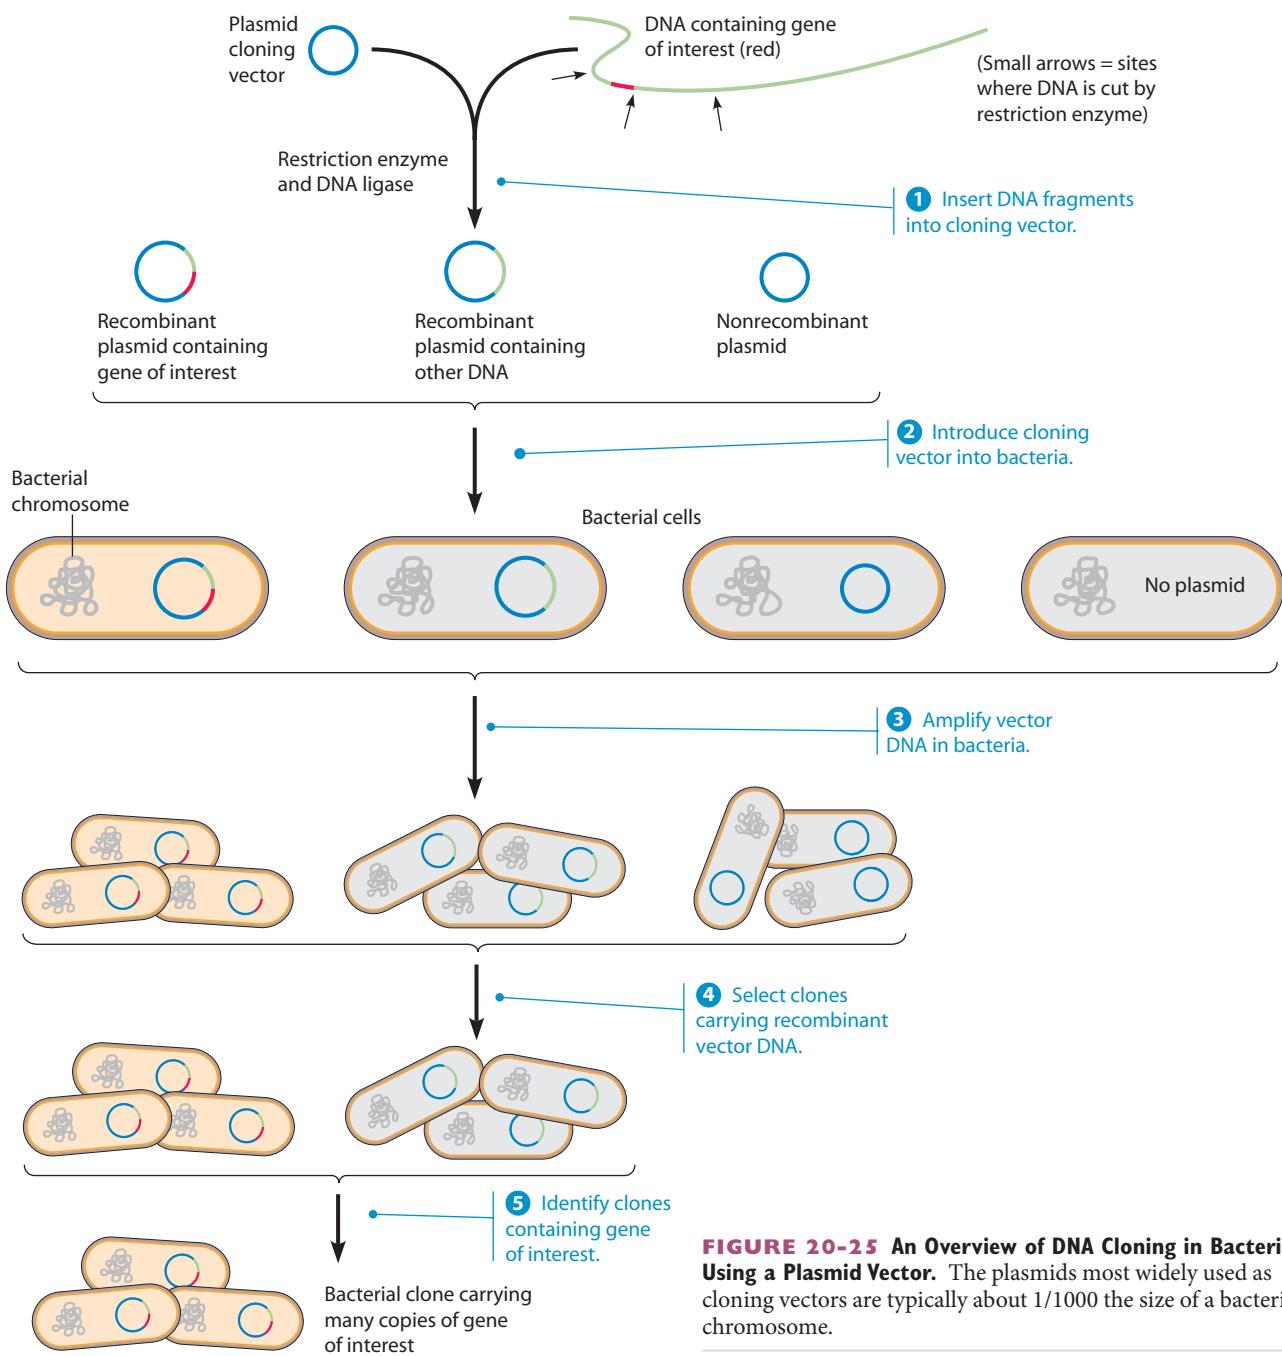

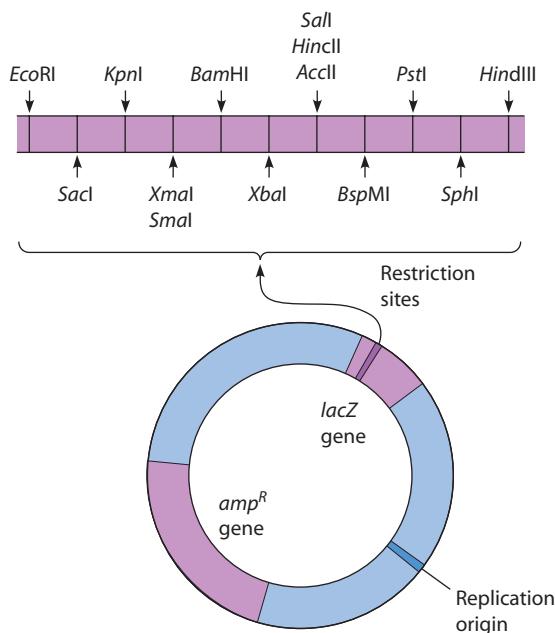

FIGURE 20-25 An Overview of DNA Cloning in Bacteria, Using a Plasmid Vector. The plasmids most widely used as cloning vectors are typically about 1/1000 the size of a bacterial chromosome.

disruption in β -galactosidase production can be used later in the cloning process to detect the presence of plasmids containing foreign DNA.

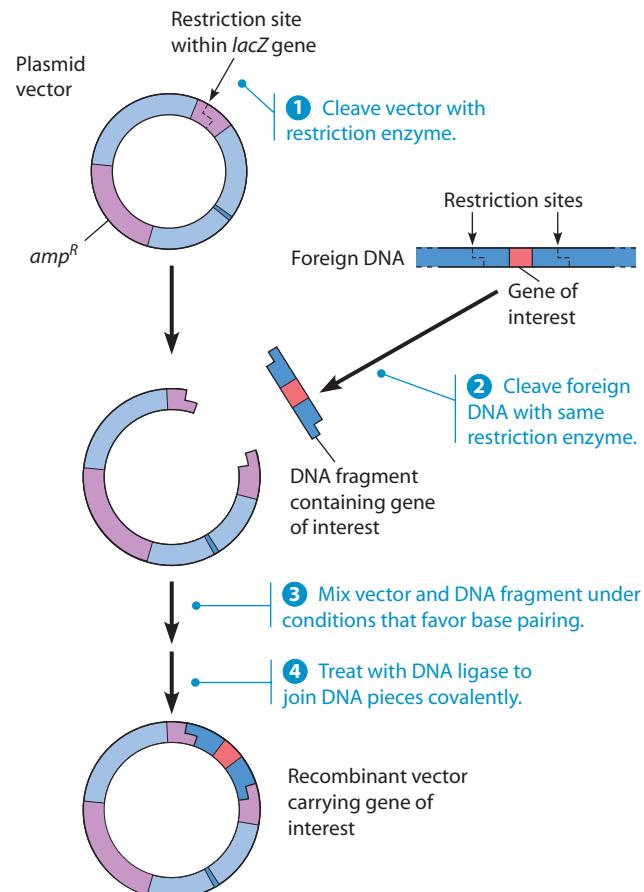

Figure 20-26b illustrates how a specific gene of interest residing in a foreign DNA source is inserted into a plasmid cloning vector, using pUC19 as the vector and a restriction enzyme that cleaves pUC19 at a single site within the *lacZ* gene. Incubation with the restriction enzyme cuts the plasmid at that site (1), making the DNA linear (opening the circle). The same restriction enzyme is used to cleave the DNA molecule containing the gene to be cloned (2). The sticky-ended fragments of foreign DNA are then incubated with the linearized vector

molecules under conditions that favor base pairing (3), followed by treatment with DNA ligase to link the molecules covalently (4). To keep the diagram simple, Figure 20-26b shows only the recombinant plasmid containing the desired fragment of foreign DNA. In practice, however, a variety of DNA products will be present, including nonrecombinant plasmids and recombinant plasmids containing other fragments generated by the action of the restriction enzyme.

2. Introduction of the Recombinant Vector into Bacterial Cells. Once foreign DNA has been inserted into a cloning vector, the resulting recombinant vector is replicated

(a) Plasmid pUC19. The pUC19 plasmid is an *E. coli* plasmid of 2686 base pairs that contains a replication origin, an ampicillin resistance gene (*amp^R*), and a *lacZ* gene coding for β-galactosidase. Eleven restriction sites are clustered within the *lacZ* gene.

(b) Procedure for inserting a foreign gene into pUC19.

FIGURE 20-26 Cloning a Gene in the Plasmid Vector pUC19. To insert foreign DNA into the plasmid, the foreign and plasmid DNAs are cleaved with a restriction enzyme that recognizes the same site, in this case a site within the *lacZ* gene. The fragments of foreign DNA are incubated with the linearized plasmid DNA under conditions that favor base pairing between sticky ends. Among the expected products will be plasmid molecules recircularized by base pairing with a single fragment of foreign DNA, and some of these will contain the gene of interest. Cells carrying such plasmids will be resistant to ampicillin and will fail to produce β-galactosidase because of the foreign DNA inserted within the *lacZ* gene.

[ACTIVITIES www.thecellplace.com](http://www.thecellplace.com) DNA cloning in a plasmid vector

by introducing it into an appropriate host cell, usually the bacterium *E. coli*. Cloning vectors are introduced into bacteria in one of two ways. If the cloning vector is phage DNA, it is incorporated into phage particles that are then used to infect an appropriate cell population. Plasmids, on the other hand, are simply introduced into the medium surrounding the target cells. Both prokaryotic and eukaryotic cells will take up plasmid DNA from the external medium, although special treatments are usually necessary to enhance the efficiency of the process. Adding calcium ions, for example, markedly increases the rate at which cells take up DNA from the external environment.

3. Amplification of the Recombinant Vector in Bacteria. After they have taken up the recombinant cloning vector, the host bacteria are plated out on a nutrient medium so that the recombinant DNA vector can be replicated, or *amplified*. In the case of a plasmid vector,

the bacteria proliferate and form colonies, each derived from a single cell. Under favorable conditions, *E. coli* will divide every 22 minutes, giving rise to a billion cells in less than 11 hours. As the bacteria multiply, the recombinant plasmids also replicate, producing an enormous number of vector molecules containing foreign DNA fragments. Under such conditions, a single recombinant plasmid introduced into one cell will be amplified several hundred billionfold in less than half a day.

In the case of phage vectors such as phage λ, a slightly different procedure is used. Phage particles containing recombinant DNA are mixed with bacterial cells, and the mixture is then placed on a culture medium under conditions that produce a continuous “lawn” of bacteria across the plate. Each time a phage particle infects a cell, the phage is replicated and eventually causes the cell to rupture and die. The released phage particles can then infect neighboring cells, repeating the process again. This

cycle eventually produces a clear zone of dead bacteria called a **plaque**, which contains large numbers of replicated phage particles derived by replication from a single type of recombinant phage (see Figure 18A-3). The millions of phage particles in each plaque contain identical molecules of recombinant phage DNA.

4. Selection of Cells Containing Recombinant DNA.

During amplification of the cloning vector, procedures are introduced that preferentially select for the growth of those cells that have successfully incorporated the vector. For plasmid vectors such as pUC19, the selection method is based on the plasmid's antibiotic-resistance genes. For example, all bacteria carrying the recombinant plasmids generated in Figure 20-26b will be resistant to the antibiotic ampicillin, since all plasmids have an intact ampicillin-resistance gene. The *amp^R* gene is a **selectable marker**, which allows only the cells carrying plasmids to grow on culture medium containing ampicillin (the medium "selects for" the growth of the ampicillin-resistant cells).

However, not all the ampicillin-resistant bacteria will carry *recombinant* plasmids—that is, plasmids containing spliced-in DNA. But those bacteria that do contain recombinant plasmids can be readily identified because the *lacZ* gene has been disrupted by the foreign DNA and, as a result, β -galactosidase will no longer be produced. The lack of β -galactosidase can be detected by a simple color test in which bacteria are exposed to a substrate that is normally cleaved by β -galactosidase into a blue-staining compound. Bacterial colonies containing the normal pUC19 plasmid will therefore stain blue, whereas colonies containing recombinant plasmids with inserted DNA fragments will appear white.

A different approach is used with phage cloning vectors, which are usually derived from phage λ DNA molecules that are only about 70% as long as normal phage DNA. As a result, these DNA molecules are too small to be packaged into functional phage particles. But if an additional fragment of DNA is inserted into the middle of such a cloning vector, it creates a recombinant DNA molecule that is larger and thus capable of being assembled into a functional phage (Figure 20-27). Hence, when phage cloning vectors are employed, the only phage particles that can successfully infect bacterial cells are those containing an inserted foreign DNA sequence.

5. Identification of Clones Containing the DNA of Interest.

The preceding steps typically generate vast numbers of bacteria producing many different kinds of recombinant DNA, only one or a few of which are relevant to the desired application. The final stage in any recombinant DNA procedure is therefore screening the bacterial colonies (or phage plaques) to identify those containing the specific DNA fragment of interest. For standard bacterial clones, this is usually done by isolating DNA from the bacteria and then using restriction enzymes to confirm

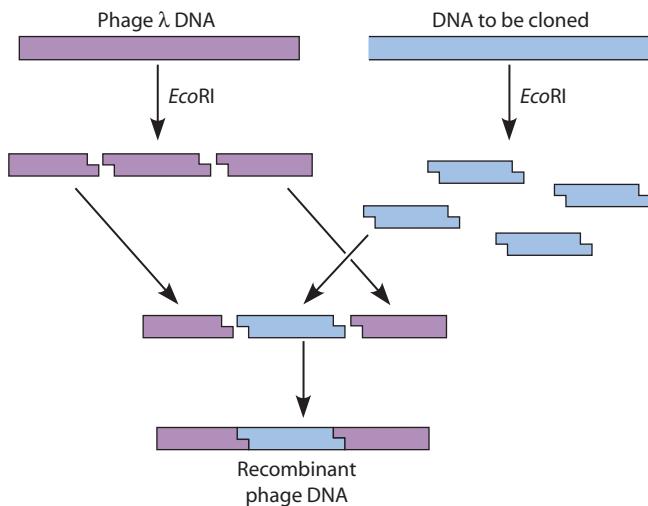

FIGURE 20-27 Bacteriophage λ as a Cloning Vector. The middle segment of the phage λ DNA molecule is removed by EcoRI cleavage and then replaced by the DNA fragment to be cloned. The inserted DNA fragment is necessary to make the phage λ DNA molecule large enough to be packaged into a functional phage particle.

that the cloned DNA has the expected pattern. The cloned DNA is then often sequenced (see page 520) to provide precise verification of the nature of the inserted DNA.

Genomic and cDNA Libraries Are Both Useful for DNA Cloning

Cloning foreign DNA in bacterial cells is now a routine procedure. In practice, obtaining a good source of DNA to serve as starting material is often one of the most difficult steps. Two different approaches are commonly used for producing the DNA starting material. In the "shotgun" approach, an organism's entire genome (or some substantial portion of it) is cleaved into a large number of restriction fragments, which are then inserted into cloning vectors for introduction into bacterial cells (or phage particles). The resulting group of clones is called a **genomic library** because it contains cloned fragments representing most, if not all, of the genome. Genomic libraries of eukaryotic DNA are valuable resources from which specific genes can be isolated, provided that a sufficiently sensitive identification technique is available. Once a rare bacterial colony containing the desired DNA fragment has been identified, it can be grown on a nutrient medium to generate as many copies of the fragment as may be needed. Of course, the DNA cuts made by a restriction enzyme do not respect gene boundaries, and some genes may be divided among two or more restriction fragments. This problem can be circumvented by carrying out a *partial DNA digestion* in which the DNA is briefly exposed to a small quantity of restriction enzyme. Under such conditions, some restriction sites remain uncut, increasing the probability that at least one intact copy of each gene will be present in the genomic library.

The alternative DNA source for cloning experiments is DNA that has been generated by copying messenger RNA (mRNA) with the enzyme *reverse transcriptase* (page 648). This reaction generates a population of **complementary DNA (cDNA)** molecules that are complementary in sequence to the mRNA employed as template (**Figure 20-28**). If the entire mRNA population of a cell is isolated and copied into cDNA for cloning, the resulting group of clones is called a **cDNA library**. The advantage of a cDNA library is that it contains only those DNA sequences that are transcribed into mRNA—presumably, the active genes in the cells or tissue from which the mRNA was prepared.

Besides being limited to transcribed genes, a cDNA library has another important advantage as a starting point for the cloning of eukaryotic genes. Using mRNA to make cDNA guarantees that the cloned genes will contain only gene-coding sequences, without the noncoding interruptions called *introns* that are common in eukaryotic genes (see Chapter 21). Introns can be so extensive that the overall length of a eukaryotic gene becomes too unwieldy for recombinant DNA manipulation. Using cDNA eliminates this problem. In addition, bacteria cannot synthesize the correct protein product of an intron-containing eukaryotic gene unless the introns have been removed—as they are in cDNA.

Once a DNA library has been constructed, how can bacteria or phage be identified that carry only the sequences that we are interested in? There are several techniques for *screening* DNA libraries. The particular technique used depends on what the researcher knows about the gene being cloned, and on the type of library. If something is known about the base sequence of the gene of interest, the researcher can employ a **nucleic acid probe**, a single-stranded molecule of DNA or RNA that can identify a desired DNA sequence by base-pairing with it. Nucleic acid probes are labeled either with radioactivity or with some other chemical group that allows the probe to be easily visualized. (In Box 18C, page 528, we saw such a probe used to identify restriction fragment bands in Southern blotting.) The researcher prepares a labeled DNA or RNA probe containing all or part of the nucleotide sequence of interest and uses it to tag the colonies that contain complementary DNA. **Figure 20-29** outlines how this *colony hybridization technique* can be used to screen for colonies carrying the desired DNA. Once the appropriate colonies have been identified, cloned DNA is recovered from these colonies by isolating the vector DNA from the bacterial cells and digesting it with the same restriction enzyme used initially.

Another screening approach focuses on the protein encoded by a gene of interest. If this protein is known and has been purified, antibodies against it can be prepared and used as probes to check bacterial colonies for the presence of the protein. Alternatively, the *function* of the protein can be measured; for example, an enzyme could be tested for its catalytic activity. Protein-screening methods obviously depend on the ability of the bacterial cells to

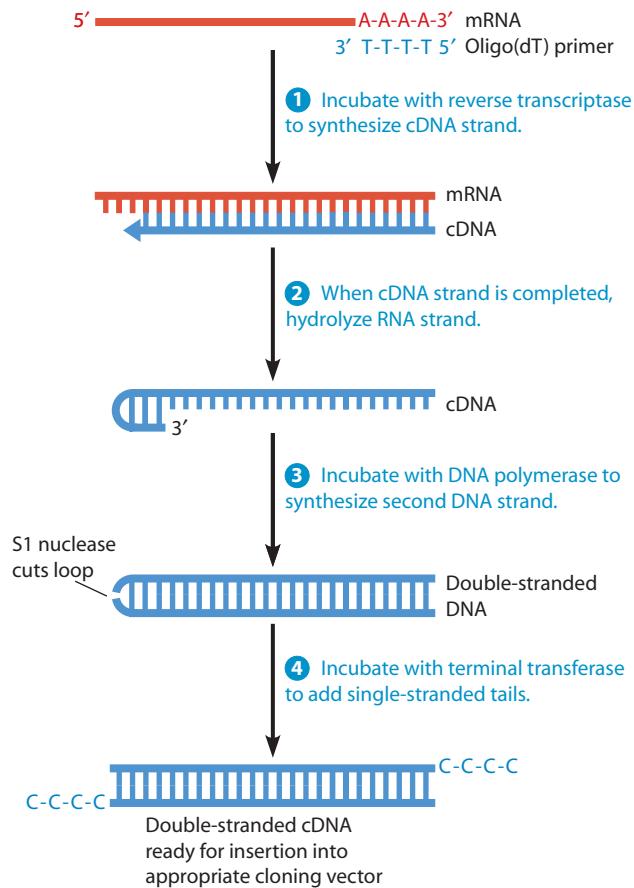

FIGURE 20-28 Preparation of Complementary DNA (cDNA) for Cloning. ① Messenger RNA is incubated with reverse transcriptase to create a complementary DNA (cDNA) strand. Oligo(dT), a short chain of thymine deoxynucleotides, can be used as a primer because eukaryotic mRNA always has a stretch of adenine nucleotides at its 3' end. ② The resulting mRNA-cDNA hybrid is treated with alkali or an enzyme to hydrolyze the RNA, leaving the single-stranded cDNA. ③ DNA polymerase can now synthesize the complementary DNA strand, using the looped-around 3' end of the first DNA strand as a primer. An enzyme called S1 nuclease is then employed to cleave the loop. ④ For efficient insertion into a cloning vector, the double-stranded DNA must have single-stranded tails that are complementary to those of the vector. These can be added by incubating with terminal transferase, an enzyme that adds nucleotides to DNA ends. For example, if short stretches of cytosine (C) nucleotides are added to the cDNA and short stretches of guanine (G) nucleotides are added to a linearized cloning vector, recombinant molecules can be generated by allowing the single-stranded C tails in the cDNA to hybridize to the single-stranded G tails in the vector. (As an alternative to step ④, short synthetic “linker” molecules containing a variety of restriction sites can be ligated to the ends of both the cDNA and a blunt-ended cloning vector. The linkers are then cleaved with a restriction enzyme that generates sticky ends.)

produce a foreign protein encoded by a cloned gene and will fail to detect cloned genes that are not expressed in the host cell. However, special *expression vectors* can be used to increase the likelihood that bacteria will transcribe eukaryotic genes properly and in large amounts. Expression vectors contain special DNA sequences that signal the bacterial cell to perform these processes.

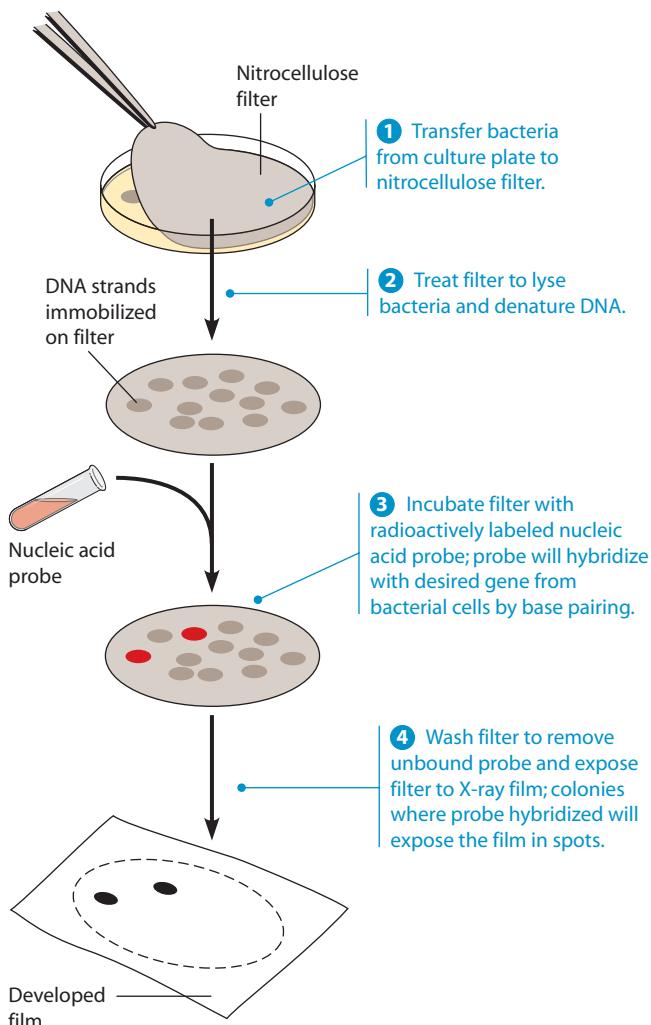

FIGURE 20-29 **Colony Hybridization Technique.** This technique is used to screen bacterial colonies for the presence of DNA that is complementary in sequence to a nucleic acid probe. Bacterial colonies are transferred from the surface of an agar culture plate onto a nitrocellulose filter, which is treated with detergent to lyse the bacteria and alkali (NaOH) to denature their DNA. The filters are then incubated with molecules of the nucleic acid probe—radioactively labeled, single-stranded DNA or RNA—which attach by base pairing to any complementary DNA present on the filter. The filter is rinsed and subjected to autoradiography, which makes visible those colonies containing DNA that is complementary in sequence to the probe.

Large DNA Segments Can Be Cloned in YACs and BACs

DNA cloning using the vectors mentioned so far is a powerful methodology, but it has an important limitation: The foreign DNA fragments cloned in these vectors cannot exceed about 30,000 base pairs (bp) in length. Eukaryotic genes are often larger than this and hence cannot be cloned in an intact form using such vectors. For genome-mapping projects, the availability of clones containing even longer stretches of DNA is desirable because the more DNA per clone, the fewer the number of clones needed to cover the entire genome.

One of the first breakthroughs in cloning longer DNA segments was the development of a vector called a **yeast artificial chromosome** (YAC). A YAC is a “minimalist” eukaryotic chromosome—it contains all the DNA sequences needed for normal chromosome replication and segregation to daughter cells—and very little else. As you might guess from your knowledge of chromosome replication and segregation (see Chapter 19), a eukaryotic chromosome requires three kinds of DNA sequences: (1) an origin of DNA replication; (2) two telomeres to allow periodic extension of the shrinking ends by telomerase; and (3) a centromere to ensure proper attachment, via a kinetochore, to spindle microtubules during cell division. If yeast versions of these three kinds of DNA sequences are combined with a segment of foreign DNA, the resulting YAC will replicate in yeast and segregate into daughter cells with each round of cell division, just like a natural chromosome. And under appropriate conditions, its foreign genes may be expressed.

Figure 20-30 outlines the construction of a typical YAC. In addition to a replication origin (ORI), centromere sequence (CEN), and two telomeres (TEL), the vector illustrated carries two genes that function as selectable markers as well as three restriction sites. In cloning experiments, the vector and foreign DNAs are cleaved with the appropriate restriction enzymes, mixed together, and joined by DNA ligase. The resulting products, which include a variety of YACs carrying different fragments of foreign DNA, are introduced into yeast cells whose cell walls have been removed. The presence of two selectable markers makes it easy to select for yeast cells containing YACs with both chromosomal “arms.” The diagram in the figure is not to scale: The YAC vector alone is only about 10,000 bp, but the inserted foreign DNA usually ranges from 300,000 to 1.5 million bp in length. In fact, YACs must carry at least 50,000 bp to be reliably replicated and segregated.

Another type of vector used for cloning large DNA fragments is the **bacterial artificial chromosome** (BAC), a derivative of the *F factor* plasmid that some bacteria employ for transferring DNA between cells during bacterial conjugation (page 621). BAC vectors are modified forms of the *F factor* plasmid that can hold up to 350,000 bp of foreign DNA and have all the components required for a bacterial cloning vector, such as replication origins, antibiotic resistance genes, and insertion sites for foreign DNA. One type of BAC facilitates the process of screening for recombinant clones by including the *SacB* gene, which converts sucrose (table sugar) into a substance that is toxic to bacteria. A *Bam*HI cloning site is located within the *SacB* gene, so when foreign DNA is inserted into the BAC vector at this site, the *SacB* gene is disrupted. When such a BAC vector is introduced into bacterial cells grown in the presence of sucrose, only cells containing BAC vector molecules with a foreign DNA insert will be able to grow. Those cells receiving BAC vector with no DNA insert will fail to grow because the *SacB* gene remains intact and produces a toxic substance from sucrose.

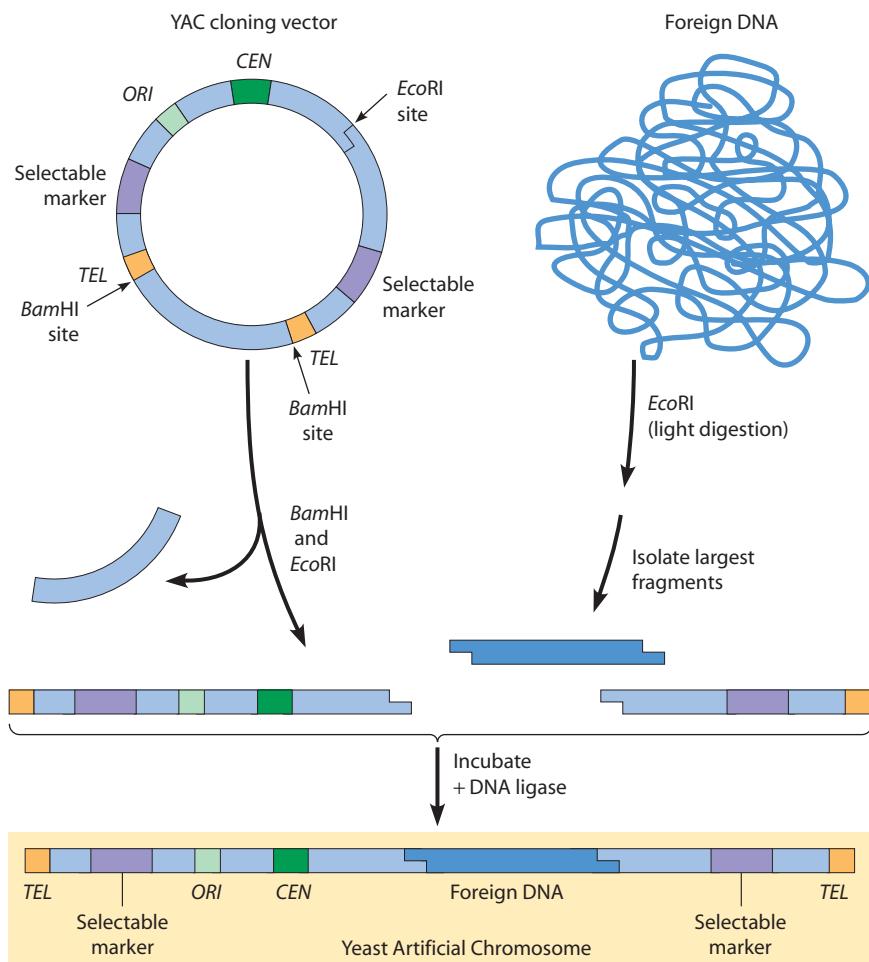

FIGURE 20-30 Construction of a Yeast Artificial Chromosome (YAC). The YAC cloning vector is a circular DNA molecule with nucleotide sequences specifying an origin of DNA replication (*ORI*), a centromere (*CEN*), two telomeres (*TEL*), and two selectable markers. It has two recognition sequences for the restriction enzyme *Bam*HI and one for *Eco*RI. Digestion of the YAC vector with both restriction enzymes produces two linear DNA fragments that together contain all the essential sequences, as well as the fragment that connected the *Bam*HI sites, which is of no further use. The fragment mixture is incubated with fragments from light digestion of foreign DNA with *Eco*RI (light digestion generates large DNA fragments because not all the restriction sites are cut), and the resulting recombinant strands are sealed with DNA ligase. Among the products will be YACs carrying foreign DNA, as shown at the bottom of the figure. After yeast cells are transformed with the products of the procedure, the colonies of cells that have received complete YACs can be identified by the properties conferred by the two selectable markers.

PCR Is Widely Used to Clone Genes from Sequenced Genomes

For many years the cloning procedures described in the preceding sections were the primary means for producing cloned genes and providing longer stretches of DNA for genome sequencing. But now that scientists have determined the genome sequences of hundreds of bacteria and several dozen eukaryotic organisms, including humans, the simpler and quicker *polymerase chain reaction* (PCR) method is more commonly used to clone genes from cDNA or genomic DNA libraries. As described in Box 19A on page 560, the PCR method simply requires that you know part of the base sequence of the gene you wish to amplify. The next step is to synthesize short, single-stranded DNA primers that are complementary to sequences located at opposite ends of the gene; these primers are then used to target the intervening DNA for amplification.

In addition to its speed and simplicity, another advantage of PCR is that it allows genes to be modified by adding desired base sequences to the primers being used. One such modification, called *epitope tagging*, involves adding a short base sequence coding for a stretch of amino acids that is recognized by a commercially available antibody. When a cloned gene produced in this way is expressed

inside cells, the protein produced by the gene contains the additional stretch of amino acids and can therefore be visualized and tracked using the antibody attached to a fluorescent dye. Another type of modification, called *polyhistidine tagging* (or *His* tagging, for short), introduces a short base sequence coding for the amino acid histidine repeated six times in succession. The presence of six adjacent histidines in a protein creates a structure that selectively binds to nickel ions, allowing the protein to be rapidly purified based on its affinity for nickel.

Genetic Engineering

Recombinant DNA technology has had an enormous impact on the field of cell biology, leading to many new insights into the organization, behavior, and regulation of genes and their protein products. Many of these discoveries would have been virtually inconceivable without such powerful techniques for isolating gene sequences. The rapid advances in our ability to manipulate genes have also opened up the field of **genetic engineering**, which involves the application of recombinant DNA technology to practical problems, primarily in medicine and agriculture. In concluding the chapter, we will briefly examine some of the areas where these practical

benefits of recombinant DNA technology are beginning to be seen.

Genetic Engineering Can Produce Valuable Proteins That Are Otherwise Difficult to Obtain

One practical benefit to emerge from recombinant DNA technology is the ability to clone genes coding for medically useful proteins that are difficult to obtain by conventional means. Among the first proteins to be produced by genetic engineering was human *insulin*, which is required by roughly 2 million diabetics in the United States to treat their disease. Supplies of insulin purified from human blood or pancreatic tissue are extremely scarce; thus, for many years diabetic patients were treated with insulin obtained from pigs and cattle, which can cause toxic reactions. Now there are several ways of producing human insulin from genetically engineered bacteria containing the human insulin gene. As a result, diabetics can be treated with insulin molecules that are identical to the insulin produced by the human pancreas.

Like insulin, a variety of other medically important proteins that were once difficult to obtain in adequate amounts are now produced using recombinant DNA technology. Included in this category are the *blood-clotting factors* needed for the treatment of hemophilia, *growth hormone* utilized for treating pituitary dwarfism, *tissue plasminogen activator (TPA)* used for dissolving blood clots in heart attack patients, *erythropoietin* employed for stimulating the production of red blood cells in patients with anemia, and *tumor necrosis factor, interferon*, and *interleukin*, which are used in treating certain kinds of cancer. Traditional methods for isolating and purifying such proteins from natural sources are quite cumbersome and tend to yield only tiny amounts of protein. Thus, before the advent of recombinant DNA technology, the supplies of such substances were inadequate and their cost was extremely high. But now that the genes for these proteins have been cloned in bacteria and yeast, large quantities of protein can be produced in the laboratory at reasonable cost.

The Ti Plasmid Is a Useful Vector for Introducing Foreign Genes into Plants

Recombinant DNA technology is also being used to modify agriculturally important plants by inserting genes designed to introduce traits such as resistance to insects, herbicides, or viral disease, or to improve a plant's nitrogen-fixing ability, photosynthetic efficiency, nutritional value, or ability to grow under adverse conditions. Cloned genes are transferred into plants by inserting them first into the **Ti plasmid**, a naturally occurring DNA molecule carried by the bacterium *Agrobacterium tumefaciens*. In nature, infection of plant cells by this bacterium leads to insertion of a small part of the plasmid DNA, called the *T DNA region*, into the plant cell chromosomal DNA; expression of the inserted DNA then triggers the formation

of an uncontrolled growth of tissue called a *crown gall tumor*. In the laboratory, the DNA sequences that trigger tumor formation can be removed from the Ti plasmid without stopping the transfer of DNA from the plasmid to the host cell chromosome. Inserting genes of interest into such modified plasmids produces vectors that can transfer foreign genes into plant cells.

The general approach for transferring genes into plants using these plasmids is summarized in **Figure 20-3 I**. The desired foreign gene is first inserted into the T DNA region of the isolated plasmid using standard recombinant DNA techniques, the plasmid is put back into the *Agrobacterium* bacteria, and these genetically engineered bacteria are then used to infect plant cells growing in culture. When the recombinant plasmid enters the plant cell, its T DNA becomes stably integrated into the plant genome and is passed on to both daughter cells at every cell division. Such cells are subsequently used to regenerate plants that contain the recombinant T DNA—and therefore the desired foreign gene—in all of their cells. The foreign gene will now be inherited by progeny plants just like any other gene. Such plants are said to be **transgenic**, a general term that refers to any type of organism, plant or animal, that carries one or more genes from another organism in all of its cells, including its reproductive cells. Transgenic plants are also commonly referred to as *GM (genetically modified)* plants.

Genetic Modification Can Improve the Traits of Food Crops

The ability to insert new genes into plants using the Ti plasmid has allowed scientists to create GM crops exhibiting a variety of new traits. For example, plants can be made more resistant to insect damage by introducing a gene cloned from the soil bacterium *Bacillus thuringiensis (Bt)*. This *Bt* gene codes for a protein that is toxic to certain insects—especially caterpillars and beetles that cause crop damage by chewing on plant leaves. Putting the *Bt* gene into plants such as cotton and corn has permitted farmers to limit their use of more hazardous pesticides for controlling insects, leading to improved crop yields and a significant return of wildlife to crop fields. When several million cotton farmers in China switched to growing such an insect-resistant strain of GM cotton, it allowed them to slash pesticide use up to 70%. This success was accompanied by increased cotton yields and a significant drop in the death toll among farmworkers from pesticide poisoning. Similar economic and health benefits have been reported by some farmers growing insect-resistant strains of GM rice. Crops engineered to resist weed-killing herbicides likewise require fewer toxic chemicals and exhibit higher yields.

Another goal of genetic modification is to improve the nutritional value of food. Consider rice, for example, which is the most common food source in the world. More than 3 billion people currently eat rice daily, and by the year 2020 at least half the world's population is

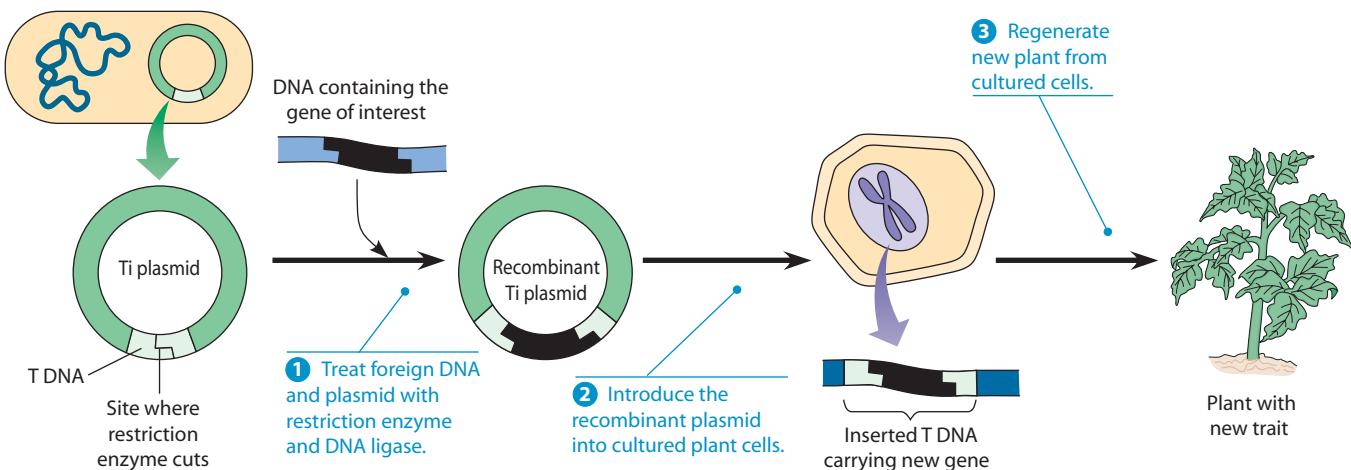

FIGURE 20-3 I Using the Ti Plasmid to Transfer Genes into Plants. Most genetic engineering in plants uses the Ti plasmid as a vector. A DNA fragment containing a gene of interest is inserted into a restriction site located in the T DNA region of the plasmid. The recombinant plasmid is then introduced into plant cells, which regenerate a new plant containing the recombinant T DNA stably incorporated into the genome of every cell.

expected to depend on rice for food. Such dependence will be especially prevalent in poor, developing countries, where much of the population also suffers from deficiencies in essential nutrients and vitamins. To illustrate how genetic engineering might be used to improve the situation, the genes required for the synthesis of β -carotene, a precursor of vitamin A, were genetically engineered into rice in 2001, and the β -carotene content of such rice was increased more than 20-fold a few years later. The resulting product, called “golden rice” because of the color imparted by β -carotene, has the potential to help alleviate a global vitamin A deficiency that now causes blindness and disease in millions of children.

Concerns Have Been Raised About the Safety and Environmental Risks of GM Crops

As the prevalence of GM crops has begun to increase, some people have expressed concerns about the possible risks associated with this technology, especially because it permits genes to cross species barriers that cannot be crossed by traditional breeding techniques. For consumers, the main focus has been on safety because it is well known that toxic and allergic reactions to things we eat can be serious and even life-threatening. Thus far, it seems clear that conventional foods already on the market, such as peanuts and Brazil nuts, pose greater allergy risks than have been demonstrated for any GM foods. Moreover, the same problem also arises when new crop strains are produced by conventional breeding techniques. In fact, conventional foods have already undergone massive changes in genetic makeup by traditional plant-breeding methods, and it can be argued that it is safer to insert carefully selected genes into plants one at a time, as is done in genetic engineering, than it is to alter thousands of genes

at a time, as is done with traditional crossbreeding of plants. When a single gene is inserted into a crop, the effects of that single gene and its protein product can be more easily assessed for safety hazards.

The possibility that GM crops may pose environmental risks has also raised concerns. In a 1999 laboratory experiment, scientists reported that monarch butterfly larvae died after being fed leaves dusted with pollen from GM corn containing the *Bt* gene. This observation led to fears that the *Bt* toxin produced by GM plants can harm friendly insects. However, the lab bench is not the farm field, and the initial studies were carried out under artificial laboratory conditions in which butterfly larvae consumed far higher doses of *Bt* toxin than they would in the real world. Subsequent data collected from farm fields containing GM crops suggest that the amount of *Bt* corn pollen encountered under real-life conditions does not pose a significant hazard to monarch butterflies.

Despite legitimate concerns about potential hazards, the GM experience has thus far revealed little evidence of significant risks to either human health or the environment. Of course, no new technology is entirely without risk, and so the safety and environmental impact of GM crops must be continually assessed. At the same time, GM crops have allowed reductions in pesticide use, and they could make a unique contribution to the fight against hunger and disease in developing countries.

Animals Can Be Genetically Modified by Adding or Knocking Out Specific Genetic Elements

Just as we have seen with plants, it is possible to genetically engineer animals. The techniques by which engineered DNA is introduced varies among different animals but often includes microinjection of engineered DNA into an

adult animal or embryo. One of the first successful demonstrations of the feasibility of gene transplantation in animals was reported by Richard Palmiter and Ralph Brinster, who transferred the gene for growth hormone into a fertilized mouse egg, thereby creating a transgenic mouse that carries a gene from another organism in its cells (**Box 20A**). Transgenic animals have been extremely useful in several ways. In the laboratory, genetic engineering has allowed the study of gene expression and the function of specific genes in living animals. For example, when proteins are engineered so that they are fused with the green fluorescent protein (GFP), their location can be followed dynamically in living cells (see page 7 and the Appendix, page A-10).

In addition to their usefulness in basic research, there are practical applications of genetic engineering in animals. One goal of such technology is to produce farm animals that can synthesize medically important human proteins (e.g., in the milk of female mammals), which can then be easily purified. Another is the production of engineered livestock as a food source. Many of the same issues we considered regarding GM crops have also been raised concerning genetically modified animals grown for food.

While adding an engineered piece of DNA to an animal using transgenic technology can be very useful, it is often even more useful to *remove* a gene of interest. One way in which this can be done exploits the ability of homologous recombination to transfer base sequences between related DNA molecules. For example, scientists can now inactivate or “knock out” individually targeted genes by inducing recombination with related pieces of nonfunctional DNA (**Figure 20-32**). This strategy has been used to create hundreds of unique strains of **knockout mice**, each defective in a single gene, and efforts are under way to create knockout strains for every one of the mouse’s roughly 25,000 genes. In 2007 Mario Capecchi, Oliver Smithies, and Martin Evans were awarded a Nobel Prize in recognition of their pioneering efforts in making the creation of knockout mice possible.

The first step in producing a knockout mouse is to synthesize an artificial DNA that is similar in base sequence to the target gene and its flanking sequences but with two important changes (Figure 20-32, ①). First, an antibiotic resistance gene (e.g., that confers resistance to neomycin) is inserted into the middle of the target gene sequence. This simultaneously renders the engineered copy of the gene nonfunctional and also allows cells that carry the DNA to survive in the presence of antibiotic. Second, DNA encoding a viral enzyme, *thymidine kinase*, is attached to the end of the DNA. If this DNA is present in a cell, it will die in the presence of an antiviral drug (e.g., ganciclovir). Next this DNA is introduced into mouse *embryonic stem cells* (ES cells), which are cells that can differentiate into all the cell types of an adult mouse (②). In very rare cases, the DNA enters the nucleus and, using mechanisms similar to those involved in meiosis, the artificial DNA aligns with complementary sequences flanking the targeted gene. Homologous recombination then replaces the targeted gene with the new,

nonfunctional copy. Only if homologous recombination occurs is the thymidine kinase gene removed from the engineered DNA and degraded by nucleases in the ES cell. In this case, the cell will survive in the presence of antibiotic (③), but it will *not* be sensitive to the antiviral drug (④). Cells identified using this double drug selection are then introduced into mouse embryos, which develop into adult mice containing tissues where the gene of interest has been inactivated (⑤). Crossbreeding such animals eventually yields strains of pure knockout mice in which both copies of the target gene (one on each chromosome) are knocked out in all tissues (⑥). By allowing scientists to study what happens when specific genes are disrupted, knockout mice have shed light on the roles played by individual genes in numerous

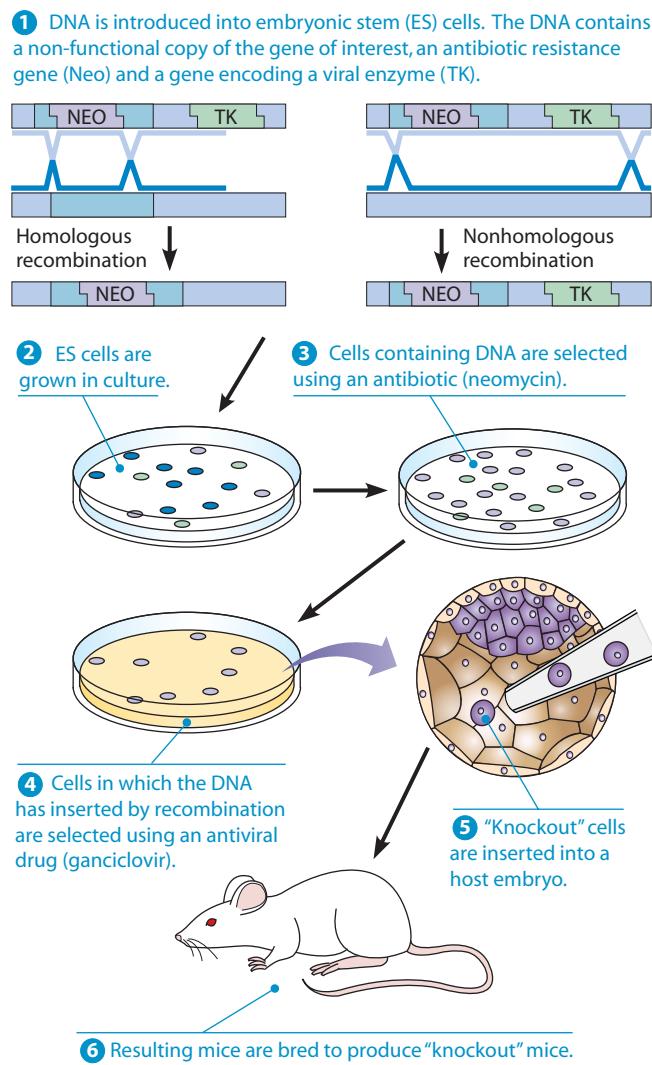

FIGURE 20-32 Making “Knockout” Mice by Homologous Recombination. The production of “knockout” mice involves

① the construction of a DNA targeting vector that contains a non-functional copy of the gene of interest, which ② is inserted into embryonic stem cells (ES cells). The ES cells are screened using two different drugs to select for rare cells in which a recombination event has occurred (③, ④). These “knockout” cells are ⑤ inserted into a host embryo, and ⑥ subsequent breeding produces mice carrying the engineered mutation.

Making “Designer” Mice

A DNA fragment containing the gene of rat growth hormone was microinjected into the pronuclei of fertilized mouse eggs. Of 21 mice that developed from these eggs, seven carried the gene and six of these grew significantly larger than their littermates. (Palmiter et al., 1982, p. 611)

With these words, a team of investigators led by Richard Palmiter and Ralph Brinster reported how a genetic trait can be introduced experimentally into mice without going through the usual procedure of breeding—that is, sexual reproduction followed by the selection of desired traits. The researchers injected rat growth hormone genes into fertilized mouse eggs, and from one of these eggs a “supermouse” developed weighing almost twice as much as its littermates (**Figure 20A-1**). The accomplishment was heralded as a significant breakthrough because it proved the feasibility of applying genetic engineering to animals, with all the scientific and practical consequences such engineering is likely to have.

Palmiter, Brinster, and their colleagues began by isolating the gene for growth hormone (GH) from a library of rat DNA, using techniques similar to those described in this chapter. The cloned GH gene, with its regulatory region deleted, was then fused to the regulatory portion of a mouse gene—the gene that codes for *metallothionein* (MT). MT is a small, metal-binding protein that is normally present in most mouse tissues and appears to be involved in regulating the level of zinc in the animal. The advantage of fusing the *MT* gene to the *GH* gene was that the expression of the *MT* gene could then be specifically induced (turned on) by zinc.

About 600 copies of the engineered DNA fragment were microinjected into fertilized mouse eggs, in a volume of about 2 picoliters (0.000002 μL). The DNA was injected into the male pronucleus, the haploid sperm nucleus that has not yet fused with the haploid egg nucleus (**Figure 20A-2**). From the 170 fertilized eggs

FIGURE 20A-1 Genetic Engineering in Mice. “Supermouse” (on the left) is significantly larger than its littermate because it was engineered to carry, and express at high levels, the gene for rat growth hormone.

that were injected and implanted back into the reproductive tracts of foster mothers, 21 animals developed. Seven of them turned out to be transgenic mice with *MT-GH* genes present in their cells. In at least one case, a transgenic mouse transmitted the *MT-GH* gene faithfully to about half of its offspring, suggesting that the gene had become stably integrated into one of its chromosomes.

Because the *GH* gene had been linked to an *MT* gene regulatory region, it was predicted that the hybrid gene could be turned on by giving the mice zinc in their drinking water. The most dramatic evidence for expression of the rat *GH* genes was that the transgenic mice grew faster and weighed about twice as much as normal mice. During the period of maximum sensitivity to growth hormone (3 weeks to 3 months of age), the transgenic animals grew three to four times as fast as their normal littermates.

This dramatic experiment proved that it is possible to introduce cloned genes into the cells of higher organisms and that such genes can become stably integrated into the genome, where they are expressed and passed on to offspring. In the years since supermouse’s creation, rapid progress has been made in most of these areas. Supermouse, it seems, was just the beginning.

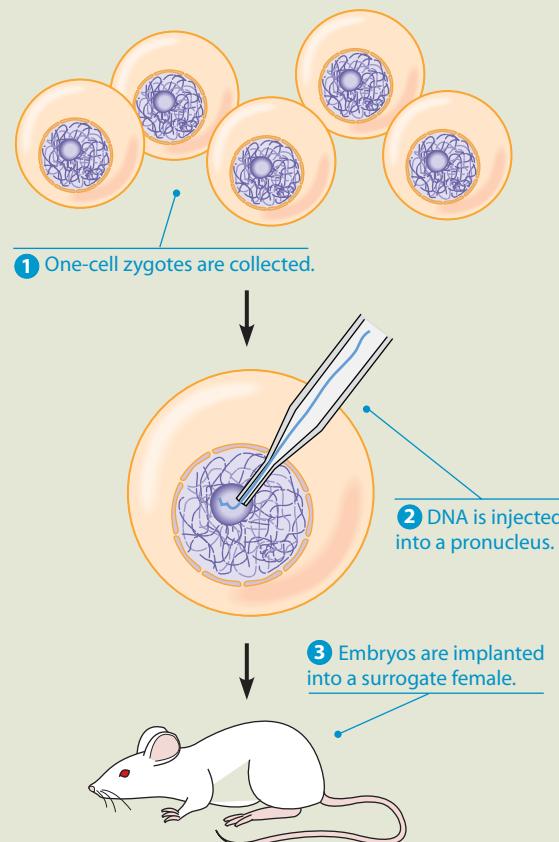

FIGURE 20A-2 Making Transgenic Mice. Fertilized mouse eggs (one-cell zygotes) are injected with DNA, typically into a pronucleus (either the nucleus derived from the sperm or egg). The injected zygotes are transferred into a surrogate mother during subsequent gestation.

human conditions, including cancer, obesity, heart disease, diabetes, arthritis, and aging.

Knockout technology has now been extended to other mammals besides mice. One use of this technology relates to *xenotransplantation*, the transplantation of tissues from one species to another. Pigs have been a major focus of such research, which aims to provide a source of temporary organs for human patients awaiting transplants. To avoid immune rejection, pigs have been produced that lack a key enzyme called α -1,3-galactosyltransferase, which normally catalyzes the addition of sugar residues to cell surfaces in pigs that contributes to the immune response.

Gene Therapies Are Being Developed for the Treatment of Human Diseases

Humans suffer from many diseases that might conceivably be cured by transplanting normal, functional copies of genes into people who possess defective, disease-causing genes. The success of transgenic and knockout mice, along with similar experiments, raised the question of whether gene transplantation techniques might eventually be applied to the problem of repairing defective genes in humans. Obvious candidates for such an approach, called *gene therapy*, include the inherited genetic diseases cystic fibrosis, hemophilia, hypercholesterolemia, hemoglobin disorders, muscular dystrophy, lysosomal storage diseases, and an immune disorder called *severe combined immunodeficiency (SCID)*.

The first person to be treated using gene therapy was a 4-year-old girl with a type of SCID caused by a defect in the gene coding for *adenosine deaminase (ADA)*. Loss of ADA activity leads to an inability to produce sufficient numbers of immune cells called *T lymphocytes*. As a result, the girl suffered from frequent and potentially life-threatening infections. In 1990, she underwent a series of treatments in which a normal copy of the cloned ADA gene was inserted into a virus, the virus was used to infect T lymphocytes obtained from the girl's blood, and the lymphocytes were then injected back into her bloodstream. The result was a significant improvement in her immune function, although the effect diminished over time, and the treatment did not seem to help most SCID patients.

In the years since these pioneering studies, considerable progress has been made in developing better techniques for delivering cloned genes into target cells and getting the genes to function properly. In the year 2000, French scientists finally reported what seemed to be a successful treatment for children with SCID (in this case, an especially severe form of SCID caused by a defective receptor gene rather than a defective ADA gene). By using a virus that was more efficient at transferring cloned genes and by devising better conditions for culturing cells during the gene transfer process, these scientists were able to restore normal levels of immune function to the children they treated. In fact, the outcome was so dramatic that, for the first time, the treated children were able to

leave the protective isolation “bubble” that had been used in the hospital to shield them from infections.

It was therefore a great disappointment when three of the ten children treated in the initial study developed leukemia a few years later. Examination of the leukemia cells revealed that the virus used to deliver the corrective gene sometimes inserts itself next to a normal gene that, when expressed abnormally, can cause cancer to arise. (In Chapter 24 we will describe exactly how such an event, called *insertional mutagenesis*, can initiate cancer development.) We should not, of course, lose sight of the fact that these studies also provided one of the first hopeful signs that gene therapy can cure a life-threatening genetic disease. But the associated cancer risks must be better understood before such treatments will become practical.

One tactic for addressing the problem of cancer risk is to change the type of virus being used to ferry genes into target cells. The SCID studies employed *retroviruses* (page 648), which randomly insert themselves into chromosomal DNA and possess sequences that inadvertently activate adjacent host genes. Another type of virus being investigated as a vehicle for gene therapy, called *adeno-associated virus (AAV)*, is less likely to insert directly into chromosomal DNA and less likely to inadvertently activate host genes when it does become inserted. Some encouraging results using this virus have been obtained in patients with *hemophilia*, an inherited disease characterized by life-threatening episodes of uncontrolled bleeding. Hemophilia is caused by genetic defects in proteins called *blood-clotting factors*, which participate in the formation of blood clots. In gene therapy trials, hemophilia patients have been injected with AAV containing a gene coding for the blood-clotting factor they require. When the patients' liver cells were infected, they produced enough blood-clotting factor to alleviate the uncontrolled bleeding normally associated with the disease. Although this “cure” lasted only about eight weeks because an immune response destroyed the modified liver cells, the immune reaction targeted a component of AAV that is only transiently present. It is therefore hoped that short-term administration of immunosuppressive drugs may help provide a more permanent cure.

In the years since the enormous potential of gene therapy was first publicized in the early 1980s, the field has been criticized for promising too much and delivering too little. But most new technologies take time to be perfected and encounter disappointments along the way, and gene therapy is no exception. Despite the setbacks, it appears likely that using normal genes to treat genetic diseases is a reachable goal that may one day become common practice, at least for a few genetic diseases that involve single gene defects. Of course, the ability to alter people's genes raises important ethical, safety, and legal concerns. The ultimate question of how society will control our growing power to change the human genome is an issue that will need to be thoroughly discussed not just by scientists and physicians, but by society as a whole.

SUMMARY OF KEY POINTS

Sexual Reproduction

- Asexual reproduction is based on mitotic cell division and produces offspring that are genetically identical (or nearly so) to the single parent. In contrast, sexual reproduction involves two parents and leads to a mixture of parental traits in the offspring.
- Sexual reproduction allows populations to adapt to environmental changes, enables desirable mutations to be combined in a single individual, and promotes genetic flexibility by maintaining a diploid genome.

Meiosis

- The life cycle of sexually reproducing eukaryotes includes both haploid and diploid phases. Haploid gametes are generated by meiosis and fuse at fertilization to restore the diploid chromosome number.
- Meiosis consists of two successive cell divisions without an intervening duplication of chromosomes. During the first meiotic division, homologous chromosomes separate and segregate into the two daughter cells. During the second meiotic division, sister chromatids separate and four haploid daughter cells are produced.
- In addition to reducing the chromosome number from diploid to haploid, meiosis differs from mitosis in that homologous chromosomes synapse during prophase of the first meiotic division, thereby allowing crossing over and genetic recombination between nonsister chromatids.

Genetic Variability: Segregation and Assortment of Alleles

- Mendel's laws of inheritance describe the genetic consequences of chromosome behavior during meiosis, even though chromosomes had not yet been discovered at the time of Mendel's experiments.
- Mendel's law of segregation states that the two (maternal and paternal) alleles of a gene are distinct entities that separate into different gametes during meiosis. The law of independent assortment states that the alleles of each gene separate independently of the alleles of other genes (now known to apply only to genes located on different chromosomes or very far apart on the same chromosome).

Genetic Variability: Recombination and Crossing Over

- The genetic variability among an organism's gametes arises partly from the independent assortment of chromosomes

during anaphase I and partly from genetic recombination during prophase I.

- The frequency of recombination between genes on the same chromosome is a measure of the distance between the two genes and can therefore be used to map their chromosomal locations.

Genetic Recombination in Bacteria and Viruses

- Besides occurring during meiosis, homologous recombination also takes place in viruses (during co-infection) and when DNA is transferred into bacterial cells by transformation, transduction, or conjugation.

Molecular Mechanism of Homologous Recombination

- Recombination involves breakage and exchange between DNA molecules exhibiting extensive sequence homology.
- Recombination is sometimes accompanied by gene conversion or the formation of DNA molecules whose two strands are not completely complementary to one another. These phenomena can be explained by recombination models involving the formation of Holliday junctions, which are regions of single-strand exchange between double-stranded DNA molecules.

Recombinant DNA Technology and Gene Cloning

- Recombinant DNA technology makes it possible to combine DNA from any two (or more) sources into a single DNA molecule.
- Combining a gene of interest with a plasmid or phage cloning vector allows the gene to be cloned (amplified) in bacterial cells. This approach, as well as the polymerase chain reaction (PCR), permits large quantities of specific gene sequences and their protein products to be prepared for research and practical purposes.

Genetic Engineering

- Recombinant DNA technology has many practical applications in medicine and agriculture. These include the ability to produce valuable proteins that are otherwise difficult to obtain and the ability to improve the traits of food crops, such as enhanced resistance to insects, herbicides, or disease. Attempts are also underway to develop gene therapies for treating human diseases.

MAKING CONNECTIONS

In this chapter, you have learned how meiosis allows the genetic information in replicated DNA molecules to be recombined during the formation of sperm and egg cells, thereby making sexual reproduction possible. Thus, in contrast to mitotic cell division (described in Chapter 19), which creates cells that are virtually identical in their DNA makeup, meiosis creates cells containing new combinations of DNA sequences. Perhaps you now may be asking: How does DNA, which has been replicated and distributed to daughter cells during mitosis or meiosis,

actually carry out its role as the source of the genetic information that specifies cellular structure and guides cellular behavior? In Chapter 21, we will begin to answer this question by exploring how DNA uses a genetic code to specify the amino acid sequence of protein molecules. The role of RNA molecules in this process will be covered in both Chapters 21 and 22. Finally, Chapter 23 examines the mechanisms used by cells for controlling expression of the genetic information stored in their DNA molecules.

PROBLEM SET

More challenging problems are marked with a •.

20-1 The Truth About Sex. For each of the following statements, indicate with an S if it is true of sexual reproduction, with an A if it is true of asexual reproduction, with a B if it is true of both, or with an N if it is true of neither.

- (a) Traits from two different parents can be combined in a single offspring.
- (b) Each generation of offspring is virtually identical to the previous generation.
- (c) Mutations are propagated to the next generation.
- (d) Some offspring in every generation will be less suited for survival than the parents, but others may be better suited.
- (e) Mitosis is involved in the life cycle.

20-2 Ordering the Phases of Meiosis. Drawings of several phases of meiosis in an organism, labeled A through F, are shown in **Figure 20-33**.

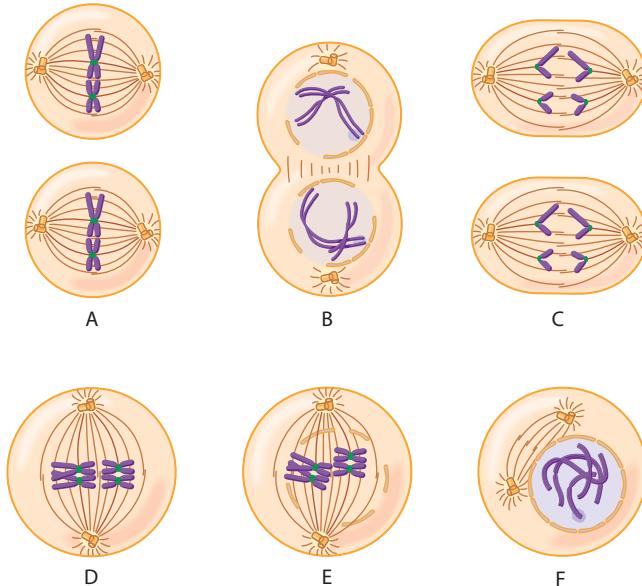

FIGURE 20-33 Six Phases of Meiosis to Be Ordered and Identified. See Problem 20-2.

- (a) What is the diploid chromosome number in this species?
- (b) Place the six phases in chronological order, and name each one.
- (c) Between which two phases do homologous centromeres separate?
- (d) Between which two phases does recombination occur?

20-3 Telling Them Apart. Briefly describe how you might distinguish between each of the following pairs of phases in the same organism:

- (a) Metaphase of mitosis and metaphase I of meiosis.
- (b) Metaphase of mitosis and metaphase II of meiosis.
- (c) Metaphase I and metaphase II of meiosis.
- (d) Telophase of mitosis and telophase II of meiosis.
- (e) Pachytene and diplotene stages of meiotic prophase I.

20-4 Your Centromere Is Showing. Suppose you have a diploid organism in which all the chromosomes contributed by the sperm have cytological markers on their centromeres that allow you to distinguish them visually from the chromosomes contributed by the egg.

- (a) Would you expect all the somatic cells (cells other than gametes) to have equal numbers of maternal and paternal centromeres in this organism? Explain.
- (b) Would you expect equal numbers of maternal and paternal centromeres in each gamete produced by that individual? Explain.

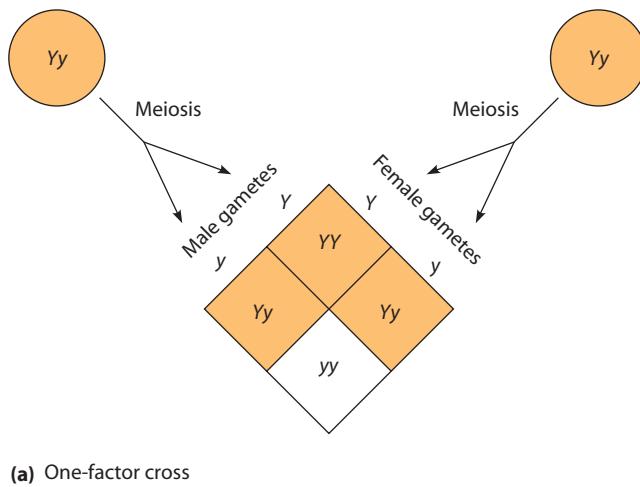

20-5 How Much DNA? Let X be the amount of DNA present in the gamete of an organism that has a diploid chromosome number of 4. Assuming all chromosomes to be of approximately the same size, how much DNA (X , $2X$, $1/2X$, and so on) would you expect in each of the following?

- (a) A zygote immediately after fertilization
- (b) A single sister chromatid
- (c) A daughter cell following mitosis
- (d) A single chromosome following mitosis
- (e) A nucleus in mitotic prophase
- (f) The cell during metaphase II of meiosis
- (g) One bivalent

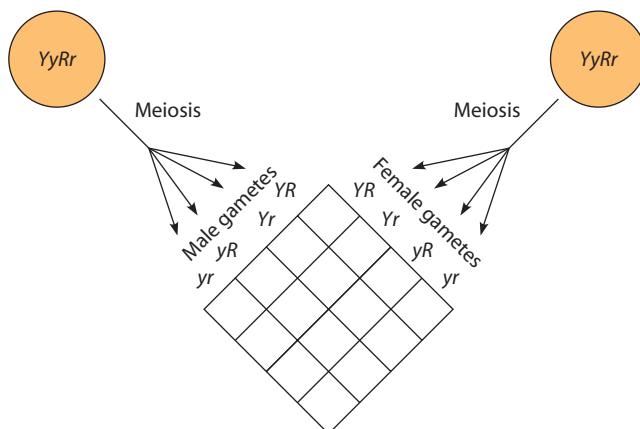

20-6 Meiotic Mistakes. Infants born with Patau syndrome have an extra copy of chromosome 13, which leads to developmental abnormalities such as cleft lip and palate, small eyes, and extra fingers and toes. Another type of genetic disorder, called Turner syndrome, results from the presence of only one sex chromosome—an X chromosome. Individuals born with one X chromosome are females exhibiting few noticeable defects until puberty, when they fail to develop normal breasts and internal sexual organs. Describe the meiotic events that could lead to the birth of an individual with either Patau syndrome or Turner syndrome.

20-7 Punnett Squares as Genetic Tools. A *Punnett square* is a diagram representing all possible outcomes of a genetic cross. The genotypes of all possible gametes from the male and female parents are arranged along two adjacent sides of a square, and each box in the matrix is then used to represent the genotype resulting from the union of the two gametes at the heads of the intersecting rows. By the law of independent assortment, all possible combinations are equally likely, so the frequency of a given genotype among the boxes represents the frequency of that genotype among the progeny of the genetic cross represented by the Punnett square.

Figure 20-34 shows the Punnett squares for two crosses of pea plants. The genetic characters involved are seed color

(a) One-factor cross

(b) Two-factor cross

FIGURE 20-34 Punnett Squares. See Problem 20-7.

(where Y is the allele for yellow seeds and y for green seeds) and seed shape (where R is the allele for round seeds and r for wrinkled seeds). The Punnett square in Figure 20-34a represents a one-factor cross between parent plants that are both heterozygous for seed color ($Yy \times Yy$). The Punnett square in Figure 20-34b is a two-factor cross between plants heterozygous for both seed color (Yy) and seed shape (Rr).

- (a) Using the Punnett square of Figure 20-34a, explain the 3:1 phenotypic ratio Mendel observed for the offspring of such a cross.
- (b) Explain why the Punnett square of Figure 20-34b is a 4×4 matrix with 16 genotypes. In general, what is the mathematical relationship between the number of heterozygous allelic pairs being considered and the number of different kinds of gametes?
- (c) How does the Punnett square of Figure 20-34b reflect Mendel's law of independent assortment?
- (d) Complete the Punnett square of Figure 20-34b by writing in each of the possible progeny genotypes. How many different genotypes will be found in the progeny? In what ratios?
- (e) For the case of Figure 20-34b, how many different phenotypes will be found in the progeny? In what ratios?

• **20-8 Genetic Mapping.** The following table provides data concerning the frequency with which four genes (w , x , y , and z) located on the same chromosome recombine with each other.

Genes	Recombination Frequency
w and x	25%
w and y	29%
w and z	17%
x and y	50%
x and z	9%

- (a) Construct a genetic map indicating the order in which these four genes occur and the number of map units that separate the genes from each other.
- (b) In constructing this map, you may have noticed that the map distances are not exactly additive. Can you provide an explanation for this apparent discrepancy?

• **20-9 Homologous Recombination.** Bacterial cells use at least three different pathways for carrying out genetic recombination. All three pathways require the RecA protein, but in each case, a different set of steps precedes the action of RecA in catalyzing strand invasion. One of these three pathways utilizes an enzyme complex called RecBCD, which binds to double-strand breaks in DNA and exhibits both helicase and single-strand nuclease activities.

- (a) Briefly describe a model showing how the RecBCD enzyme complex might set the stage for genetic recombination.
- (b) When bacterial cells are co-infected with two different strains of bacteriophage 1, genes located near certain regions of the phage DNA, called *CHI sites*, recombine at much higher frequencies than other genes do. However, in mutant bacteria lacking the RecBCD protein, genes located near CHI sites do not recombine any more frequently than do other genes. How can you modify your model to accommodate this additional information?

20-10 Gene Cloning and Recombination. Not only are the plasmid vectors used in molecular biology engineered, but the strains of *E. coli* used in cloning are as well.

- (a) Nearly all strains of *E. coli* used in DNA cloning carry mutations in the *recA* gene that result in loss of RecA activity. Why would a *recA* mutation make an *E. coli* cell a better host for propagating recombinant plasmid DNA?

- (b) Recall that restriction endonucleases are normally made by bacteria such as *E. coli* (Box 18B, page 520). *E. coli* used in molecular biology also carry mutations in restriction endonucleases. Why do you think these mutations would be useful?

Gene Expression: I. The Genetic Code and Transcription

So far, we have described DNA as the genetic material of cells and organisms. We have come to understand its structure, chemistry, and replication, as well as the way it is packaged into chromosomes and parceled out to daughter cells during mitotic and meiotic cell divisions. Now we are ready to explore how DNA is expressed—that is, how the coded information it contains is used to guide the production of RNA and protein molecules. Our discussion of this important subject is divided among three chapters. The present chapter deals with the nature of the genetic code and how information stored in DNA guides the synthesis of RNA molecules in the process we call transcription. Chapter 22 describes how RNA molecules are then used to guide the synthesis of specific proteins in the process known as translation. Finally, Chapter 23 elaborates on the various mechanisms used by cells to control transcription and translation, thereby leading to the regulation of gene expression. To put these topics in context, we start here with an overview of the roles played by DNA, RNA, and proteins in gene expression.

The Directional Flow of Genetic Information

As mentioned at the beginning of this series of chapters, the flow of genetic information in cells generally proceeds from DNA to RNA to protein (see Figure 18-1). DNA (more precisely, a segment of one DNA strand) first serves as a template for the synthesis of an RNA molecule, which in most cases then directs the synthesis of a particular protein. (In a few cases, the RNA is the final product of gene expression and functions as such within the cell.) The principle of directional information flow from DNA to RNA to protein is known as the *central dogma of molecular biology*, a term coined by Francis Crick soon after the

double-helical model of DNA was first proposed. This principle is summarized as follows:

Thus, the flow of genetic information involves replication of DNA, transcription of information carried by DNA into the form of RNA, and translation of this information from RNA into protein. The term **transcription** is used when referring to RNA synthesis using DNA as a template to emphasize that this phase of gene expression is simply a transfer of information from one nucleic acid to another, so the basic “language” remains the same. In contrast, protein synthesis is called **translation** because it involves a language change—from the nucleotide sequence of an RNA molecule to the amino acid sequence of a polypeptide chain.

RNA that is translated into protein is called **messenger RNA (mRNA)** because it carries a genetic message from DNA to the ribosomes, where protein synthesis actually takes place. In addition to mRNA, two other types of RNA are involved in protein synthesis: **ribosomal RNA (rRNA)** molecules, which are integral components of the ribosome, and **transfer RNA (tRNA)** molecules, which serve as intermediaries that translate the coded base sequence of messenger RNA and bring the appropriate amino acids to the ribosome. Note that ribosomal and transfer RNAs do not themselves code for proteins; genes coding for these two types of RNA are examples of genes whose final products are RNA molecules rather than protein chains. The involvement of all three major classes of RNA in the overall flow of information from DNA to protein is outlined in **Figure 21-1**.

In the years since it was first formulated by Crick, the central dogma has been refined in various ways. For example, many viruses with RNA genomes have been found to synthesize RNA molecules using RNA as a

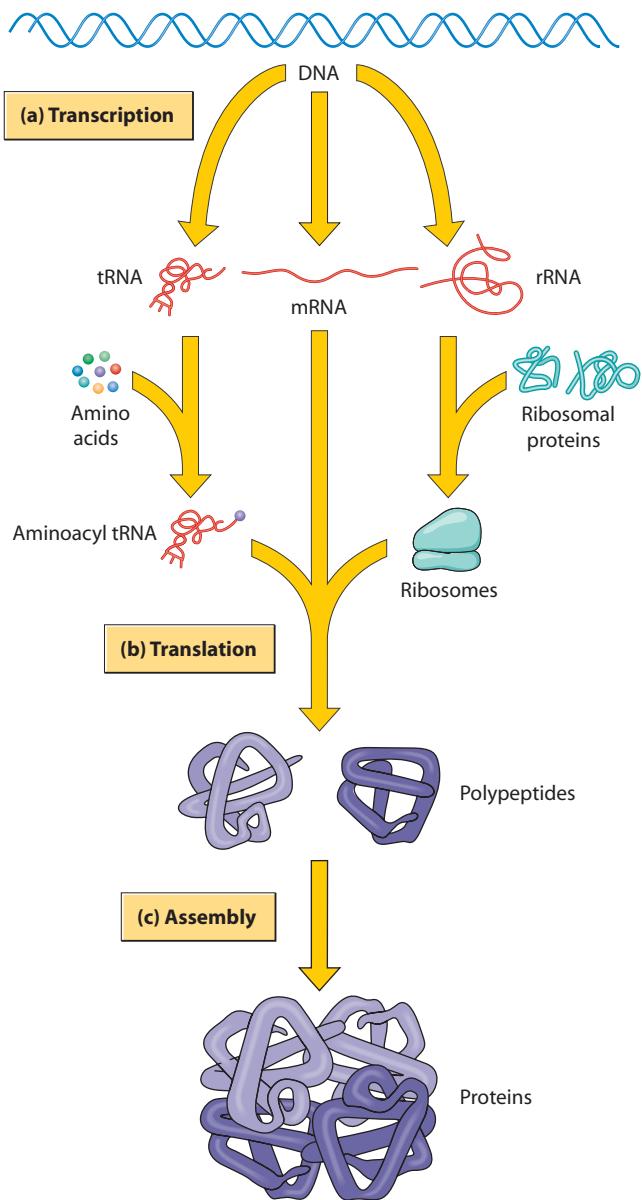

FIGURE 21-1 RNAs as Intermediates in the Flow of Genetic Information. All three major classes of RNA—tRNA, mRNA, and rRNA—are (a) synthesized by transcription of the appropriate DNA sequences (genes) and (b) involved in the subsequent process of translation (polypeptide synthesis). The appropriate amino acids are brought to the mRNA and ribosome by tRNA. A tRNA molecule carrying an amino acid is called an aminoacyl tRNA. Polypeptides then fold and (c) assemble into functional proteins. The specific polypeptides shown here are the globin chains of the protein hemoglobin. For simplicity, this figure omits many details that will be described in this chapter and the next.

template. Other RNA viruses, such as HIV, carry out *reverse transcription*, whereby the viral RNA is used as a template for DNA synthesis—a “backward” flow of genetic information. (Box 21A discusses these viruses and the role of reverse transcription in rearranging DNA sequences.) But despite these variations on the original model, the principle that information flows from DNA to RNA to protein remains the main operating principle by which all cells use their genetic information.

The Genetic Code

The essence of gene expression lies in the relationship between the nucleotide base sequence of DNA molecules and the linear order of amino acids in protein molecules. This relationship is based on a set of rules known as the **genetic code**. The cracking of that code, which tells us how DNA can code for proteins, is one of the major landmarks of twentieth-century biology.

During the flow of information from DNA to RNA to protein, it is easy to envision how information residing in a DNA base sequence could be passed to mRNA through the mechanism of complementary base pairing. But how does a base sequence in mRNA use its “message” to guide the synthesis of a protein molecule, which consists of a sequence of amino acids? What is needed, of course, is knowledge of the appropriate code—the set of rules that determines which nucleotides in mRNA correspond to which amino acids. Until it was cracked in the early 1960s, this genetic code was a secret code in a double sense: Before scientists could figure out the exact coding relationship between the base sequence of a DNA molecule and the amino acid sequence of a protein, they first had to become aware that such a relationship existed at all. That awareness arose from the discovery that mutations in DNA can lead to changes in proteins.

Experiments on *Neurospora* Revealed That Genes Can Code for Enzymes

The link between gene mutations and proteins was first detected experimentally by George Beadle and Edward Tatum in the early 1940s using the common bread mold, *Neurospora crassa*. *Neurospora* is a relatively self-sufficient organism that can grow in a *minimal medium* containing only sugar, inorganic salts, and the vitamin biotin. From these few ingredients, *Neurospora*'s metabolic pathways produce everything else the organism requires. To investigate the influence of genes on these metabolic pathways, Beadle and Tatum treated a *Neurospora* culture with X-rays to induce genetic mutations. Such treatments generated mutant strains that had lost the ability to survive in the minimal culture medium, although they could be grown on a *complete medium* supplemented with a variety of amino acids, nucleosides, and vitamins.

Such observations suggested that the *Neurospora* mutants had lost the ability to synthesize certain amino acids or vitamins and could survive only when these nutrients were added to the growth medium. To determine exactly which nutrients were required, Beadle and Tatum transferred the mutant cells to a variety of growth media, each containing a single amino acid or vitamin added as a supplement to the minimal medium. This approach led to the discovery that one mutant strain would grow only in a medium supplemented with vitamin B₆, a second mutant would grow only when the medium was supplemented with the amino acid arginine, and so forth. A large number of different mutants were eventually

characterized, each impaired in its ability to synthesize a particular amino acid or vitamin.

Because amino acids and vitamins are synthesized by metabolic pathways involving multiple steps, Beadle and Tatum set out to identify the particular step in each pathway that had become defective. They approached this task by supplementing the minimal medium with metabolic precursors of a given amino acid or vitamin rather than with the amino acid or vitamin itself. By finding out which precursors supported the growth of each mutant strain, they were able to infer that each mutation disabled a single enzyme-catalyzed step in a pathway for making a particular compound. There was, in other words, a one-to-one correspondence between each genetic mutation and the lack of a specific enzyme required in a metabolic pathway. From these findings, Beadle and Tatum formulated the *one gene–one enzyme hypothesis*, which stated that each gene controls the production of a single type of enzyme.

Most Genes Code for the Amino Acid Sequences of Polypeptide Chains

The theory that genes direct the production of enzyme molecules represented a major advance in our understanding of gene action, but it provided little insight into the question of how genes accomplish this task. The first clue to the underlying mechanism emerged a few years later in the laboratory of Linus Pauling, who was studying the inherited disease *sickle-cell anemia*. The red blood cells of individuals suffering from sickle-cell anemia exhibit an abnormal, “sickle” shape that causes the cells to become trapped and damaged when they pass through small blood vessels (Figure 21-2). In trying to identify the reason for this behavior, Pauling decided to analyze the properties of *hemoglobin*, the major protein of red blood cells. Because hemoglobin is a charged molecule, he used the technique of *electrophoresis*, which separates charged molecules from one another by placing them in an electric field. Pauling found that hemoglobin from

sickle cells migrated at a different rate than normal hemoglobin, suggesting that the two proteins differ in electric charge. Since some amino acids have charged side chains, Pauling proposed that the difference between normal and sickle-cell hemoglobin lay in their amino acid compositions.

One way to test this hypothesis would be to determine the amino acid sequence of the normal and mutant forms of hemoglobin. At the time of Pauling’s discovery in the early 1950s, the largest protein to have been sequenced was less than one-tenth the size of hemoglobin, so determining the complete amino acid sequence of hemoglobin would have been a monumental undertaking. Fortunately, an ingenious shortcut devised by Vernon Ingram made it possible to identify the amino acid abnormality in sickle-cell hemoglobin without determining the protein’s complete amino acid sequence. Ingram used the protease *trypsin* to cleave hemoglobin into peptide fragments, which were then separated from each other as shown in Figure 21-3 (page 650). When Ingram examined the peptide patterns of normal and sickle-cell hemoglobin, he discovered that only one peptide differed between the two proteins. Analysis of the amino acid makeup of the altered peptide revealed that a glutamic acid in normal hemoglobin had been replaced by a valine in sickle-cell hemoglobin. Since glutamic acid is negatively charged and valine is neutral, this substitution explains the difference in electrophoretic behavior between normal and sickle-cell hemoglobin originally observed by Pauling.

This single change from a glutamic acid to valine (caused by a single base-pair change in DNA) is enough to alter the way that hemoglobin molecules pack into red blood cells. Normal hemoglobin is jellylike in consistency, but sickle-cell hemoglobin tends to form a kind of crystal when it delivers oxygen to and picks up carbon dioxide from tissues. The crystalline array deforms the red blood cell into a sickled shape that blocks blood flow in capillaries and leads to a debilitating, potentially fatal, disease.

Following Ingram’s discovery that a gene mutation alters a single amino acid in sickle-cell hemoglobin, subsequent studies revealed the existence of other abnormal forms of hemoglobin, some of which involve mutations in a different gene. Two different genes are able to influence the amino acid sequence of the same protein because hemoglobin is a multisubunit protein containing two different kinds of polypeptide chains. The amino acid sequences of the two types of chains, called the α and β chains, are specified by two different genes.

The discoveries by Pauling and Ingram necessitated several refinements in the one gene–one enzyme concept of Beadle and Tatum. First, the fact that hemoglobin is not an enzyme indicates that genes encode the amino acid sequences of proteins in general, not just enzymes. In addition, the discovery that different genes code for the α and β chains of hemoglobin reveals that each gene encodes the sequence of a polypeptide chain, not necessarily a complete protein. Thus, the original hypothesis was refined into the *one gene–one polypeptide theory*.

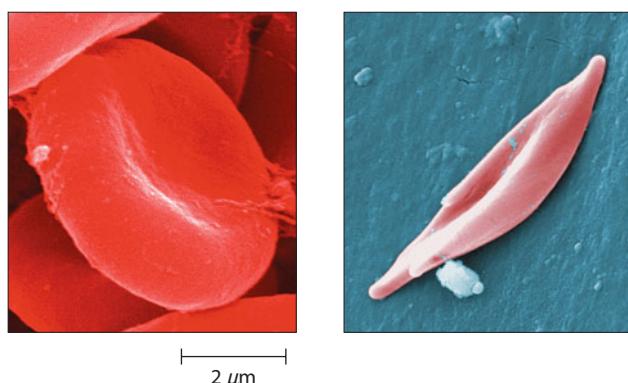

FIGURE 21-2 Normal and Sickled Red Blood Cells. The micrograph on the right reveals the abnormal shape of a sickled cell. This distorted shape, which is caused by a mutated form of hemoglobin, allows sickled cells to become trapped and damaged when passing through small blood vessels (SEMs).

Reverse Transcription, Retroviruses, and Retrotransposons

Transcription generally proceeds in the direction described in the central dogma, with DNA serving as a template for RNA synthesis. In certain cases, however, the process can be reversed and RNA serves as a template for DNA synthesis. This process of *reverse transcription* is catalyzed by the enzyme **reverse transcriptase**, first discovered by Howard Temin and David Baltimore in certain viruses with RNA genomes. Viruses that carry out reverse transcription are called **retroviruses**. Examples of retroviruses include some important pathogens, such as the *human immunodeficiency virus (HIV)*, which causes *acquired immune deficiency syndrome (AIDS)*, and a number of viruses that cause cancers in animals.

Retroviruses

Figure 21A-1 depicts the reproductive cycle of a typical retrovirus. In the virus particle, two copies of the RNA genome are enclosed within a protein capsid that is surrounded by a membranous envelope. Each RNA copy has a molecule of reverse transcriptase attached to it. The virus first (1) binds to the surface of the host cell, and its envelope fuses with the plasma membrane, releasing the capsid and its contents into the cytoplasm. Once inside the cell, the viral reverse transcriptase (2) catalyzes the synthesis of a DNA strand that is complementary to the viral RNA and then (3) catalyzes the formation of a second DNA strand complementary to the first. The result is a double-stranded DNA version of the viral genome. (4) This double-stranded DNA then enters the nucleus and integrates into the host cell's chromosomal DNA, much as the DNA genome of a lysogenic phage integrates into the DNA of the bacterial chromosome (see Box 18A). Like a prophage, the integrated viral genome, called a *provirus*, is replicated every time the cell replicates its own DNA. (5) Transcription of the proviral DNA (by cellular enzymes) produces RNA transcripts that function in two ways. First, they serve as (6) mRNA molecules that direct the synthesis of viral proteins (capsid protein, envelope protein, and reverse transcriptase). Second, (7) some of these same RNA transcripts are packaged with the viral proteins into new virus particles. (8) The new viruses then "bud" from the plasma membrane without necessarily killing the cell.

The ability of a retroviral genome to integrate into host cell DNA helps explain how some retroviruses can cause cancer. These viruses, called *RNA tumor viruses*, are of two types. Viruses of the first type carry a cancer-causing *oncogene* in their genomes, along with the genes coding for viral proteins. As we will see in Chapter 24, an oncogene is a mutated version of a normal cellular gene (a *proto-oncogene*) that codes for proteins used to regulate cell growth and division. For example, the oncogene carried by the Rous sarcoma virus (a chicken virus that was the first RNA tumor

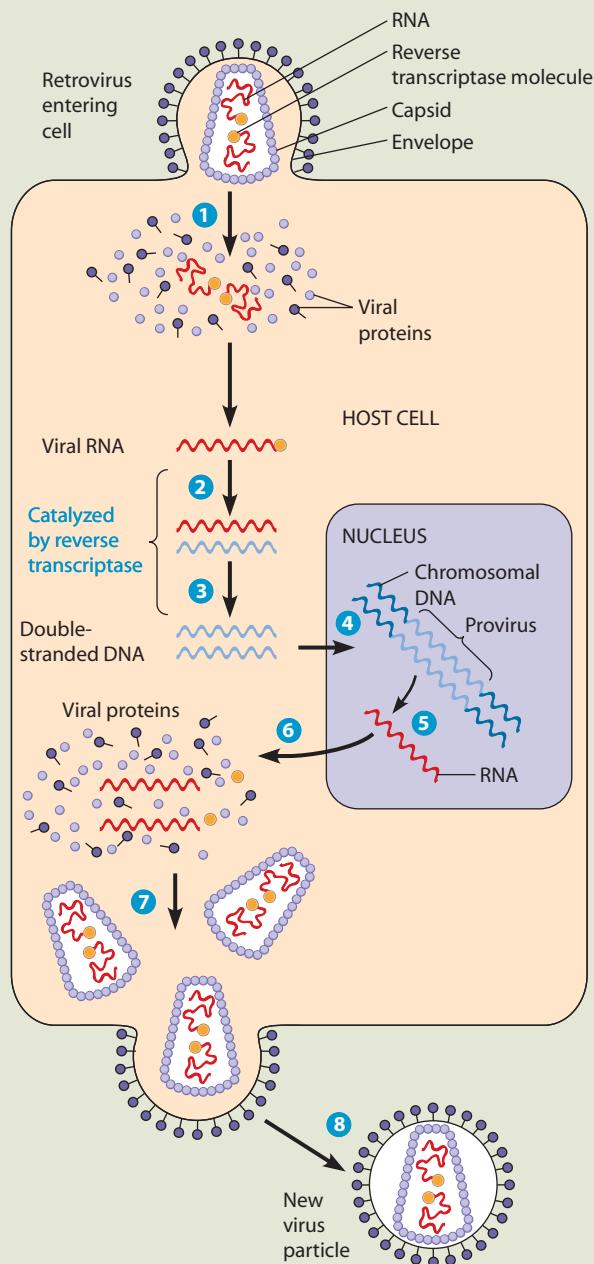

FIGURE 21A-1 The Reproductive Cycle of a Retrovirus.

ACTIVITIES www.thecellplace.com Retrovirus (HIV) reproductive cycle

According to this theory, the nucleotide sequence of a gene determines the sequence of amino acids in a polypeptide chain. In the mid-1960s, this prediction was confirmed in the laboratory of Charles Yanofsky, where the locations of dozens of mutations in the bacterial gene coding for a subunit of the enzyme tryptophan synth-

ase were determined. As predicted, the positions of the mutations within the gene correlated with the positions of the resulting amino acid substitutions in the tryptophan synthase polypeptide chain.

Showing that a gene's base sequence specifies the amino acid sequence of a polypeptide chain represented a

virus to be discovered) is a modified version of a cellular gene for a protein kinase. The protein product of the viral gene is hyperactive, and the cell cannot control it in the normal way. As a result, cells expressing this gene proliferate wildly, producing cancerous tumors called *sarcomas*. RNA tumor viruses of the second type do not themselves carry oncogenes, but integration of their genomes into the host chromosome alters the cellular DNA in such a way that a normal proto-oncogene is converted into an oncogene.

Retrotransposons

Reverse transcription also occurs in normal eukaryotic cells in the absence of viral infection. Much of it involves DNA elements called **retrotransposons**. In Chapter 18, we saw that transposable elements are DNA segments that can move themselves from one site to another within the genome. Retrotransposons are a special type of transposable element that use reverse transcription to carry out this movement. As outlined in **Figure 21A-2**, the transposition mechanism begins with **1** transcription of the retrotransposon DNA followed by **2** translation of the resulting RNA, which produces a protein exhibiting both reverse transcriptase and endonuclease activities. **3** Next, the retrotransposon RNA and protein bind to chromosomal DNA at some other location, and **4** the endonuclease cuts one of the DNA strands. **5** The reverse transcriptase then uses the retrotransposon RNA as a template to make a DNA copy that is **6** integrated into the target DNA site.

Although retrotransposons do not transpose themselves very often, they can attain very high copy numbers within a genome. We encountered one example in Chapter 18—the *Alu* family of sequences. *Alu* sequences are only 300 base pairs long, and they do not encode a reverse transcriptase. But by using a reverse transcriptase encoded elsewhere in the genome, they have sent copies of themselves throughout the genomes of humans and other primates. The human genome contains about a million *Alu* sequences that together represent about 11% of the total DNA. Another type of retrotransposon, called an *L1* element, is even more prevalent, accounting for roughly 17% of human DNA. The *L1* retrotransposon is larger than *Alu* and encodes its own reverse transcriptase and endonuclease, as illustrated in Figure 21A-2. The reason that genomes retain so many copies of retrotransposon sequences such as *L1* and *Alu* is not well understood, but they are thought to contribute to evolutionary flexibility and variability.

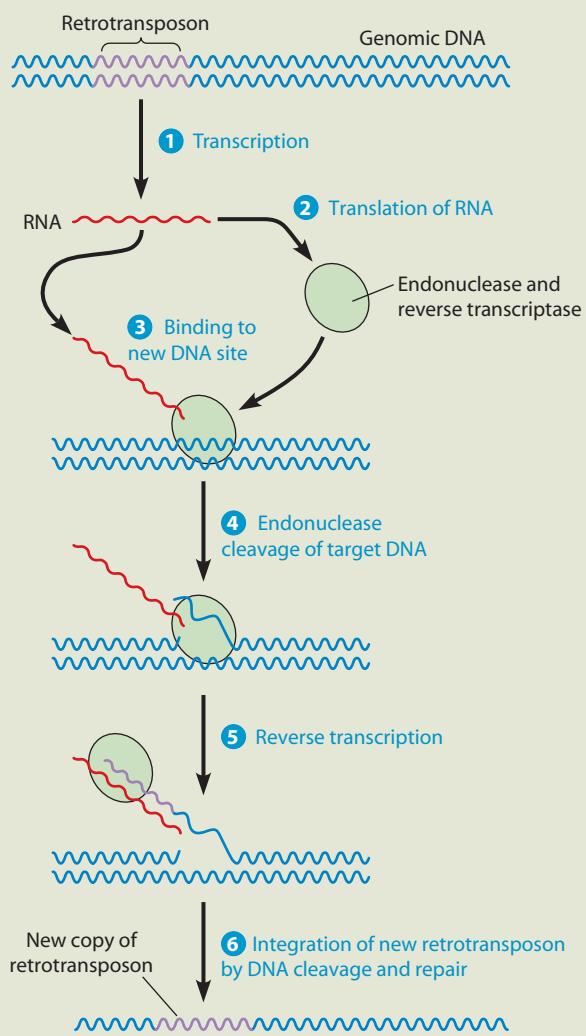

FIGURE 21A-2 Movement of a Retrotransposon.

major milestone, but subsequent developments have revealed that gene function is often more complicated than this, especially in eukaryotes. As we will see later in the chapter, most eukaryotic genes contain noncoding sequences interspersed among the coding regions and so do not exhibit a complete linear correspondence with

their polypeptide product. Moreover, the coding sequences in such genes can be read in various combinations to produce different mRNAs, each coding for a unique polypeptide chain. This phenomenon, called *alternative splicing* (page 673), allows dozens or even hundreds of different polypeptides to be produced from a single gene.

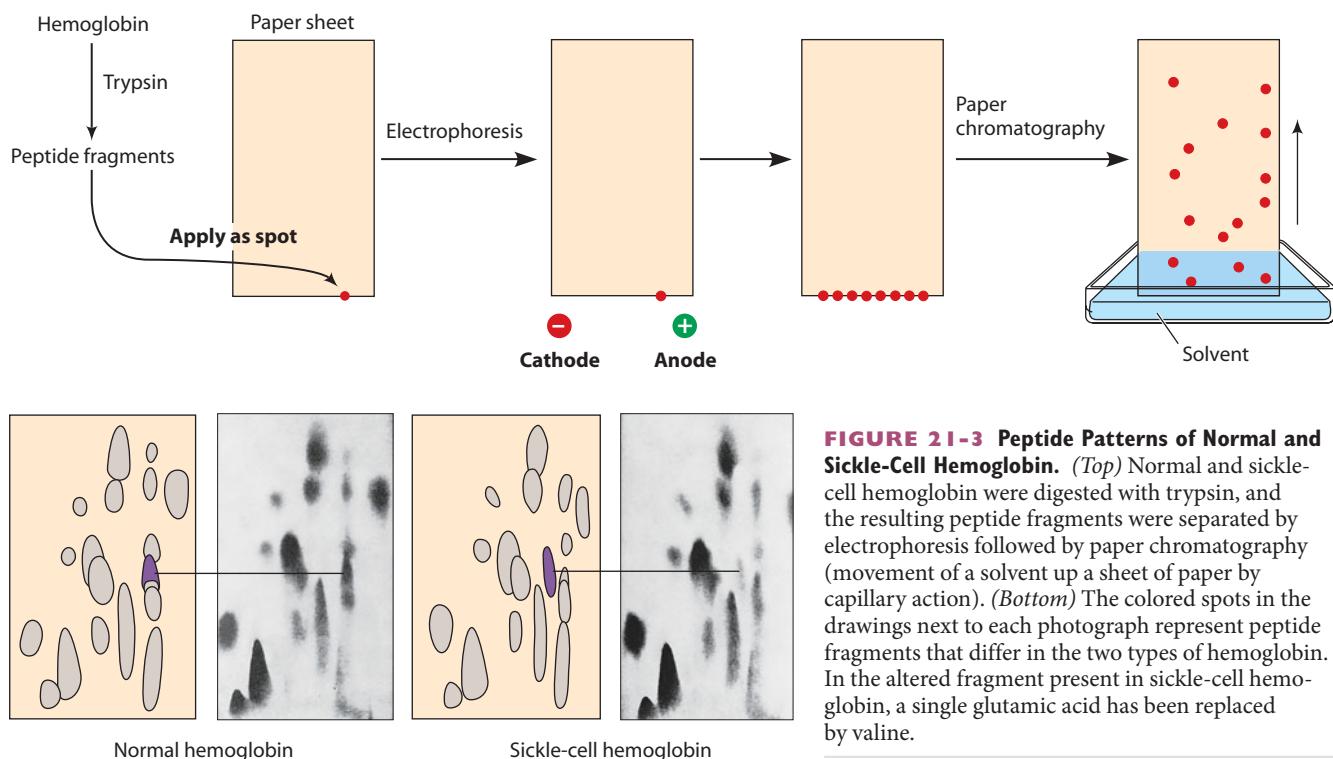

FIGURE 21-3 Peptide Patterns of Normal and Sickled-Cell Hemoglobin. (Top) Normal and sickle-cell hemoglobin were digested with trypsin, and the resulting peptide fragments were separated by electrophoresis followed by paper chromatography (movement of a solvent up a sheet of paper by capillary action). (Bottom) The colored spots in the drawings next to each photograph represent peptide fragments that differ in the two types of hemoglobin. In the altered fragment present in sickle-cell hemoglobin, a single glutamic acid has been replaced by valine.

Therefore, in eukaryotes the one gene–one polypeptide theory does not always hold true; for most genes, a more accurate description is *one gene–many polypeptides*.

To further complicate our description of gene function, several types of genes do not produce polypeptide chains at all. These genes code for RNA molecules such as ribosomal RNAs (page 666), transfer RNAs (page 665), small nuclear RNAs (page 671), and microRNAs (page 750), each of which performs a unique function. So even *one gene–many polypeptides* is an inadequate description that needs to be replaced by a broader view of gene function: **Genes** are best defined as functional units of DNA that code for the amino acid sequence of one or more polypeptide chains or, alternatively, for one of several types of RNA that perform functions other than specifying the amino acid sequence of polypeptide chains.

The Genetic Code Is a Triplet Code

Given a sequence relationship between DNA and proteins, the next question is: How many nucleotides in DNA are needed to specify each amino acid in a protein? We know that the information in DNA must reside in the sequence of the four nucleotides that constitute the DNA: A, T, G, and C. These are the only “letters” of the DNA alphabet. Because the DNA language has to contain at least 20 “words,” one for each of the 20 amino acids found in protein molecules, the DNA word coding for each amino acid must consist of more than one nucleotide. A doublet code involving two adjacent nucleotides would not be adequate, as four

kinds of nucleotides taken two at a time can generate only $4^2 = 16$ different combinations.

But with three nucleotides per word, the number of different words that can be produced with an alphabet of just four letters is $4^3 = 64$. This number is more than sufficient to code for 20 different amino acids. In the early 1950s, such mathematical arguments led biologists to suspect the existence of a **triplet code**—that is, a code in which three base pairs in double-stranded DNA are required to specify each amino acid in a polypeptide. But direct evidence for the triplet nature of the code was not provided until ten years later. To understand the nature of that evidence, we first need to become acquainted with frameshift mutations.

Frameshift Mutations. In 1961, Francis Crick, Sydney Brenner, and their colleagues provided genetic evidence for the triplet nature of the code by studying the mutagenic effects of the chemical *proflavin* on bacteriophage T4. Their work is well worth considering, not just for the critical evidence it provided concerning the nature of the code but also because of the ingenuity that was needed to understand the significance of their observations.

Proflavin is one of several **acridine dyes** commonly used as **mutagens** (mutation-inducing agents) in genetic research. Acridines are interesting mutagens because they act by causing the addition or deletion of single base pairs in DNA. Sometimes, mutants generated by acridine treatment of a wild-type (“normal”) virus or organism appear to revert to wild-type when treated with more of the same type of mutagen. Closer examination often reveals, however, that the reversion is not a true reversal of the

original mutation but the acquisition of a second mutation that maps very close to the first.

Such mutations display an interesting kind of arithmetic. If the first alteration is called a plus (+) mutation, then the second can be called a minus (−) mutation. By itself, each creates a mutant phenotype. But when they occur close together as a double mutation, they cancel each other out and the virus or organism exhibits the normal, wild-type phenotype. (Properly speaking, the phenotype is said to be *pseudo wild-type* because, despite its wild-type appearance, two mutations are present.) Such behavior can be explained using the analogy in **Figure 21-4**. Suppose that line 1 represents a wild-type “gene” written in a language that uses three-letter words. When we “translate” the line by starting at the beginning and reading three letters at a time, the message of the gene is readily comprehensible. A plus mutation is the addition of a single letter within the message (line 2). That change may seem minor, but since the message is always read three letters at a time, the insertion of an extra letter early in the sequence means that all the remaining letters are read out of phase. There is, in other words, a shift in the *reading frame*, and the result is a garbled message from the point of the insertion onward. A minus mutation can be explained in a similar way because the deletion of a single letter also causes the reading frame to shift, resulting in another garbled message (line 3). Such **frameshift mutations** are typical effects of acridine dyes and other mutagens that cause the insertion or deletion of individual base pairs.

Individually, plus and minus mutations always change the reading frame and garble the message. But when a plus and a minus mutation occur in close proximity within the same gene, they can largely cancel out each other’s effect. In such cases, the insertion caused by the plus mutation compensates for the deletion caused by the minus mutation,

and the message is intelligible from that point on (line 4). Notice, however, that double mutations with either two additions (+/++; line 5) or two deletions (−/−; line 6) do not cancel in this way. They remain out of phase for the remainder of the message.

Evidence for a Triplet Code. When Crick and Brenner generated T4 phage mutants with proflavin, they obtained results similar to those in the hypothetical example illustrated in Figure 21-4 involving a language that uses three-letter words. They found that minus mutants, which exhibited an abnormal phenotype, could acquire a second mutation that caused them to revert to the wild-type (or more properly, *pseudo wild-type*) phenotype. The second mutation was always a plus mutation located at a site different from, but close to, the original minus mutation. In other words, mutants reverting to the wild-type phenotype exhibited a −/+ pattern of mutations. Crick and Brenner observed many examples of −/+ (or +−) mutants exhibiting the wild-type phenotype in their experiments. But when they generated ++ or −− double mutants by recombination, no wild-type phenotypes were ever seen.

Crick and Brenner also constructed triple mutants of the same types (+/+/+ or −−−−) and found that many of them now reverted to wild-type phenotypes. This finding, of course, can be readily understood by consulting lines 7 and 8 of Figure 21-4: The reading frame (based on three-letter words) at the beginning and end of that hypothetical message remains the same when three letters are either added or removed. The portion of the message between the first and third mutations is garbled, but provided these are close enough to each other, enough of the sentence may remain to convey an intelligible message.

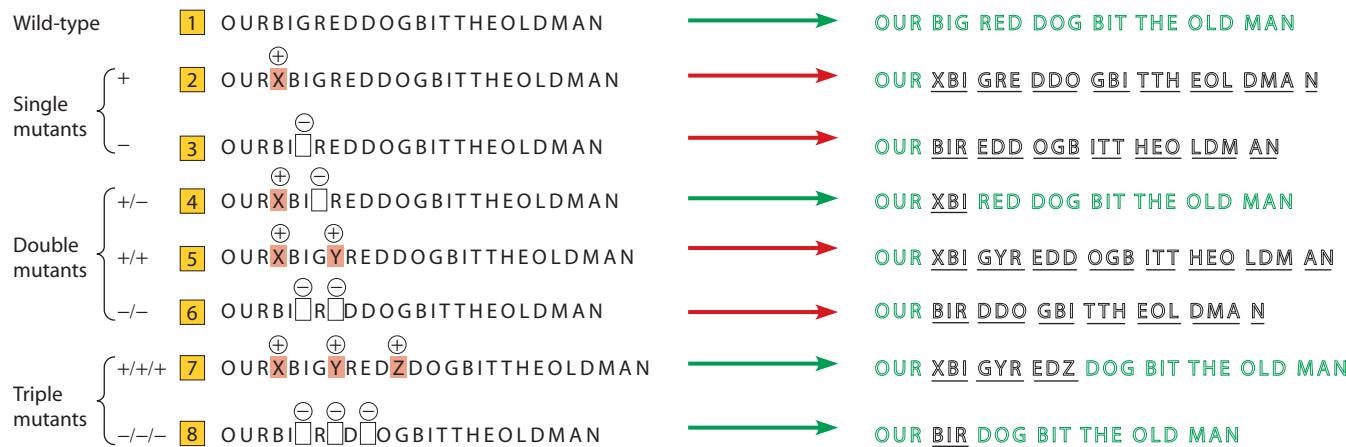

FIGURE 21-4 **Frameshift Mutations.** The effect of frameshift mutations can be illustrated with an English sentence. The wild-type sentence (line 1) consists of three-letter words. When read in the correct frame, it is fully comprehensible. The insertion (line 2) or deletion (line 3) of a single letter shifts the reading frame and garbles the message from that point onward. (Garbled words due to shifts in the reading frame are underlined.) Double mutants containing a deletion that “cancels” a prior insertion have a restored reading frame from the point of the second mutation onward (line 4). However, double insertions (line 5) or double deletions (line 6) produce garbled messages. Triple insertions (line 7) or deletions (line 8) garble part of the message but restore the reading frame with the net addition or deletion of a single word.

Applying this concept of a three-letter code to DNA, Crick and Brenner concluded that adding or deleting a single base pair will shift the reading frame of the gene from that point onward, and a second, similar change shifts the reading frame yet again. Therefore, from the site of the first mutation onward, the message is garbled. But after a third change of the same type, the original reading frame is restored, and the only segment of the gene translated incorrectly is the segment between the first and third mutations. Such errors can often be tolerated when the genetic message is translated into the amino acid sequence of a protein, provided the affected region is short and the changes in amino acid sequence do not destroy protein function. This is why the individual mutations in a triple mutant with wild-type phenotype map so closely together. Subsequent sequencing of wild-type polypeptides from such triple mutants confirmed the slightly altered sequences of amino acids that would be expected.

Based on their finding that wild-type phenotypes are often maintained in the presence of three base-pair additions (or deletions) but not in the presence of one or two, Crick and Brenner concluded that the nucleotides making up a DNA strand are read in groups of three. In other words, the genetic code is a triplet code in which the reading of a message begins at a specific starting place (to ensure the proper reading frame) and then proceeds three nucleotides at a time, with each such triplet translated into the appropriate amino acid, until the end of the message is reached. Keep in mind that in establishing the triplet nature of the code, Crick and Brenner did not have Figure 21-4 to assist them. Their ability to deduce the correct explanation from their analysis of proflavin-induced mutations is an especially inspiring example of the careful, often ingenious reasoning that almost always accompanies significant advances in science.

The Genetic Code Is Degenerate and Nonoverlapping

From the fact that so many of their triple mutants were viable, Crick and Brenner drew an additional conclusion: Most of the 64 possible nucleotide triplets must specify amino acids, even though proteins have only 20 different kinds of amino acids. If only 20 of the 64 possible combinations of nucleotides “made sense” to the cell, the chances of a meaningless triplet appearing in the out-of-phase stretches would be high. Such triplets would surely interfere with protein synthesis, and frameshift mutants would revert to wild-type behavior only rarely.

But Crick and Brenner frequently detected reversion to wild-type behavior, so they reasoned that most of the 64 possible triplets must code for amino acids. Since there are only 20 amino acids, this told them that the genetic code is a **degenerate code**—that is, a given amino acid can be specified by more than one nucleotide triplet. Degeneracy serves a useful function in enhancing the adaptability of the coding system. If only 20 triplets were assigned a coding function (one for each of the 20 amino acids), any

mutation in DNA that led to the formation of any of the other 44 possible triplets would interrupt the genetic message at that point. Therefore, the susceptibility of such a coding system to disruption would be very great.

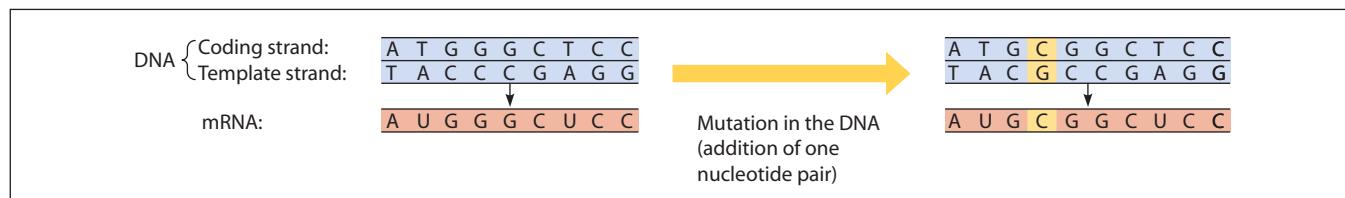

A further conclusion from Crick and Brenner’s work—which we have implicitly assumed—is that the genetic code is *nonoverlapping*. In an *overlapping* code, the reading frame would advance only one or two nucleotides at a time along a DNA strand so that each nucleotide would be read two or three times. **Figure 21-5** compares a nonoverlapping code with an overlapping code in which the reading frame advances one nucleotide at a time. With such an overlapping code, the insertion or deletion of a single base pair in the gene would lead to the insertion or deletion of one amino acid at one point in the polypeptide and would change several adjacent amino acids, but it would not affect the reading frame of the remainder of the gene. This means that if the genetic code were overlapping, Crick and Brenner would not have observed their frameshift mutations. Thus, their results clearly indicated the nonoverlapping nature of the code: Each nucleotide is a part of one, and only one, triplet.

Interestingly, although the genetic code is always translated in a nonoverlapping way, there are cases where a particular segment of DNA is translated in more than one reading frame. For example, certain viruses with very small genomes have overlapping genes, as was first discovered in 1977 for phage ϕ X174. In this phage’s DNA, one gene is completely embedded within another gene, and, to complicate matters further, a third gene overlaps them both! The three genes are translated in different reading frames. Other instances of overlapping genes are found in bacteria, where some genes overlap by a few nucleotides at their boundaries.

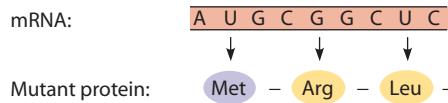

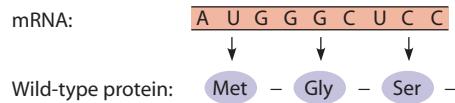

Messenger RNA Guides the Synthesis of Polypeptide Chains

After the publication of Crick and Brenner’s historic findings in 1961, it took only five years for the meaning of each of the 64 triplets in the genetic code to be elucidated. Before we look at how that was done, let us first describe the role of RNA in the coding system. As we usually describe it, the genetic code refers not to the order of nucleotides in double-stranded DNA but to their order in the single-stranded mRNA molecules that actually direct protein synthesis. As indicated at the top of Figure 21-5, mRNA molecules are transcribed from DNA using a base-pairing mechanism similar to DNA replication, with two significant differences.

1. In contrast to DNA replication, where both DNA strands are copied, only one of the two DNA strands—the **template strand**—serves as a template for mRNA formation during transcription. The nontemplate DNA strand, although not directly involved in transcription, is by convention called the **coding strand** because it is similar in sequence to the single-stranded mRNA molecules that carry the coded message.

(a) Nonoverlapping code

(b) Overlapping code

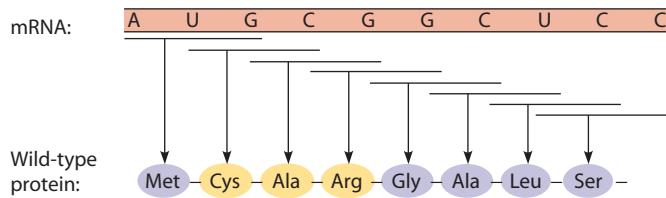

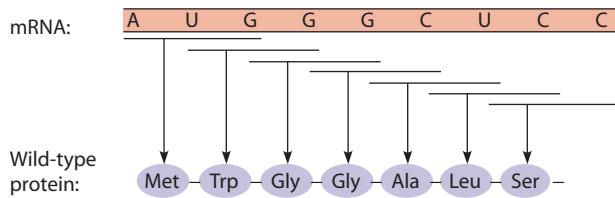

FIGURE 21-5 Effect of Inserting a Single Base Pair on Proteins Encoded by Overlapping and Nonoverlapping Genetic Codes.

Genetic Codes. One strand of the DNA duplex at the top, called the *template strand*, is transcribed into the nine-nucleotide segment of mRNA shown, according to the same base-pairing rules used in DNA replication, except the base U is used in RNA in place of T. (The complementary DNA strand, with a sequence essentially identical to that of the mRNA, is called the *coding strand*.) (a) With a nonoverlapping code, the reading frame advances three nucleotides at a time, and this mRNA segment is therefore read as three successive triplets, coding for the amino acids methionine, glycine, and serine. (See Figure 21-6 for amino acid coding rules.) If the DNA duplex is mutated by insertion of a single base pair (the yellow-shaded CG pair in the top box), the mRNA will have an additional nucleotide. This insertion alters the reading frame beyond that point, so the remainder of the mRNA is read incorrectly and all amino acids are wrong. In the example shown, the insertion occurs near the beginning of the message, and the only similarity between the wild-type protein and the mutant protein is the first amino acid (methionine). (b) In one type of overlapping code, the reading frame advances only one nucleotide at a time. The wild-type protein will therefore contain three times as many amino acids as would a protein generated from the same mRNA using a nonoverlapping code. Insertion of a single base pair in the DNA again results in an mRNA molecule with one extra nucleotide. However, in this case the effect of the insertion on the protein is modest; two amino acids in the wild-type protein are replaced by three different amino acids in the mutant protein, but the remainder of the protein is normal. The frameshift mutations that Crick and Brenner found in their studies with the mutagen proflavin would not have been observed if the genetic code were overlapping. Accordingly, their data indicated the code to be nonoverlapping.

- The mechanism used to copy sequence information from a DNA template strand to a complementary molecule of RNA utilizes the same base-pairing rules as DNA replication, with the single exception that the base uracil (U) is employed in RNA where the base thymine (T) would have been incorporated into DNA. This substitution is permitted because U and T can both form hydrogen bonds with the base A. During DNA replication the base A pairs with T, whereas in transcription the base A pairs with U. Hence the sequence of an mRNA molecule is not exactly the same as the DNA coding strand, in that mRNA contains the base U anywhere the coding DNA strand has the base T.

How do we know that mRNA molecules, produced by this transcription process, are responsible for directing the order in which amino acids are linked together during protein synthesis? This relationship was first demonstrated experimentally in 1961 by Marshall Nirenberg and J. Heinrich Matthei, who pioneered the use of *cell-free*

systems for studying protein synthesis. In such systems, protein synthesis can be studied outside living cells by mixing together isolated ribosomes, amino acids, an energy source, and an extract containing soluble components of the cytoplasm. Nirenberg and Matthei found that adding RNA to cell-free systems increased the rate of protein synthesis, raising the question of whether the added RNA molecules were functioning as messages that determined the amino acid sequences of the proteins being manufactured. To address this question, they decided to add synthetic RNA molecules of known base composition to the cell-free system to see if such RNA molecules would influence the type of protein being made.

Their initial experiments took advantage of an enzyme called *polynucleotide phosphorylase*, which can be used to make synthetic RNA molecules of predictable base composition. Unlike the enzymes involved in cellular transcription, polynucleotide phosphorylase does not require a template but simply assembles available nucleotides randomly into a linear chain. If only one or two of the four ribonucleotides (ATP, GTP, CTP, and

UTP) are provided, the enzyme will synthesize RNA molecules with a restricted base composition. The simplest RNA molecule results when a single kind of nucleotide is used because the only possible product is an RNA *homopolymer*—that is, a polymer consisting of a single repeating nucleotide. For example, when polynucleotide phosphorylase is incubated with UTP as the sole substrate, the product is a homopolymer of uracil, called poly(U). When Nirenberg and Matthei added poly(U) to a cell-free protein-synthesizing system, they observed a marked increase in the incorporation of one particular amino acid, phenylalanine, into polypeptide chains. Synthetic RNA molecules containing bases other than uracil did not stimulate phenylalanine incorporation, whereas poly(U) enhanced the incorporation of only phenylalanine.

From these observations, Nirenberg and Matthei concluded that poly(U) directs the synthesis of polypeptide chains consisting solely of phenylalanine. This observation represented a crucial milestone in the development of the messenger RNA concept, for it was the first demonstration that the base sequence of an RNA molecule determines the order in which amino acids are linked together during protein synthesis.

The Codon Dictionary Was Established Using Synthetic RNA Polymers and Triplets

Once it had been shown that RNA functions as a messenger that guides the process of protein synthesis, the exact nature of the triplet coding system could be elucidated. Nucleotide triplets in mRNA, called **codons**, are the actual coding units read by the translational machinery during protein synthesis. The four bases present in RNA are the purines adenine (A) and guanine (G) and the pyrimidines cytosine (C) and uracil (U), so the 64 triplet codons consist of all 64 possible combinations of these four “letters” taken three at a time. And since mRNA molecules are synthesized in the $5' \rightarrow 3'$ direction (like DNA) and are translated starting at the $5'$ end, the 64 codons by convention are always written in the $5' \rightarrow 3'$ order.

These triplet codons in mRNA determine the amino acids that will be incorporated during protein synthesis, but which amino acid does each of the 64 triplets code for? The discovery that poly(U) directs the incorporation of phenylalanine during protein synthesis allowed Nirenberg and Matthei to make the first codon assignment: The triplet UUU in mRNA must code for the amino acid phenylalanine. Subsequent studies on the coding properties of other synthetic homopolymers, such as poly(A) and poly(C), quickly revealed that AAA codes for lysine and CCC codes for proline. (Because of unexpected structural complications, poly(G) is not a good messenger and was not tested.)

After the homopolymers had been tested, polynucleotide phosphorylase was employed to create *copolymers* containing a mixture of two nucleotides. For example, incubating polynucleotide phosphorylase with the precur-

sors CTP and ATP yielded a copolymer built from C's and A's but in no predictable order. Such a copolymer contains a random mixture of eight different codons: CCC, CCA, CAC, ACC, AAC, ACA, CAA, and AAA. When this copolymer was used to direct protein synthesis, the resulting polypeptides incorporated 6 of the 20 possible amino acids. It was already known from the homopolymer studies that two of these amino acids were specified by the codons CCC and AAA, but the codons for the other four amino acids could not be unambiguously assigned.

Further progress depended on an alternative means of codon assignment devised by Nirenberg's group. Instead of using long polymers, they synthesized 64 very short RNA molecules, each only three nucleotides long. They then conducted studies to see which amino acid bound to the ribosome in response to each of these triplets. (In such experiments, tRNA molecules actually carry the amino acids to the ribosome.) With this approach, they were able to determine most of the codon assignments.

Meanwhile, a refined method of polymer synthesis had been devised in the laboratory of H. Gobind Khorana. Khorana's approach was similar to that of Nirenberg and Matthei but with the important difference that the polymers he synthesized had defined sequences. Thus, he could produce a synthetic mRNA molecule with the strictly alternating sequence UAUUA.... Such an RNA copolymer has only two codons, UAU and AUA, and they alternate in strict sequence. When Khorana added this particular RNA to a cell-free protein-synthesizing system, a polypeptide containing only tyrosine and isoleucine was produced. Khorana was therefore able to narrow the possible codon assignments for UAU and AUA to these two particular amino acids. When the results obtained with such synthetic polymers were combined with the findings of Nirenberg's binding studies, most of the codons could be assigned unambiguously.

Of the 64 Possible Codons in Messenger RNA, 61 Code for Amino Acids

By 1966, just five years after the first codon was identified, the approaches we have just described allowed all 64 codons to be assigned—that is, the entire genetic code had been worked out, as shown in **Figure 21–6**. The elucidation of the code confirmed several properties that had been deduced earlier from indirect evidence. All 64 codons are in fact used in the translation of mRNA. Sixty-one of the codons specify the addition of specific amino acids to the growing polypeptide, and one of these (AUG) also plays a prominent role as a **start codon** that initiates the process of protein synthesis. The remaining three codons (UAA, UAG, and UGA) are **stop codons** that instruct the cell to terminate synthesis of the polypeptide chain.

It is clear from examining Figure 21-6 that the genetic code is *unambiguous*: Every codon has one and only one meaning. The figure also shows the *degenerate* nature of the code—that is, many of the amino acids are specified by

		Second position							
		U	C	A	G				
First position	U	UUU UUC UCC UUA UUG	UCU UCC UCA UCG	UAU UAC Stop UAA UAG	UGU UGC Stop UGA Trp	U C A G			
	C	CUU CUC CUA CUG	CCU CCC CCA CCG	CAU CAC CAA CAG	CGU CGC CGA CGG	U C A G			
	A	AUU AUC AUU AUG Met/start	ACU ACC ACA ACG	AAU AAC AAA AAG	AGU AGC AGA AGG	U C A G			
	G	GUU GUC GUA GUG	GCU GCC GCA GCG	GAU GAC GAA GAG	GGU GGC GGA GGG	U C A G			

FIGURE 21-6 The Genetic Code. The code “words” are three-letter codons present in the nucleotide sequence of mRNA, as read in the 5' → 3' direction. Letters represent the nucleotide bases uracil (U), cytosine (C), adenine (A), and guanine (G). Each codon specifies either an amino acid or a stop signal. To decode a codon, read down the left edge for the first letter, then across the grid for the second letter, and then down the right edge for the third letter. For example, the codon AUG represents methionine. (As we will see in Chapter 22, AUG is also a start signal.)

more than one codon. There are, for example, two codons for histidine (His), four for threonine (Thr), and six for leucine (Leu). Although degeneracy may sound wasteful, it serves a useful function in enhancing the adaptability of the coding system. As we noted earlier, if there were only one codon for each of the 20 amino acids, then any mutation that created one of the remaining 44 codons would terminate synthesis of the growing polypeptide chain at that point. But with a degenerate code, most mutations simply cause codon changes that alter the specified amino acid. The change in a protein's behavior that results from a single amino acid alteration is often quite small, and in some cases may even be advantageous. Moreover, mutations in the third base of a codon frequently do not change the specified amino acid at all, as you can see in Figure 21-6. For example, a mutation that changes the codon ACU to ACC, ACA, or ACG does not alter the corresponding amino acid, which is threonine (Thr) in all four cases.

The validity of the codon assignments summarized in Figure 21-6 has been confirmed by analyzing the amino acid sequences of mutant proteins. For example, we learned earlier in the chapter that sickle-cell hemoglobin differs from normal hemoglobin at a single amino acid position, where valine is substituted for glutamic acid. The genetic code table reveals that glutamic acid may be encoded by either GAA or GAG. Whichever triplet is employed, a single base change could create a codon for valine. For example, GAA might have been changed to GUA, or GAG might have been changed to GUG. In either case, a glutamic acid codon would be converted into a valine codon. Many other mutant proteins have been examined in a similar way. In nearly all cases, the amino acid substitutions are consistent with a single base change in a triplet codon.

The Genetic Code Is (Nearly) Universal

A final property of the genetic code worth noting is its near universality. Except for a few cases, all organisms studied so far—prokaryotes as well as eukaryotes—use the same basic genetic code. Even viruses, though they are nonliving entities, employ this same code. In other words, the 64 codons almost always stand for the same amino acids or stop signals specified in Figure 21-6, suggesting that this coding system was established early in the history of life on Earth and has remained largely unchanged over billions of years of evolution.

However, several exceptions to the standard genetic code do exist, most notably in mitochondria and in a few bacteria and other unicellular organisms. In the case of mitochondria, which contain their own DNA and carry out both transcription and translation, the genetic code can differ in several ways from the standard code. One difference involves the codon UGA, which is a stop codon in the standard code but is translated as tryptophan in mammalian and yeast mitochondria. Conversely, AGA is a stop codon in mammalian mitochondria, even though in most other systems (including yeast mitochondria) it codes for arginine. Such anomalies result from alterations in the properties of transfer RNA (tRNA) molecules found in mitochondria. As you will learn in the next chapter, tRNA molecules play a key role in the genetic code because they recognize codons in mRNA and bring the appropriate amino acid to each codon during the process of protein synthesis. Differences in the types of tRNA molecules present in mitochondria appear to underlie the ability to read codons such as UAG and AGA differently than in the standard genetic code.

Some bacteria also employ a few codons in a nonstandard way, as do the nuclear genomes of certain protozoa and fungi. For example, the fungus *Candida* produces an unusual tRNA that brings serine to mRNAs containing the codon CUG rather than bringing the normally expected amino acid, leucine. In an especially interesting case, observed in organisms as diverse as bacteria and mammals, a variation of the genetic code allows the incorporation of

a 21st amino acid, *selenocysteine*, in which the sulfur atom of cysteine is replaced by an atom of selenium. In mRNAs coding for the few rare proteins that contain selenocysteine, the meaning of a UGA codon is changed from a stop codon to a codon specifying selenocysteine. In such cases, folding of the mRNA molecule causes specific UGA codons to bind to a special tRNA carrying selenocysteine, rather than functioning as stop codons that terminate protein synthesis. A similar mechanism permits another stop codon, UAG, to specify incorporation of a 22nd amino acid, *pyrrolysine*.

Transcription in Bacterial Cells

Now that you have been introduced to the genetic code that governs the relationship between nucleotide sequences in DNA and the amino acid sequences of protein molecules, we can discuss the specific steps involved in the flow of genetic information from DNA to protein. The first stage in this process is the transcription of a nucleotide sequence in DNA into a sequence of nucleotides in RNA. RNA is chemically similar to DNA, but it contains ribose instead of deoxyribose as its sugar, has the base uracil (U) in place of thymine (T), and is usually single stranded. As in other areas of molecular genetics, the fundamental principles of RNA synthesis were first elucidated in bacteria, where the molecules and mechanisms are relatively simple. For that reason, we will start with transcription in bacteria.

Transcription Is Catalyzed by RNA Polymerase, Which Synthesizes RNA Using DNA as a Template

Transcription of DNA is carried out by the enzyme **RNA polymerase**, which catalyzes the synthesis of RNA using DNA as a template. Bacterial cells have a single kind of RNA polymerase that synthesizes all three major classes of RNA—mRNA, tRNA, and rRNA. The enzymes from different bacteria are quite similar, and the RNA polymerase from *Escherichia coli* has been especially well characterized. It is a large protein consisting of two α subunits, two β subunits that differ enough to be identified as β and β' , and a dissociable subunit called the **sigma (σ) factor**. Although the *core enzyme* lacking the sigma subunit is competent to carry out RNA synthesis, the *holoenzyme* (complete enzyme containing all of its subunits) is required to ensure initiation at the proper sites within a DNA molecule. The sigma subunit plays a critical role in this process by promoting the binding of RNA polymerase to specific DNA sequences, called *promoters*, found at the beginnings of genes. Bacteria contain a variety of different sigma factors that selectively initiate the transcription of specific categories of genes, as we will discuss in Chapter 23. After the sigma factor guides RNA polymerase to an appropriate promoter site, the sigma factor is usually released during the early stages of transcription.

Transcription Involves Four Stages: Binding, Initiation, Elongation, and Termination

Transcription is the synthesis of an RNA molecule whose base sequence is complementary to the base sequence of a template DNA strand. **Figure 21-7** provides an overview of RNA synthesis from a single **transcription unit**, a segment of DNA whose transcription gives rise to a single, continuous RNA molecule. The process of transcription begins with ① the binding of RNA polymerase to a DNA promoter sequence, which triggers local unwinding of the DNA double helix. Using one of the two DNA strands as a template, RNA polymerase then ② initiates the synthesis of an RNA chain. After initiation has taken place, the RNA polymerase molecule moves along the DNA template,

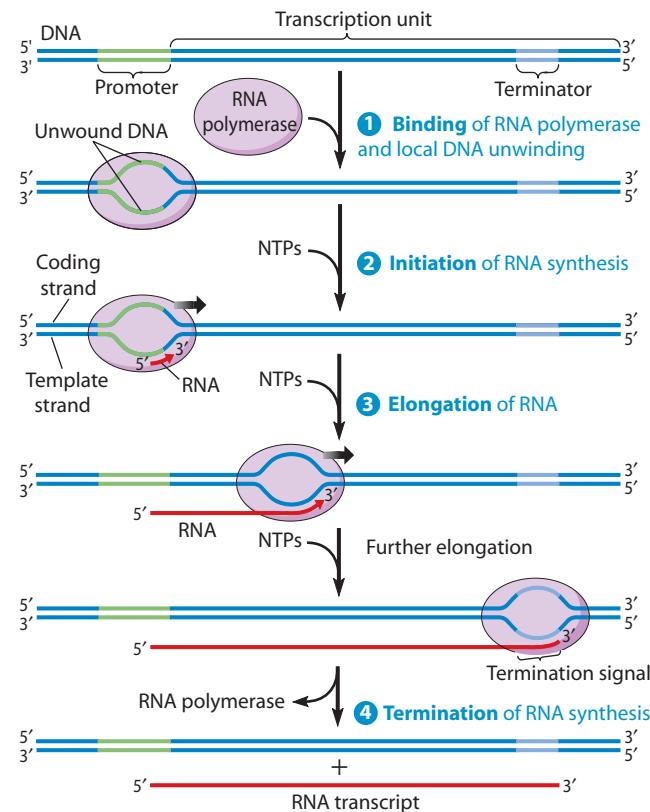

FIGURE 21-7 An Overview of Transcription. Transcription of DNA occurs in four main stages: ① binding of RNA polymerase to DNA at a promoter, ② initiation of transcription on the template DNA strand, ③ subsequent elongation of the RNA chain, and ④ eventual termination of transcription, accompanied by the release of RNA polymerase and the completed RNA product from the DNA template. RNA polymerase moves along the template strand of the DNA in the $3' \rightarrow 5'$ direction, and the RNA molecule grows in the $5' \rightarrow 3'$ direction. The supercoiling generated by DNA unwinding ahead of the moving RNA polymerase is relieved through the action of topoisomerases (not shown). The general scheme illustrated here holds for transcription in all organisms. NTPs (ribonucleoside triphosphate molecules) = ATP, GTP, CTP, and UTP.

unwinding the double helix and ③ elongating the RNA chain as it goes. During this process, the enzyme catalyzes the polymerization of nucleotides in an order determined by their base pairing with the DNA template strand. Eventually the enzyme transcribes a special base sequence called a *termination signal*, which ④ terminates RNA synthesis and causes the completed RNA molecule to be released and RNA polymerase to dissociate from the DNA template.

Although transcription is a complicated process, it can be thought of in four distinct stages: binding, initiation, elongation, and termination. We will now look at each stage in detail, as it occurs in *E. coli*. You can refer back to Figure 21-7 throughout this discussion to see how each step fits into the overall process.

Binding of RNA Polymerase to a Promoter Sequence. The first step in RNA synthesis is the *binding* of RNA polymerase to a DNA **promoter site**—a specific sequence of several dozen base pairs that determines where RNA synthesis starts and which DNA strand is to serve as the template strand. Each transcription unit has a promoter site located near the beginning of the DNA sequence to be transcribed. By convention, promoter sequences are described in the $5' \rightarrow 3'$ direction on the coding strand, which is the strand that lies opposite the template strand. The terms **upstream** and **downstream** are used to refer to DNA sequences located toward the $5'$ or $3'$ end of the coding strand, respectively. Therefore the region where the promoter is located is said to be upstream of the transcribed sequence. Binding of RNA polymerase to the promoter is mediated by the sigma subunit and leads to unwinding of a short stretch of DNA in the area where transcription will begin, exposing the two separate strands of the double helix.

Promoter sequences were initially identified by *DNA footprinting* and *electrophoretic mobility shift assays*, techniques for locating the DNA region to which a DNA-binding protein has become bound (**Box 21B**). More

recently, *chromatin immunoprecipitation (ChIP)* has been used to assess binding of proteins to specific genomic DNA sequences in eukaryotes. Sequences essential to the promoter region have also been identified by deleting or adding specific base sequences to cloned genes and then testing the ability of the altered DNA to be transcribed by RNA polymerase. Such techniques have revealed that DNA promoter sites differ significantly among bacterial transcription units. How, then, does a single kind of RNA polymerase recognize them all? Enzyme recognition and binding, it turns out, depend only on several very short sequences located at specific positions within each promoter site. The identities of the nucleotides making up the rest of the promoter are irrelevant for this purpose.

Figure 21-8 highlights the essential sequences in a typical bacterial promoter. The point where transcription will begin, called the *startpoint*, is almost always a purine and often an adenine. Approximately 10 bases upstream of the startpoint is the six-nucleotide sequence TATAAT, called the -10 sequence or the *Pribnow box*, after its discoverer. By convention, the nucleotides are numbered from the startpoint (+1), with positive numbers to the right (downstream) and negative ones to the left (upstream). The -1 nucleotide is immediately upstream of the startpoint (there is no “0”). At or near the -35 position is the six-nucleotide sequence TTGACA, called the -35 sequence.

The -10 and the -35 sequences (and their positions relative to the startpoint) have been conserved during evolution, but they are not identical in all bacterial promoters or even in all the promoters in a single genome. For example, the -10 sequence in the promoter for one of the *E. coli* tRNA genes is TATGAT, whereas the -10 sequence for a group of genes needed for lactose breakdown in the same organism is TATGTT, and the sequence given in Figure 21-8 is TATAAT. The particular promoter sequences shown in the figure are **consensus sequences**, which consist of the most common nucleotides at each position within a given sequence. Mutations that cause significant deviations from the consensus sequences tend

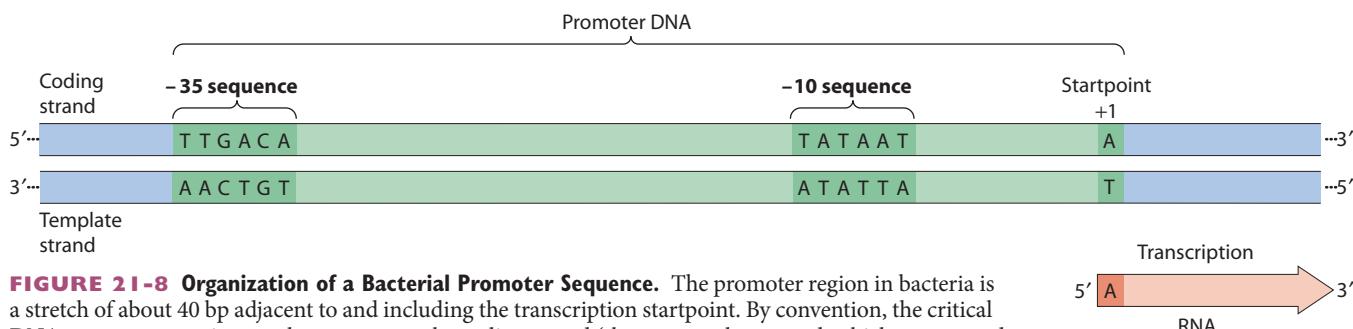

FIGURE 21-8 Organization of a Bacterial Promoter Sequence. The promoter region in bacteria is a stretch of about 40 bp adjacent to and including the transcription startpoint. By convention, the critical DNA sequences are given as they appear on the coding strand (the nontemplate strand, which corresponds in sequence to the RNA transcript). Essential features of the promoter are the startpoint (designated +1 and usually an A), the six-nucleotide -10 sequence, and the six-nucleotide -35 sequence. As their names imply, the two key sequences are located approximately 10 nucleotides and 35 nucleotides upstream from the startpoint. The sequences shown here are consensus sequences, which means they have the most commonly found base at each position. The numbers of nucleotides separating the consensus sequences from each other and from the startpoint are important for promoter function, but the identity of these nucleotides is not.

Identifying Protein-Binding Sites on DNA

The initiation of transcription depends on the interactions of proteins with specific DNA sequences. Thus, the researcher seeking to understand transcription needs to know about transcriptional proteins and the DNA sequences they bind to.

DNA footprinting is one technique that has been used to locate the DNA sites where specific proteins attach. The underlying principle is that the binding of a protein to a particular DNA sequence should protect that sequence from degradation by enzymes or chemicals. A version of footprinting, outlined in **Figure 21B-1**, employs a DNA-degrading enzyme called DNase I, which attacks the bonds between nucleotides more or less at random. In this example, the starting material is a DNA fragment that has been labeled at its 5' end with radioactive phosphate (indicated with red stars).

In step ①, a sample of the radioactive DNA is first mixed with the DNA-binding protein under study. Another sample, without the added protein, serves as the control. ② Both samples are briefly incubated with a low concentration of DNase I—conditions ensuring that most of the DNA molecules will be cleaved only once. The arrowheads indicate possible cleavage sites in the DNA. ③ The two incubation mixtures are submitted to electrophoresis and visualized by autoradiography. The control lane (on the right) has nine bands because every possible cleavage site has been cut. However, the other lane (on the left) is missing some of the bands because the protein that was bound to the DNA protected some of the cleavage sites during DNase treatment. The blank region in this lane is the “footprint” that identifies the location and length of the DNA sequence in contact with the DNA-binding protein.

Along with DNA footprinting, a technique known as an *electrophoretic mobility shift assay* (EMSA) (also called a *gel shift assay*) has been used to confirm DNA-protein binding. In this approach, a specific DNA sequence is mixed with a DNA-binding protein or a cellular extract containing such a protein. If the protein binds to the DNA sequence, it will result in the DNA sequence moving more slowly when subjected to gel electrophoresis. This shift in mobility indicates that the protein binds to the DNA sequences of interest.

A newer approach, called the *chromatin immunoprecipitation* (ChIP) assay, is now widely used to study protein-binding sites in the DNA of eukaryotic chromatin. In the ChIP assay, cells are first treated with formaldehyde to generate stable crosslinks between proteins and the DNA sites they are bound to. Next, the cells are

disrupted to shear chromatin into small fragments, and the chromatin fragments are treated with an antibody directed against a protein of interest. DNA fragments bound to that particular protein will be precipitated by the antibody, and the sequence of the precipitated DNA can then be analyzed.

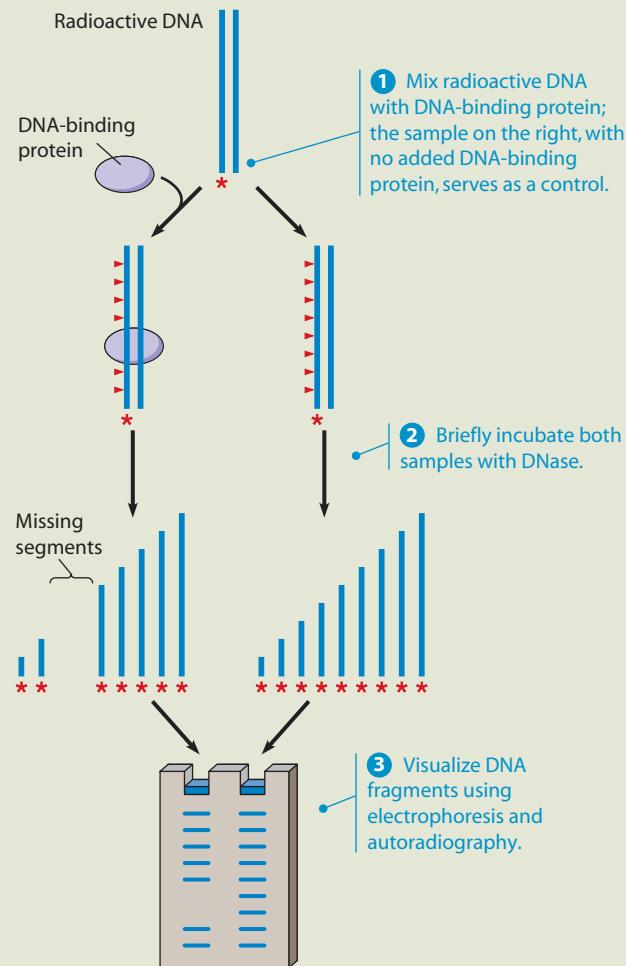

FIGURE 21B-1 DNase Footprinting as a Tool to Identify DNA Sites That Bind Specific Proteins.

to interfere with promoter function and may even eliminate promoter activity entirely.

Initiation of RNA Synthesis. Once an RNA polymerase molecule has bound to a promoter site and locally unwound the DNA double helix, *initiation* of RNA synthesis can take place. One of the two exposed segments of single-stranded DNA serves as the template for the synthesis of RNA, using incoming ribonucleoside triphosphate molecules (NTPs) as

substrates. The DNA strand that carries the promoter sequence determines which way the RNA polymerase faces, and the enzyme's orientation in turn determines which DNA strand it transcribes (see Figure 21-7). As soon as the first two incoming NTPs are hydrogen-bonded to the complementary bases of the DNA template strand at the startpoint, RNA polymerase catalyzes the formation of a phosphodiester bond between the 3'-hydroxyl group of the first NTP and the 5'-phosphate of the second,

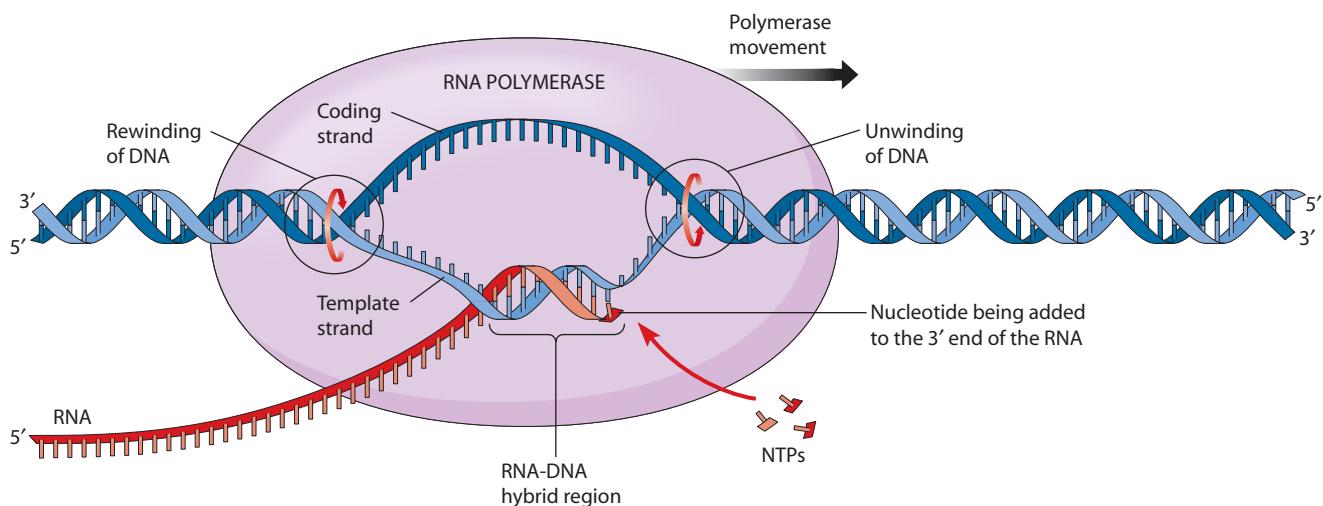

FIGURE 21-9 Closeup of a Bacterial Elongation Complex. During elongation, RNA polymerase binds to about 30 bp of DNA. (Recall that each complete turn of the DNA double helix is about 10 bp.) At any given moment, about 18 bp of DNA are unwound, and the most recently synthesized RNA is still hydrogen-bonded to the DNA, forming a short RNA–DNA hybrid about 8–9 bp long. The total length of growing RNA bound to the enzyme and/or DNA is about 25 nucleotides.

accompanied by the release of pyrophosphate (PP_i). The polymerase then advances along the template strand as additional nucleotides are added one by one, the 5'-phosphate of each new nucleotide joining to the 3'-hydroxyl group of the growing RNA chain, until the chain is about nine nucleotides long. At this point the sigma factor generally detaches from the RNA polymerase molecule, and the initiation stage is complete.

Elongation of the RNA Chain. Chain elongation (Figure 21-9) now continues as RNA polymerase moves along the DNA molecule, untwisting the helix bit by bit and adding one complementary nucleotide at a time to the growing RNA chain. The enzyme moves along the template DNA strand from the 3' toward the 5' end. Because complementary base pairing between the DNA template strand and the newly forming RNA chain is antiparallel, *the RNA strand is elongated in the 5' → 3' direction* as each successive nucleotide is added to the 3' end of the growing chain. (This is the same direction in which DNA strands are synthesized during DNA replication.) As the RNA chain grows, the most recently added nucleotides remain base-paired with the DNA template strand, forming a short RNA–DNA hybrid about 8–9 bp long. As the polymerase moves forward, the DNA ahead of the enzyme is unwound to permit the RNA–DNA hybrid to form. At the same time, the DNA behind the moving enzyme is rewound into a double helix. The supercoiling that would otherwise be generated by this unwinding and rewinding is released through the action of topoisomerases, just as in DNA replication (page 562).

Like DNA polymerase, RNA polymerases possess a 3' → 5' exonuclease activity that might in theory allow improperly base-paired nucleotides to be removed from the 3' end of a growing RNA chain after an incorrect base

has been incorporated. However, this intrinsic exonuclease activity is relatively weak, and an alternative mechanism for correcting errors is used instead. When a noncomplementary nucleotide is incorporated into a growing RNA chain by mistake, the RNA polymerase backs up slightly, and the noncomplementary nucleotide participates in catalyzing its own removal along with removal of the previously incorporated nucleotide. Such *RNA proofreading* appears to be sufficient for correcting mistakes that arise during transcription, especially since occasional errors in RNA molecules are not as critical as errors in DNA replication because numerous RNA copies are transcribed from each gene; hence a few inaccurate copies can be tolerated. In contrast, only one copy of each DNA molecule is made when DNA is replicated prior to cell division. Since each newly forming cell receives only one set of DNA molecules, it is crucial that the copying mechanism used in DNA replication be extremely accurate.

Termination of RNA Synthesis. Elongation of the growing RNA chain proceeds until RNA polymerase copies a special sequence, called a **termination signal**, that triggers the end of transcription. In bacteria, two classes of termination signals can be distinguished based on whether they require the participation of a protein called **rho (ρ) factor**. RNA molecules terminated without the aid of the rho factor contain a short GC-rich sequence followed by several U residues near their 3' end (Figure 21-10). Since GC base pairs are held together by three hydrogen bonds, whereas AU base pairs are joined by only two hydrogen bonds, this configuration promotes termination in the following way: First, the GC region contains sequences that are complementary to each other, causing the RNA to spontaneously fold into a **hairpin loop** that tends to pull the RNA molecule away from the DNA.

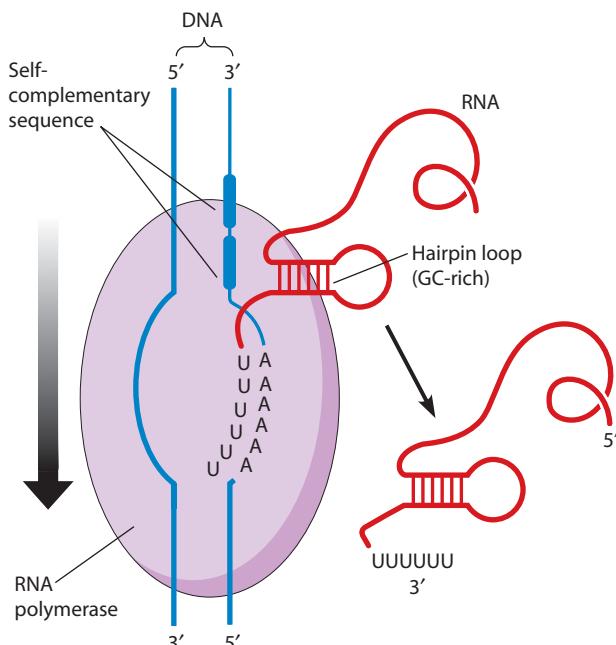

FIGURE 21-10 Termination of Transcription in Bacterial Genes That Do Not Require the Rho Termination Factor. A short self-complementary sequence near the end of the gene allows the newly formed RNA molecule to form a hairpin loop structure that helps dissociate the RNA from the DNA template.

Then the weaker bonds between the sequence of U residues and the DNA template are broken, releasing the newly formed RNA molecule.

In contrast, RNA molecules that do not form a GC-rich hairpin loop require participation of the rho factor for termination. Genes coding for such RNAs were first discovered in experiments in which purified DNA obtained from bacteriophage λ was transcribed with purified RNA polymerase. Some genes were found to be transcribed into RNA molecules that are longer than the RNAs produced in living cells, suggesting that transcription was not terminating properly. This problem could be corrected by adding rho factor, which binds to specific termination sequences 50–90 bases long located near the 3' end of newly forming RNA molecules. The rho factor acts as an ATP-dependent unwinding enzyme, moving along the newly forming RNA molecule toward its 3' end and unwinding it from the DNA template as it proceeds.

Whether termination depends on rho or on the formation of a hairpin loop, it results in the release of the newly transcribed RNA molecule and of the core RNA polymerase. The core polymerase can then bind sigma factor again and reinitiate RNA synthesis at another promoter.

Transcription in Eukaryotic Cells

Transcription in eukaryotic cells involves the same four stages described in Figure 21-7, but the process in eukaryotes is more complicated than that in bacteria. The main differences are as follows:

- Three different RNA polymerases transcribe the nuclear DNA of eukaryotes. Each synthesizes one or more classes of RNA.

Eukaryotic promoters are more varied than bacterial promoters. Not only are different types of promoters employed for the three polymerases, but there is great variation within each type—especially among the ones for protein-coding genes. Furthermore, some eukaryotic promoters are actually located *downstream* from the transcription startpoint.

Binding of eukaryotic RNA polymerases to DNA requires the participation of additional proteins, called *transcription factors*. Unlike the bacterial sigma factor, eukaryotic transcription factors are not part of the RNA polymerase molecule. Rather, some of them must bind to DNA *before* RNA polymerase can bind to the promoter and initiate transcription. Thus, transcription factors, rather than RNA polymerase itself, determine the specificity of transcription in eukaryotes. In this chapter, we limit our discussion to the class of factors that are essential for the transcription of all genes transcribed by an RNA polymerase. We defer discussion of the regulatory class of transcription factors, which selectively act on specific genes, until Chapter 23.

- Protein–protein interactions play a prominent role in the first stage of eukaryotic transcription. Although some transcription factors bind directly to DNA, many attach to other proteins—either to other transcription factors or to RNA polymerase itself.
- RNA cleavage is more important than the site where transcription is terminated in determining the location of the 3' end of the RNA product.
- Newly forming eukaryotic RNA molecules typically undergo extensive RNA processing (chemical modification) both during and, to a larger extent, after transcription.

We will now examine these various aspects of eukaryotic transcription, starting with the existence of multiple forms of RNA polymerase.

RNA Polymerases I, II, and III Carry Out Transcription in the Eukaryotic Nucleus

Table 21-1 summarizes some properties of the three RNA polymerases that function in the nucleus of the eukaryotic cell, along with two other polymerases found in mitochondria and chloroplasts. The nuclear enzymes are designated RNA polymerases I, II, and III. As the table indicates, these enzymes differ in their location within the nucleus and in the kinds of RNA they synthesize. The nuclear RNA polymerases also differ in their sensitivity to various inhibitors, such as α -amanitin, a deadly toxin produced by the mushroom *Amanita phalloides* (the “death

Table 21-1 Properties of Eukaryotic RNA Polymerases

RNA Polymerase	Location	Main Products	α -Amanitin Sensitivity
I	Nucleolus	Precursor for 28S rRNA, 18S rRNA, and 5.8S rRNA	Resistant
II	Nucleoplasm	Pre-mRNA, most snRNA, and microRNA	Very sensitive
III	Nucleoplasm	Pre-tRNA, 5S rRNA, and other small RNAs	Moderately sensitive*
Mitochondrial	Mitochondrion	Mitochondrial RNA	Resistant
Chloroplast	Chloroplast	Chloroplast RNA	Resistant

*In mammals.

cap” fungus; the F-actin binding drug phalloidin, introduced in Chapter 15, also comes from this organism).

RNA polymerase I resides in the nucleolus and is responsible for synthesizing an RNA molecule that serves as a precursor for three of the four types of rRNA found in eukaryotic ribosomes (28S rRNA, 18S rRNA, and 5.8S rRNA). This enzyme is not sensitive to α -amanitin. Its association with the nucleolus is understandable, for the nucleolus is the site of ribosomal RNA synthesis and ribosomal subunit assembly (page 543).

RNA polymerase II is found in the nucleoplasm and synthesizes precursors to mRNA, the class of RNA molecules that code for proteins. Rather than being diffusely distributed throughout the nucleus, active molecules of polymerase II are located in discrete clusters, called *transcription factories*, that represent sites where active genes come together to be transcribed. In addition to producing mRNA precursors, RNA polymerase II synthesizes most of the *snRNAs*—small nuclear RNAs involved in posttranscriptional RNA processing—and the *microRNAs*, which regulate the translation and stability of specific mRNAs and, to a lesser extent, control the transcription of certain genes. Polymerase II is responsible for producing the greatest variety of RNA molecules and is extremely sensitive to α -amanitin, which explains the toxicity of this compound to humans and other animals.

RNA polymerase II differs from polymerases I and III at its C terminus, where it has extra amino acids. The C terminus of RNA polymerase II can be phosphorylated at a variety of locations, to produce what is sometimes called a phosphorylation “code.” This “code” dramatically affects the functions of polymerase II, and correlates with where the enzyme is located along the DNA as it continues transcription. As a result, this most versatile of the RNA polymerases is also the most tightly regulated.

RNA polymerase III is also a nucleoplasmic enzyme, but it synthesizes a variety of small RNAs, including tRNA precursors and the smallest type of ribosomal RNA, 5S rRNA. Mammalian RNA polymerase III is sensitive to α -amanitin but only at higher levels of the toxin than are required to inhibit RNA polymerase II. (The comparable enzymes of some other eukaryotes, such as insects and yeasts, are insensitive to α -amanitin.)

Structurally, RNA polymerases I, II, and III are somewhat similar to each other as well as to bacterial core RNA

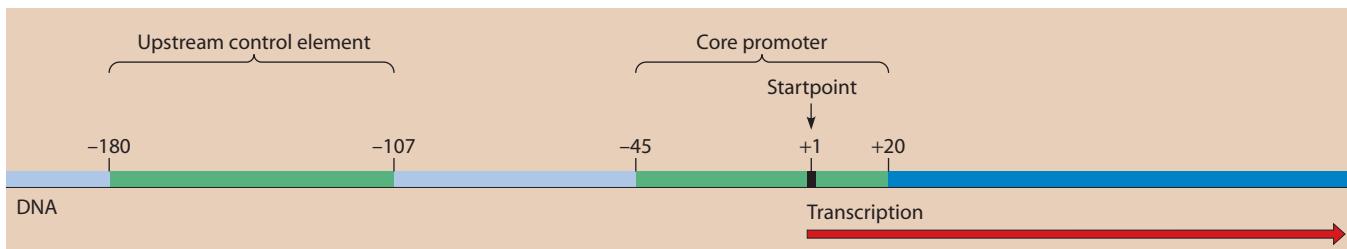

polymerase. The three enzymes are all quite large, with multiple polypeptide subunits and molecular weights around 500,000. RNA polymerase II, for example, has more than ten subunits of at least eight different types. The three biggest subunits are evolutionarily related to the bacterial RNA polymerase subunits α , β , and β' . Three of the smaller subunits lack that relationship but are also found in RNA polymerases II and III. The RNA polymerases of mitochondria and chloroplasts resemble their bacterial counterparts closely, as you might expect from the probable origins of these organelles as endosymbiotic bacteria (see Box 11A, page 298). Like bacterial RNA polymerase, the mitochondrial and chloroplast enzymes are resistant to α -amanitin.

Three Classes of Promoters Are Found in Eukaryotic Nuclear Genes, One for Each Type of RNA Polymerase

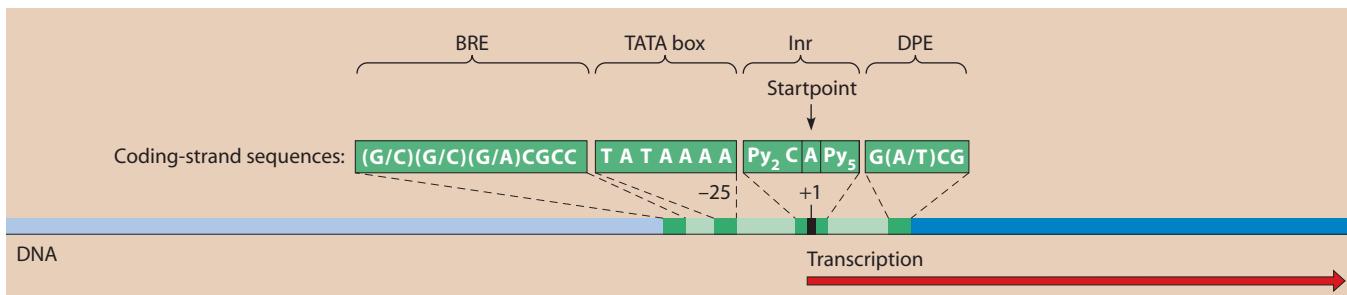

The promoters that eukaryotic RNA polymerases bind to are even more varied than bacterial promoters, but they can be grouped into three main categories, one for each type of polymerase. **Figure 21-11** shows examples of the three types of promoters.

The promoter used by RNA polymerase I—that is, the promoter of the transcription unit that produces the precursor for the three largest rRNAs—has two parts (Figure 21-11a). The part called the **core promoter**—defined as the smallest set of DNA sequences able to direct the accurate initiation of transcription by RNA polymerase—actually extends into the nucleotide sequence to be transcribed. The core promoter is sufficient for proper initiation of transcription, but transcription is made more efficient by the presence of an *upstream control element*, which for RNA polymerase I is a fairly long sequence similar (though not identical) to the core promoter. Attachment of transcription factors to both parts of the promoter facilitates the binding of RNA polymerase I to the core promoter and enables it to initiate transcription at the startpoint.

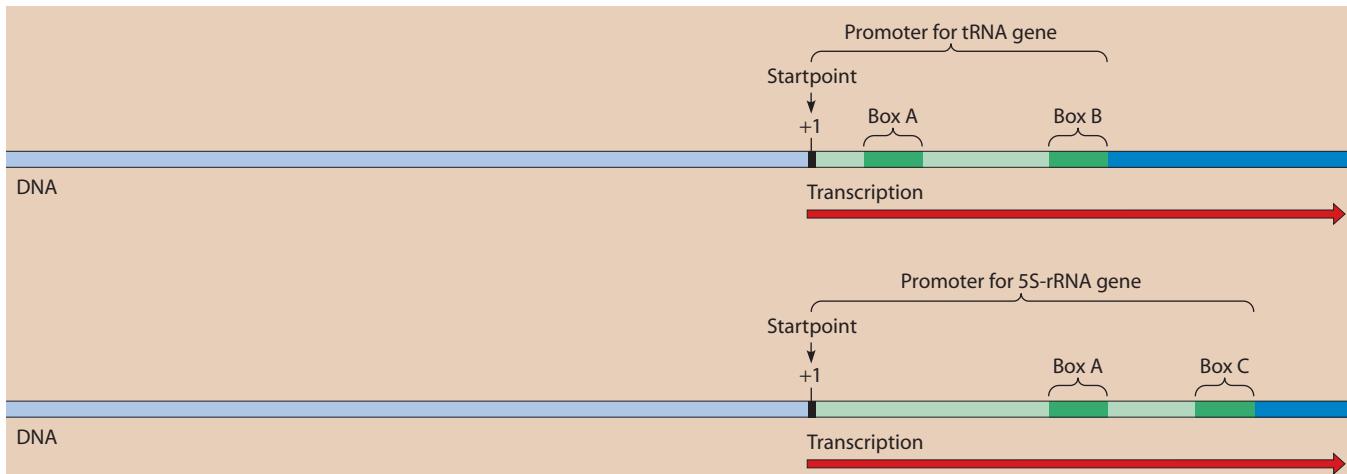

In the case of RNA polymerase II, at least four types of DNA sequences are involved in core promoter function (Figure 21-11b). These four elements are (1) a short **initiator (Inr)** sequence surrounding the transcription startpoint (which is often an A, as in bacteria); (2) the **TATA box**, which consists of a consensus sequence of

(a) Promoter for RNA polymerase I

(b) Core promoter elements for RNA polymerase II

(c) Two types of promoters for RNA polymerase III

FIGURE 21-11 Examples of Eukaryotic Promoters For RNA Polymerases I, II, and III. (a) The promoter for RNA polymerase I has two parts, a core promoter surrounding the startpoint and an upstream control element. After the binding of appropriate transcription factors to both parts, the RNA polymerase binds to the core promoter. (b) The typical promoter for RNA polymerase II has a short initiator (Inr) sequence, consisting mostly of pyrimidines (Py), combined with either a TATA box or a downstream promoter element (DPE). Promoters containing a TATA box may also include a TFIIB recognition element (BRE) as part of the core promoter. (c) The promoters for RNA polymerase III vary in structure, but the ones for tRNA genes and 5S-rRNA genes are located entirely downstream of the startpoint, within the transcribed sequence. Boxes A, B, and C are DNA consensus sequences, each about 10 bp long. In tRNA genes, about 30–60 bp of DNA separate boxes A and B. In 5S-rRNA genes, about 10–30 bp separate boxes A and C.

TATA followed by two or three more A's, usually located about 25 nucleotides upstream from the startpoint; (3) the **TFIIB recognition element (BRE)** located slightly upstream of the TATA box; and (4) the **downstream promoter element (DPE)** located about 30 nucleotides downstream from the startpoint. These four elements are organized into two general types of core promoters: **TATA-driven promoters**, which contain an Inr sequence and a TATA box with or without an associated BRE, and **DPE-driven promoters**, which contain DPE and Inr sequences but no TATA box or BRE. Besides being found

in eukaryotes, TATA-driven promoters are also present in archaea, a key piece of evidence supporting the idea that in some ways, archaea resemble eukaryotes more closely than they resemble bacteria (page 76).

By itself, a core promoter (TATA-driven or DPE-driven) is capable of supporting only a *basal* (low) level of transcription. However, most protein-coding genes have additional short sequences further upstream—*upstream control elements*—that improve the promoter's efficiency. Some of these upstream elements are common to many different genes; examples include the **CAAT box** (consensus

sequence GCCCAATCT in animals and yeasts) and the *GC box* (consensus sequence GGGCGG). The locations of these elements relative to a gene's startpoint vary from gene to gene. The elements within 100–200 nucleotides of the startpoint are often called *proximal control elements* to distinguish them from *enhancer* elements, which tend to be farther away and can even be located downstream of the gene. We will return to proximal control elements and enhancers in Chapter 23.

The sequences important in promoter activity are often identified by deleting specific sequences from a cloned DNA molecule, which is then tested for its ability to serve as a template for gene transcription, either in a test tube or after introduction of the DNA into cultured cells. For example, when transcription of the gene for β -globin (the β chain of hemoglobin) is investigated in this way, deletion of either the TATA box or an upstream CAAT box reduces the rate of transcription at least tenfold.

In contrast to RNA polymerases I and II, the RNA polymerase III molecule uses promoters that are entirely *downstream* of the transcription unit's startpoint when transcribing genes for tRNAs and 5S rRNA. The promoters used by tRNA and 5S-rRNA genes are different, but in both cases the consensus sequences fall into two blocks of about 10 bp each (Figure 21-11c). The tRNA promoter has consensus sequences called *box A* and *box B*. The promoters for 5S-rRNA genes have box A (positioned farther from the startpoint than in tRNA-gene promoters) and another critical sequence, called *box C*. (Not shown in the figure is a third type of RNA polymerase III promoter, an upstream promoter that is used for the synthesis of other kinds of small RNA molecules.)

The promoters used by all the eukaryotic RNA polymerases must be recognized and bound by transcription factors before the RNA polymerase molecule can bind to DNA. We turn now to these transcription factors.

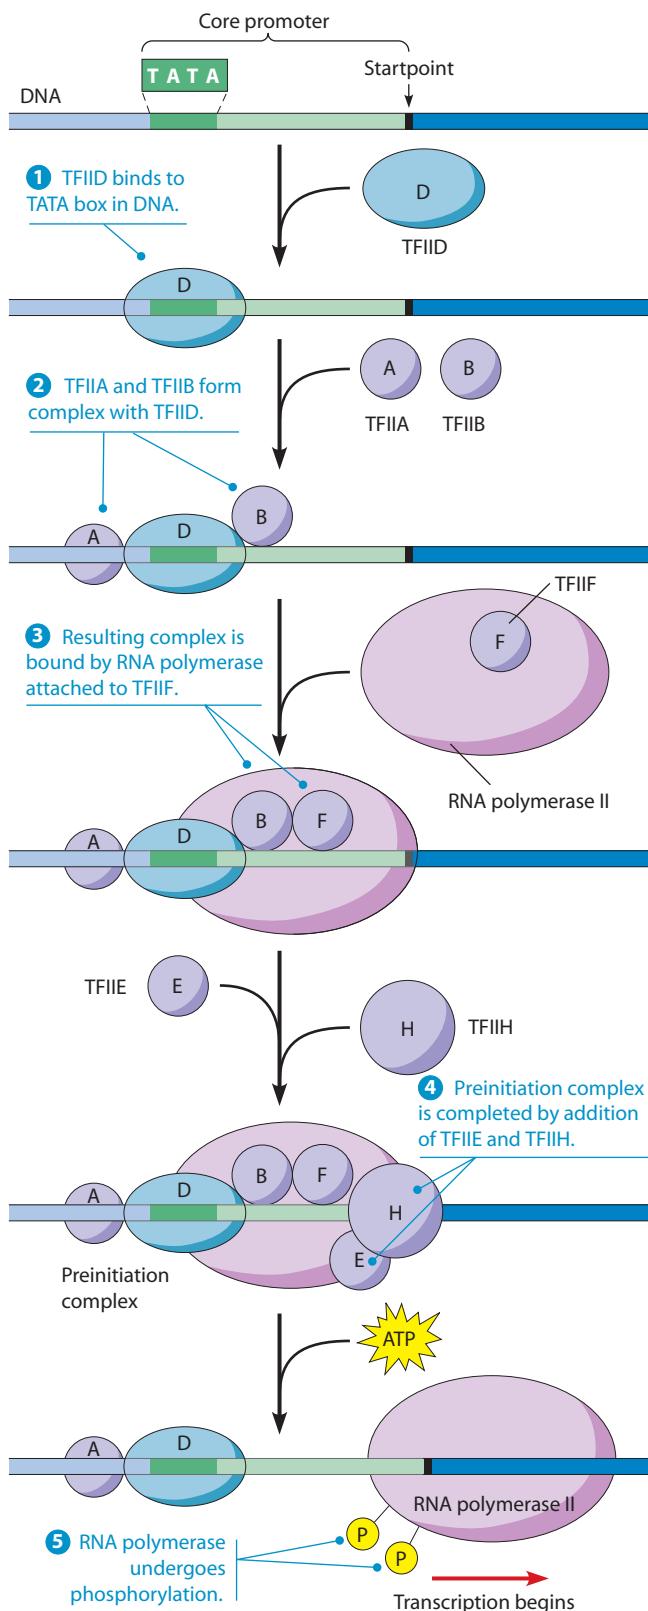

General Transcription Factors Are Involved in the Transcription of All Nuclear Genes

A **general transcription factor** is a protein that is always required for an RNA polymerase molecule to bind to its promoter and initiate RNA synthesis, regardless of the identity of the gene involved. Eukaryotes have many such transcription factors; their names usually include "TF" (for transcription factor), a roman numeral identifying the

FIGURE 21-12 Role of General Transcription Factors in Binding RNA Polymerase II to DNA. This figure outlines the sequential binding of six general transcription factors (called TFII_{_}, where _{_} is a letter identifying the particular factor) and RNA polymerase. After the final activation step involving ATP-dependent phosphorylation of the RNA polymerase molecule, the polymerase can initiate transcription. In intact chromatin, the efficient binding of general transcription factors and RNA polymerase to DNA requires the participation of additional regulatory proteins that open up chromatin structure and facilitate assembly of the preinitiation complex at specific genes (see Figure 23-23).

polymerase they aid, and a capital letter that identifies each individual factor (for example, TFIIA, TFIIB, and so forth).

Using RNA polymerase II as an example, **Figure 21-12** illustrates the involvement of general transcription factors in the binding of RNA polymerase to a TATA-containing promoter site in DNA. General transcription

factors bind to promoters in a defined order, starting with TFIID. Notice that while TFIID binds directly to a DNA sequence (the TATA box in this example or the DPE sequence in the case of DPE-driven promoters), the other transcription factors interact primarily with each other. Hence, protein-protein interactions play a crucial role in the binding stage of eukaryotic transcription. RNA polymerase II does not bind to the DNA until several steps into the process. Eventually, a large complex of proteins, including RNA polymerase, becomes bound to the promoter region to form a *preinitiation complex*.

Before RNA polymerase II can actually initiate RNA synthesis, it must be released from the preinitiation complex. A key role in this process is played by the general transcription factor TFIIH, which possesses both a helicase activity that unwinds DNA and a protein kinase activity that catalyzes the phosphorylation of RNA polymerase II. Phosphorylation changes the shape of RNA polymerase, thereby releasing it from the transcription factors so that it can initiate RNA synthesis at the start-point. At the same time, the helicase activity of TFIIH is thought to unwind the DNA so that the RNA polymerase molecule can begin to move.

TFIID, the initial transcription factor to bind to the promoter, is worthy of special note. Its ability to recognize and bind to DNA promoter sequences is conferred by one of its subunits, the **TATA-binding protein (TBP)**, which combines with a variable number of additional protein subunits to form TFIID. Despite its name, the ability of TBP to bind to DNA, illustrated in **Figure 21-13**,

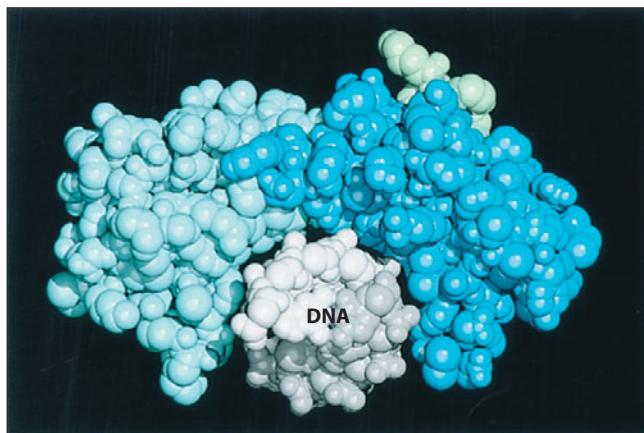

FIGURE 21-13 TATA-Binding Protein (TBP) Bound to DNA. In this computer graphic model, TBP is shown bound to DNA (white and gray, viewed looking down its axis). TBP differs from most DNA-binding proteins in that it interacts with the minor groove of DNA, rather than the major groove, and imparts a sharp bend to the DNA. The TBP molecule shown here is from the plant *Arabidopsis thaliana*, but TBP has been highly conserved during evolution. Dark and light blue differentiate the two symmetrical domains of the polypeptide, and light green is used for its nonconserved N-terminal segment. When TBP is bound to DNA, other transcription factors can interact with the convex surface of the TBP “saddle.” TBP is involved in transcription initiation for all types of eukaryotic promoters.

is not restricted to TATA-containing promoters. TBP can also bind to promoters lacking a TATA box, including promoters used by RNA polymerases I and III. Depending on the type of promoter, TBP associates with different proteins, and for promoters lacking a TATA box, much of TBP’s specificity is probably derived from its interaction with these associated proteins.

In addition to general transcription factors and RNA polymerase II, several other kinds of proteins are required for the efficient transcription and regulated activation of specific genes. Some of these proteins are involved in opening up chromatin structure to facilitate the binding of RNA polymerase to DNA. Others are *regulatory transcription factors*, which activate specific genes by binding to upstream control elements and recruiting *coactivator proteins* that in turn facilitate assembly of the RNA polymerase preinitiation complex. The identities and roles of these additional proteins will be described in Chapter 23, which covers the regulation of gene expression (see Figure 23-22).

Elongation, Termination, and RNA Cleavage Are Involved in Completing Eukaryotic RNA Synthesis

After initiating transcription, RNA polymerases move along the DNA and synthesize a complementary RNA copy of the DNA template strand. Special proteins facilitate the disassembly of nucleosomes in front of the moving polymerase and their immediate reassembly after the enzyme passes. If an area of DNA damage is encountered, RNA polymerase may become stalled temporarily while the damage is corrected by proteins that carry out DNA excision repair (page 568).

Termination of transcription is governed by an assortment of signals that differ for each type of RNA polymerase. For example, transcription by RNA polymerase I is terminated by a protein factor that recognizes an 18-nucleotide termination signal in the growing RNA chain. Termination signals for RNA polymerase III are also known; they always include a short run of U’s (as in bacterial termination signals), and no ancillary protein factors are needed for their recognition. Hairpin structures do not appear to be involved in termination by either polymerase I or polymerase III.

For RNA polymerase II, transcripts destined to become mRNA are often cleaved at a specific site before transcription is actually terminated. The cleavage site is 10–35 nucleotides downstream from a special AAUAAA sequence in the growing RNA chain. The polymerase may continue transcription for hundreds or even thousands of nucleotides beyond the cleavage site, but this additional RNA is quickly degraded. The cleavage site is also the site for the addition of a *poly(A) tail*, a string of adenine nucleotides found at the 3’ end of almost all eukaryotic mRNAs. Addition of the poly(A) tail is part of RNA processing, our next topic.

RNA Processing

An RNA molecule newly produced by transcription, called a **primary transcript**, frequently must undergo chemical changes before it can function in the cell. We use the term **RNA processing** to mean all the chemical modifications necessary to generate a final RNA product from the primary transcript that serves as its precursor. Processing typically involves removal of portions of the primary transcript, and it may also include the addition or chemical modification of specific nucleotides. For example, methylation of bases or ribose groups is a common modification of individual nucleotides. In addition to chemical modifications, other posttranscriptional events, such as association with specific proteins or (in eukaryotes) passage from the nucleus to the cytoplasm, are often necessary before the RNA can function.

In this section, we examine the most important processing steps involved in the production of rRNA, tRNA, and mRNA from their respective primary transcripts. Although the term *RNA processing* is most often associated with eukaryotic systems, bacteria process some of their RNA as well. We therefore include examples involving both eukaryotic and bacterial RNAs.

Ribosomal RNA Processing Involves Cleavage of Multiple rRNAs from a Common Precursor

Ribosomal RNA (rRNA) is by far the most abundant and most stable form of RNA found in cells. Typically, rRNA represents about 70–80% of the total cellular RNA, tRNA represents about 10–20%, and mRNA accounts for less than 10%. In eukaryotes, cytoplasmic ribosomes contain four types of rRNA, usually identified by their differing sedimentation rates during centrifugation (page 95). **Table 21-2** lists the sedimentation coefficients (S values) of these different types of rRNA. The smaller of the two ribosomal subunits has a single 18S rRNA molecule. The larger subunit contains three rRNA molecules, one of about 28S (as low as 25S in some species) and the other two of about 5.8S and 5S. In bacterial ribosomes, only

three species of rRNA are present: a 16S molecule associated with the small subunit and molecules of 23S and 5S associated with the large subunit.

Of the four kinds of rRNA in eukaryotic ribosomes, the three larger ones (28S, 18S, and 5.8S) are encoded by a single transcription unit that is transcribed by RNA polymerase I in the nucleolus to produce a single primary transcript called **pre-rRNA** (**Figure 21-14**). The DNA sequences that code for these three rRNAs are separated within the transcription unit by segments of DNA called *transcribed spacers*. The presence of three different rRNA genes within a single transcription unit ensures that the cell makes these three rRNAs in equal quantities. Most eukaryotic genomes have multiple copies of the pre-rRNA transcription unit, arranged in one or more tandem arrays (Figure 21-14a). These multiple copies facilitate production of the large amounts of ribosomal RNA typically needed by cells. The human haploid genome, for example, has 150–200 copies of the pre-rRNA transcription unit, distributed among five chromosomes. *Nontranscribed spacers* separate the transcription units within each cluster.

After RNA polymerase I has transcribed the pre-rRNA transcription unit, the resulting pre-rRNA molecule is processed by a series of cleavage reactions that remove the transcribed spacers and release the mature rRNAs (Figure 21-14c, d). The transcribed spacer sequences are then degraded. The pre-rRNA is also processed by the addition of methyl groups. The main site of methylation is the 2'-hydroxyl group of the sugar ribose, although a few bases are methylated as well. The methylation process, as well as pre-rRNA cleavage, are guided by a special group of RNA molecules, called **snoRNAs** (small nucleolar RNAs), which bind to complementary regions of the pre-rRNA molecule and target specific sites for methylation or cleavage.

Pre-rRNA methylation has been studied by incubating cells with radioactive *S-adenosyl methionine*, which is the methyl group donor for cellular methylation reactions. When human cells are incubated with radioactive S-adenosyl methionine, all of the radioactive methyl groups initially incorporated into the pre-rRNA molecule are eventually found in the finished 28S, 18S, and 5.8S rRNA products, indicating that the methylated segments are selectively conserved during rRNA processing. Methylation may help to guide RNA processing by protecting specific regions of the pre-rRNA molecule from cleavage. In support of this hypothesis, it has been shown that depriving cells of one of the essential components required for the addition of methyl groups leads to disruption of pre-rRNA cleavage patterns.

In mammalian cells, the pre-rRNA molecule has about 13,000 nucleotides and a sedimentation coefficient of 45S. The three mature rRNA molecules generated by cleavage of this precursor contain only about 52% of the original RNA. The remaining 48% (about 6200 nucleotides) consists of transcribed spacer sequences that are removed and degraded during the cleavage steps. The rRNA precursors of some other eukaryotes contain smaller amounts of spacer sequences, but in all cases the pre-rRNA is larger

Table 21-2 RNA Components of Cytoplasmic Ribosomes

Source	Ribosomal Subunit	rRNA	
		Sedimentation Coefficient	Nucleotides
Bacterial cells	Large (50S)	23S	2900
		5S	120
	Small (30S)	16S	1540
		5.8S	160
Eukaryotic cells	Large (60S)	25–28S	≤4700
		5S	120
		18S	1900

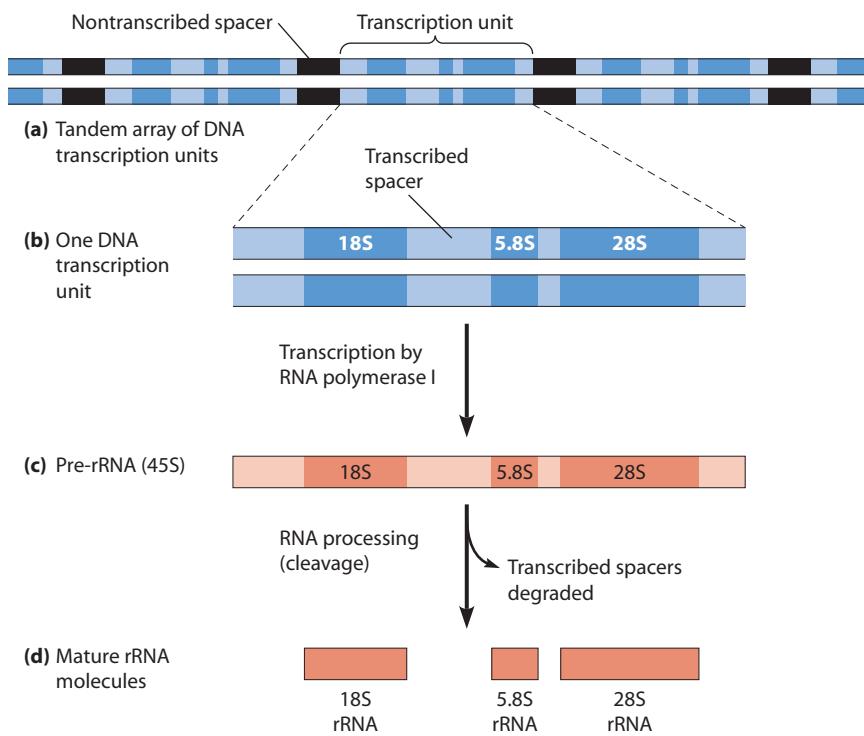

FIGURE 21-14 Eukaryotic rRNA Genes: Processing of Primary Transcripts. (a) The eukaryotic transcription unit that includes the genes for the three largest rRNAs occurs in multiple copies, arranged in tandem arrays. Nontranscribed spacers (black) separate the units. (b) Each transcription unit includes the genes for the three rRNAs (darker blue) and four transcribed spacers (lighter blue). (c) The transcription unit is transcribed by RNA polymerase I into a single long transcript (pre-rRNA) with a sedimentation coefficient of about 45S. (d) RNA processing yields mature 18S, 5.8S, and 28S rRNA molecules. RNA cleavage actually occurs in a series of steps. The order of steps varies with the species and cell type, but the final products are always the same three types of rRNA molecules.

than the aggregate size of the three rRNA molecules made from it. Thus, some processing is always required.

Processing of pre-rRNA in the nucleolus is accompanied by assembly of the RNA with proteins to form ribosomal subunits. In addition to the 28S, 18S, and 5.8S rRNAs generated by pre-rRNA processing, the ribosome assembly process also requires 5S rRNA. The gene for 5S rRNA constitutes a separate transcription unit that is transcribed by RNA polymerase III rather than RNA polymerase I. It, too, occurs in multiple copies arranged in long, tandem arrays. However, 5S-rRNA genes are not usually located near the genes for the larger rRNAs and so do not tend to be associated with the nucleolus. Unlike pre-rRNA, the RNA molecules generated during transcription of 5S-rRNA genes require little or no processing.

As in eukaryotes, ribosome formation in prokaryotic cells involves processing of multiple rRNAs from a larger precursor. *E. coli*, for example, has seven rRNA transcription units scattered about its genome. Each contains genes for all three bacterial rRNAs—23S rRNA, 16S rRNA, and 5S rRNA—plus several tRNA genes. Processing of the primary transcripts produced from these transcription units involves two sets of enzymes, one for the rRNAs and one for the tRNAs.

Transfer RNA Processing Involves Removal, Addition, and Chemical Modification of Nucleotides

Cells synthesize several dozen kinds of tRNA molecules, each designed to bring a particular amino acid to one or more codons in mRNA. However, all tRNA molecules

share a common general structure, as illustrated in Figure 21-15. A mature tRNA molecule contains only 70–90 nucleotides, some of which are chemically modified. Base pairing between complementary sequences located in different regions causes each tRNA molecule to fold into a secondary structure containing several *hairpin loops*, illustrated in the figure. Most tRNAs have four base-paired regions, indicated by the light blue dots in part b of the figure. In some tRNAs, a fifth such region is present at the *variable loop*. Each of these base-paired regions is a short stretch of RNA double helix. Molecular biologists call the tRNA secondary structure a *cloverleaf* structure because it resembles a cloverleaf when drawn in two dimensions. However, in its normal three-dimensional tertiary structure, the molecule is folded so that the overall shape actually resembles the letter “L” (see Figure 22-3b).

Like ribosomal RNA, transfer RNA is synthesized in a precursor form in both eukaryotic and prokaryotic cells. Processing of these **pre-tRNA** molecules involves several different events, as shown in Figure 21-15a for yeast tyrosine tRNA: ① At the 5' end, a short *leader sequence* of 16 nucleotides is removed from the pre-tRNA. ② At the 3' end, the two terminal nucleotides of the pre-tRNA are removed and replaced with the trinucleotide CCA, which is a common structural feature of all tRNA molecules. (Some tRNAs already have CCA in their primary transcripts and therefore do not require modification at the 3' end.) ③ In a typical tRNA molecule, about 10–15% of the nucleotides are chemically modified during pre-tRNA processing. The principal modifications include methylation of bases and sugars and creation of unusual bases such as dihydrouracil, ribothymine, pseudouridine, and inosine.

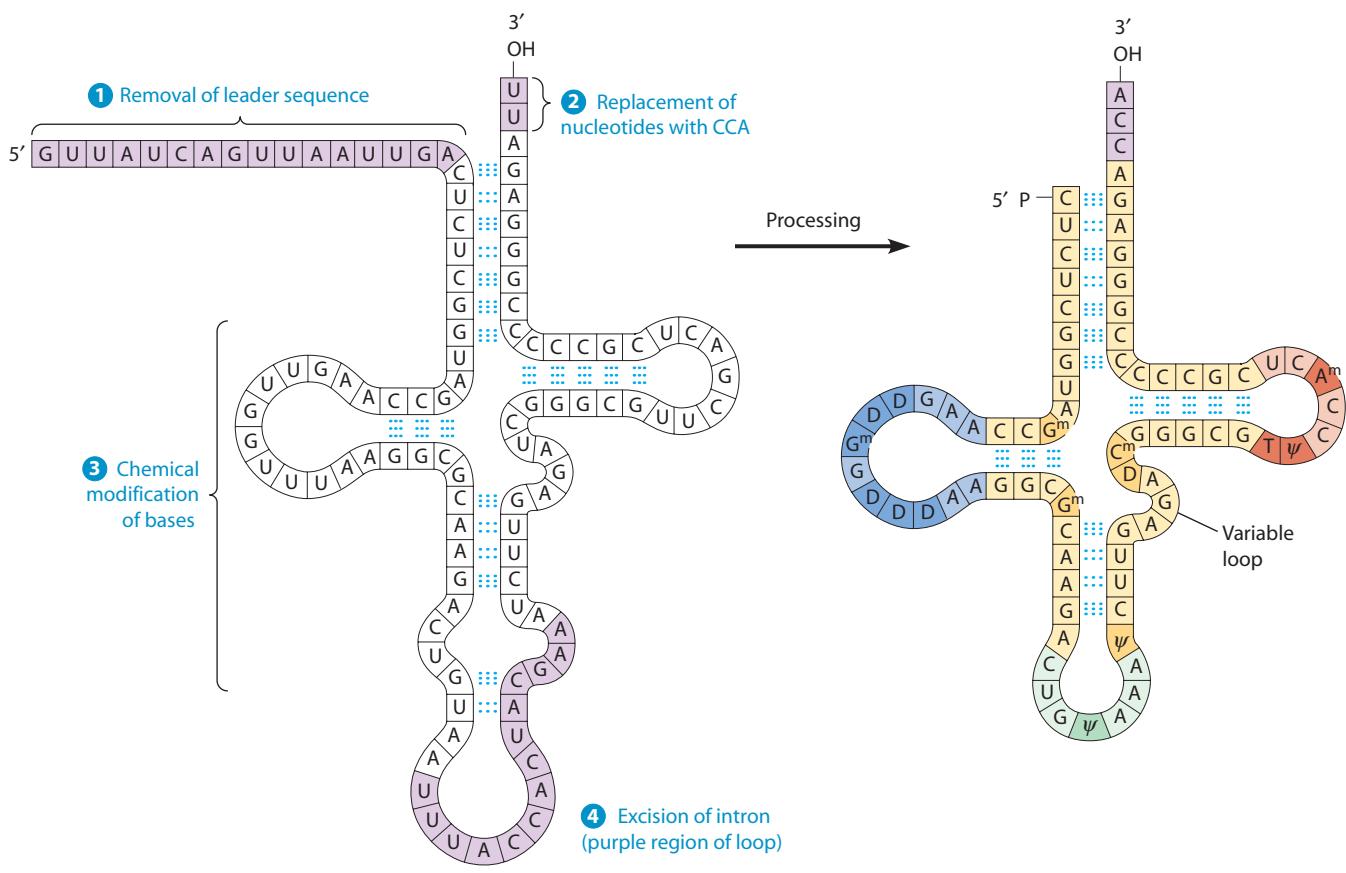

FIGURE 21-15 Processing and Secondary Structure of Transfer RNA. (a) Every tRNA gene is transcribed as a precursor that must be processed into a mature tRNA molecule. In this primary transcript for yeast tyrosine tRNA, all regions highlighted in purple are removed during processing. Processing for this tRNA involves ① removal of the leader sequence at the 5' end, ② replacement of two nucleotides at the 3' end by the sequence CCA (which serves as an attachment site for amino acids in all mature tRNAs), ③ chemical modification of certain bases, and ④ excision of an intron. (b) The mature tRNA in a flattened, cloverleaf representation, which clearly shows the base pairing between self-complementary stretches in the molecule. Modified bases (darker colors) are abbreviated as A^m for methyladenine, G^m for methylguanine, C^m for methylcytosine, D for dihydrouracil, T for ribothymine, and ψ for pseudouridine.

The processing of yeast tyrosine tRNA is also characterized by the removal of an internal 14-nucleotide sequence (④), although the transcripts for most tRNAs do not require this kind of excision. An internal segment of an RNA transcript that must be removed to create a mature RNA product is called an *RNA intron*. We will consider introns in more detail during our discussion of mRNA processing because they are a nearly universal feature of mRNA precursors in eukaryotic cells. For the present, we simply note that some eukaryotic tRNA precursors contain introns that must be eliminated by a precise mechanism that cuts and splices the precursor molecule at exactly the same location every time. The cutting-splicing mechanism involves two separate enzymes, an RNA endonuclease and an RNA ligase, which are similar from species to species, even among organisms that are evolutionarily distant from one another. In an experiment that demonstrates this point vividly, cloned genes for the yeast tyrosine tRNA shown in Figure 21-15

were microinjected into eggs of *Xenopus laevis*, the African clawed frog. Despite the long evolutionary divergence between fungi and amphibians, the yeast genes placed in the frog eggs were transcribed and processed properly, including removal of the 14-nucleotide intron.

Messenger RNA Processing in Eukaryotes Involves Capping, Addition of Poly(A), and Removal of Introns

Bacterial mRNA is, in almost all cases, an exception to the generalization that RNA requires processing before it can be used by the cell. Most bacterial mRNA is synthesized in a form that is ready for translation, even before the entire RNA molecule has been completed. Moreover, transcription in bacteria is not separated by a membrane barrier from the ribosomes responsible for translation, so bacterial mRNA molecules in the process of being synthesized by RNA polymerase often have ribosomes already associated

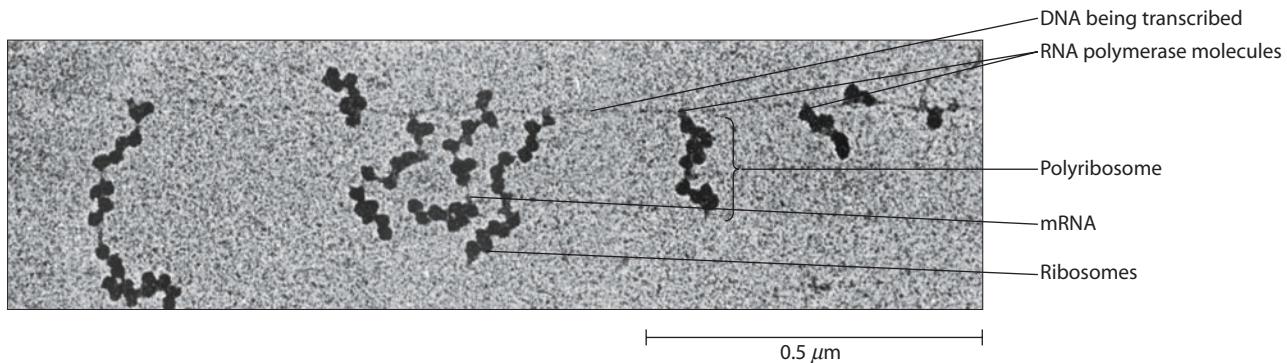

FIGURE 21-16 Coupling of Transcription and Translation in Bacterial Cells. This electron micrograph shows *E. coli* DNA being transcribed by RNA polymerase molecules that are moving from right to left. Attached to each polymerase molecule is a strand of mRNA still in the process of being transcribed. The large dark particles attached to each growing mRNA strand are ribosomes that are actively translating the partially complete mRNA. (The polypeptides being synthesized are not visible.) A cluster of ribosomes attached to a single mRNA strand is called a polyribosome (TEM).

with them. The electron micrograph in **Figure 21-16** shows this coupling of transcription and translation in a bacterial cell.

In contrast, transcription and translation in eukaryotic cells are separated in both time and space: Transcription takes place in the nucleus, whereas translation occurs mainly in the cytoplasm. Substantial processing is required in the nucleus to convert primary transcripts into mature mRNA molecules that are ready to be transported to the cytoplasm and translated. Primary transcripts are often very long, typically ranging from 2000 to 20,000 nucleotides. This size heterogeneity is reflected in the term *heterogeneous nuclear RNA (hnRNA)*, which refers to the nonribosomal, nontransfer RNA found in eukaryotic nuclei. hnRNA consists of a mixture of mRNA molecules and their precursors, **pre-mRNA**. Conversion of pre-mRNA molecules into functional mRNAs usually requires the removal of nucleotide sequences and the addition of 5' caps and 3' tails, as will be described in the following sections. The C-terminal domain of one of the subunits of RNA polymerase II plays a key role in coupling these RNA processing events to transcription, presumably by acting as a platform for the assembly of the protein complexes involved in pre-mRNA processing.

5' Caps and 3' Poly(A) Tails. Most eukaryotic mRNA molecules bear distinctive modifications at both ends. At the 5' end, they all possess a modified nucleotide called a **5' cap**, and at the 3' end they usually have a long stretch of adenine ribonucleotides known as a **poly(A) tail**.

A 5' cap is simply a guanosine nucleotide that has been methylated at position 7 of the purine ring and is “backward”—that is, the bond joining it to the 5' end of the RNA molecule is a 5' → 5' linkage rather than the usual 3' → 5' bond (**Figure 21-17**). This distinctive feature of eukaryotic mRNA is added to the primary transcript shortly after initiation of RNA synthesis. As part of the capping process, the ribose rings of the first,

and often the second, nucleotides of the RNA chain can also become methylated, as shown in Figure 21-17. The 5' cap contributes to mRNA stability by protecting the molecule from degradation by nucleases that attack RNA at the 5' end. The cap also plays an important role in positioning mRNA on the ribosome for the initiation of translation.

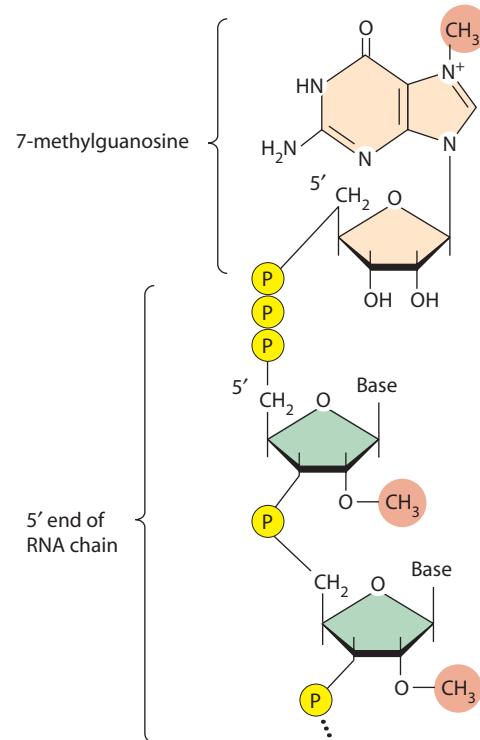

FIGURE 21-17 Cap Structure Located at the 5' End of Eukaryotic Pre-mRNA and mRNA Molecules. The methyl groups attached to the first two riboses at the 5' end of the RNA chain are not always present. Notice that the bond joining the RNA to 7-methylguanosine is a 5' -to-5' linkage rather than the usual 5' -to-3' linkage.

In addition to the 5' cap, a poly(A) tail ranging from 50–250 nucleotides in length is present at the 3' end of most eukaryotic mRNA molecules. (In animal cells, mRNAs coding for the major histones are among the few mRNAs known to lack such a poly(A) tail.) It is clear that poly(A) must be added after transcription because genes do not contain long stretches of thymine (T) nucleotides that could serve as a template for the addition of poly(A). Direct support for this conclusion has come from the isolation of the enzyme *poly(A) polymerase*, which catalyzes the addition of poly(A) sequences to RNA without requiring a DNA template.

The addition of poly(A) is part of the process that creates the 3' end of most eukaryotic mRNA molecules. Unlike bacteria, where specific termination sequences halt transcription at the 3' end of newly forming mRNAs, the transcription of eukaryotic pre-mRNAs often proceeds hundreds or even thousands of nucleotides beyond the site destined to become the 3' end of the final mRNA molecule. A special signal—consisting of an AAUAAA sequence located slightly upstream from this site and a GU-rich and/or U-rich element downstream from the site—determines where the poly(A) tail should be added. As shown in **Figure 21-18**, this signaling element triggers cleavage of the primary transcript 10–35 nucleotides downstream from the AAUAAA sequence, and poly(A) polymerase catalyzes formation of the poly(A) tail. In addition to creating the poly(A) tail, the processing events associated with the AAUAAA signal may also help to trigger the termination of transcription.

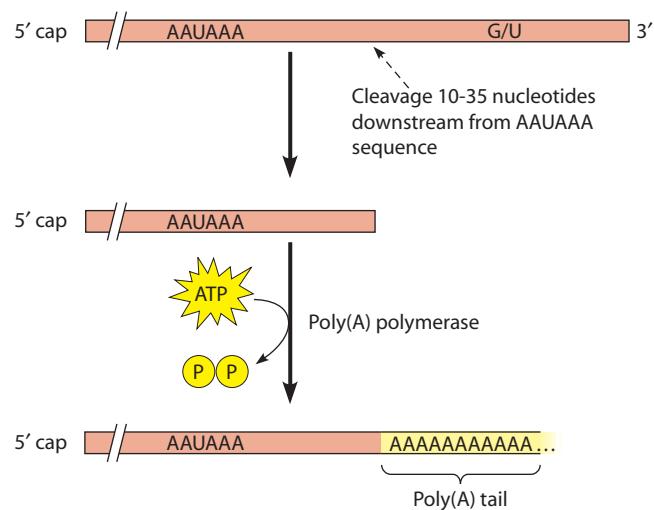

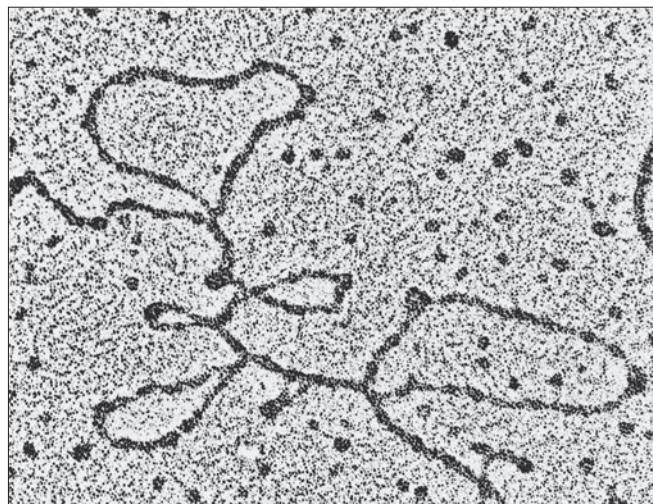

FIGURE 21-18 Addition of a Poly(A) Tail to Pre-mRNA.

Transcription of eukaryotic pre-mRNAs often proceeds beyond the 3' end of the mature mRNA. The RNA chain is then cleaved about 10–35 nucleotides downstream from a special AAUAAA sequence, followed by the addition of a poly(A) tail catalyzed by poly(A) polymerase. The proper AAUAAA sequence is distinguished by the presence of an accompanying downstream GU-rich and/or U-rich element (designated "G/U" in the diagram).

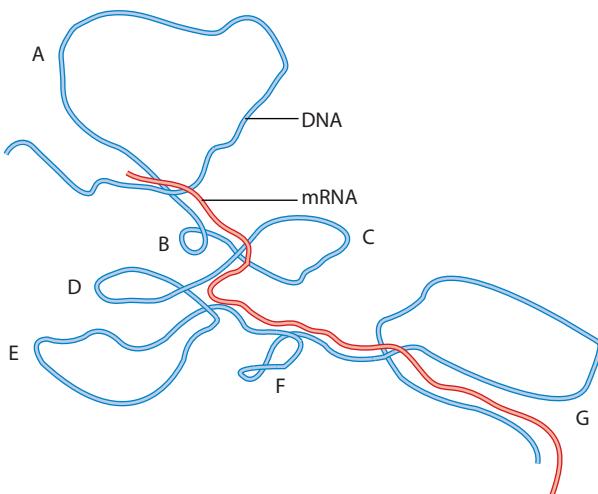

The poly(A) tail seems to have several functions. Like the 5' cap, it protects mRNA from nuclease attack and, as a result, the length of the poly(A) influences mRNA stability (the longer the tail, the longer the life span of the mRNA in the cytoplasm). In addition, poly(A) is recognized by specific proteins involved in exporting mRNA from the nucleus to the cytoplasm, and it may also help ribosomes recognize mRNA as a molecule to be translated. In the laboratory, poly(A) tails can be used to isolate mRNA from the more prevalent rRNA and tRNA. RNA extracted from cells is simply passed through a column packed with particles coated with poly(dT), which are single strands of DNA consisting solely of thymine nucleotides. Molecules with poly(A) tails bind to the poly(dT) via complementary base pairing, while other RNA molecules pass through. The poly(A)-containing mRNA can then be removed from the column by changing the ionic conditions.

The Discovery of Introns. In eukaryotic cells, the precursors for most mRNAs (and for some tRNAs and rRNAs) contain **introns**, which are *sequences within the primary transcript that do not appear in the mature, functional RNA*. The discovery of introns was a great surprise to biologists. It had already been shown for numerous bacterial genes that the amino acid sequence of the polypeptide chain produced by a gene corresponds exactly with a sequence of contiguous nucleotides in DNA. This relationship was first demonstrated by Charles Yanofsky in the early 1960s and, as better methods for sequencing DNA and proteins became available, was confirmed by direct comparison of nucleotide and amino acid sequences. Biologists naturally assumed the same would turn out to be true for eukaryotes.

It was therefore a shock in 1977 when Philip Sharp and Richard Roberts independently reported the identification of eukaryotic genes that do not follow this pattern but are instead interrupted by stretches of nucleotides—**introns**—that are not represented in either the functional mRNA or its protein product. The widespread importance of introns in eukaryotes led to the awarding of the 1993 Nobel Prize in Medicine to Sharp and Roberts. The existence of introns was first shown by *R looping*, a technique in which single-stranded RNA is hybridized to double-stranded DNA under conditions that favor the formation of *heteroduplexes*, hybrids between complementary regions of RNA and DNA. The mRNA hybridizes to the template strand of the DNA, leaving the other, displaced strand as a single-stranded DNA loop that can be easily identified using electron microscopy. With eukaryotic mRNAs coding for such proteins as human β -globin and chick ovalbumin, the surprising result was that *multiple* loops were seen (**Figure 21-19**). This unexpected result indicated that the DNA sequences coding for a typical eukaryotic mRNA are not continuous with each other but instead are separated by intervening sequences that do not appear in the final mRNA. The intervening sequences that disrupt the linear continuity

(a)

(b)

FIGURE 21-19 Demonstration of Introns in Protein-Coding Genes. Mature mRNA molecules were allowed to hydrogen-bond to the DNA (gene) from which they had been transcribed, forming a hybrid molecule (heteroduplex). The resulting hybrid molecules were then examined with an electron microscope. The example shown here is the chicken ovalbumin gene. (a) An electron micrograph showing the loops produced in a heteroduplex (TEM). (b) An interpretive diagram showing the positions of the mRNA and the unpaired loops of DNA, which correspond to introns (A-G).

of the message-encoding regions of a gene are the introns (*intervening sequences*), and the sequences destined to appear in the final mRNA are referred to as **exons** (because they are *expressed*).

Once they had been reported for a few genes, introns began popping up everywhere. The use of restriction mapping and DNA sequencing techniques has led to the conclusion that introns are present in most protein-coding genes of multicellular eukaryotes, although the size and number of the introns can vary considerably (Table 21-3). The human β -globin gene, for example, has only two

Table 21-3 Examples of Genes with Introns

Gene	Organism	Number of Introns	Number of Exons
Actin	<i>Drosophila</i>	1	2
β -Globin	Human	2	3
Insulin	Human	2	3
Actin	Chicken	3	4
Albumin	Human	14	15
Thyroglobulin	Human	36	37
Collagen	Chicken	50	51
Titin	Human	233	234

introns, one of 120 bp and the other of 550 bp. Together, these account for about 40% of the total length of the gene. For many mammalian genes, an even larger fraction of the gene consists of introns. An extreme example is the human dystrophin gene, a mutant form of which causes Duchenne muscular dystrophy. This gene is over 2 million bp long and has 85 introns, representing more than 99% of the gene's DNA!

The discovery of introns that do not appear in mature mRNA molecules raises the question of whether the introns present in DNA are actually transcribed into the primary transcript (pre-mRNA). This question has been addressed by experiments in which pre-mRNA and DNA were mixed together and the resulting hybrids examined by electron microscopy. In contrast to the appearance of hybrids between mRNA and DNA, which exhibit multiple R loops where the DNA molecule contains sequences that are not present in the mRNA (Figure 21-19), pre-mRNA hybridizes in one continuous stretch to the DNA molecule, forming a single R loop. Scientists have therefore concluded that pre-mRNA molecules represent continuous copies of their corresponding genes, containing introns as well as sequences destined to become part of the final mRNA. This means that converting pre-mRNA into mRNA requires specific mechanisms for removing introns, as we now describe.

Spliceosomes Remove Introns from Pre-mRNA

To produce a functional mRNA from a pre-mRNA that contains introns, eukaryotes must somehow remove the introns and splice together the remaining RNA segments (exons). The entire process of removing introns and rejoining the exons is termed **RNA splicing**. As an example, Figure 21-20 shows both the primary transcript (pre-mRNA) of the β -globin gene and the mature end-product (mRNA) that results after removal of the two introns.

The relevance of RNA splicing for human health has become apparent from the discovery that roughly 15% of inherited human diseases involve splicing errors in pre-mRNA. Precise splicing is critical because a single nucleotide error would alter the mRNA reading frame and render it useless. Splicing precision can be disrupted by altering short base sequences at either end of an intron,

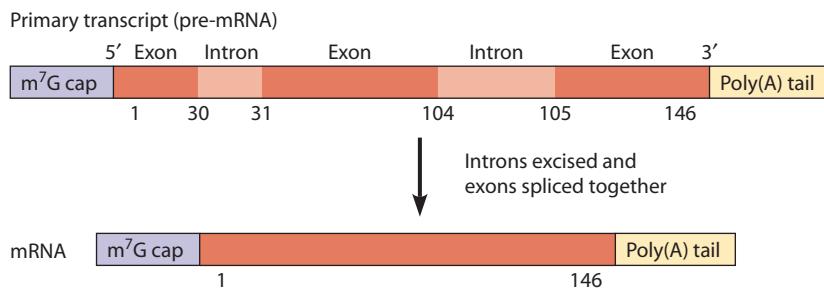

FIGURE 21-20 An Overview of RNA Splicing.

The capped and tailed primary transcript of the human gene for β -globin contains three exons (dark red) and two introns (light red). The numbers refer to codon positions in the final mRNA. In the mature mRNA that results from RNA splicing, the introns have been excised and the exons joined together to form a molecule with a continuous coding sequence. The cell's ribosomes will translate this message into a polypeptide of 146 amino acids.

ACTIVITIES www.thecellplace.com RNA splicing

suggesting that these sequences determine the location of the 5' and 3' splice sites—that is, the points where the two ends of an intron are cleaved during its removal. Analysis of the base sequences of hundreds of different introns has revealed that the 5' end of an intron typically starts with the sequence GU and the 3' end terminates with AG. In addition, a short stretch of bases adjacent to these GU and AG sequences tends to be similar among different introns. The base sequence of the remainder of the intron appears to be largely irrelevant to the splicing process. Though introns vary from a few dozen to thousands of nucleotides in length, most of the intron can be artificially removed without altering the splicing process. One exception is a special sequence located several dozen nucleotides upstream from the 3' end of the intron and referred to as

the *branch-point*. The branch-point plays an important role in the mechanism that removes introns.

Intron removal is catalyzed by **spliceosomes**, which are large, molecular complexes consisting of five kinds of RNA combined with more than 200 proteins. Electron microscopy has revealed that spliceosomes assemble on pre-mRNA molecules while the pre-mRNA is still being synthesized (Figure 21-21), indicating that intron removal can begin before transcription of pre-mRNA is completed. Spliceosomes are assembled on pre-mRNAs from a group of smaller RNA-protein complexes called **snRNPs** (small nuclear ribonucleoproteins) and additional proteins. Each snRNP (pronounced “snurp”) contains one or two small molecules of a special type of RNA known as **snRNA** (small nuclear RNA).

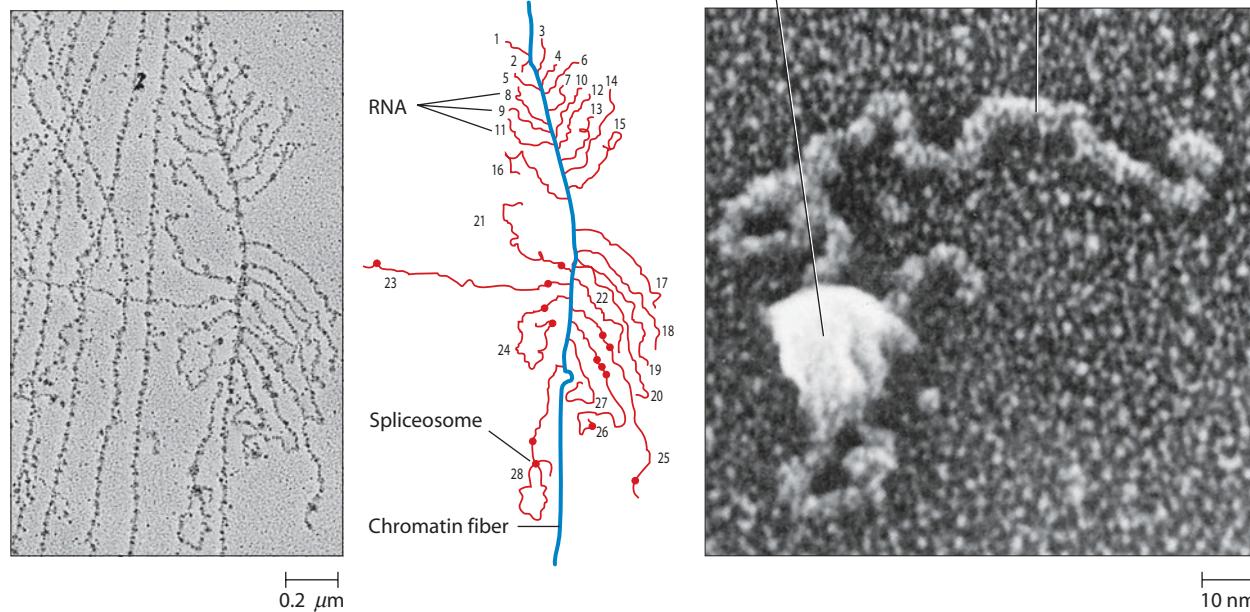

FIGURE 21-21 Spliceosomes Visualized by Electron Microscopy. The electron micrograph on the left shows chromatin fibers in the process of being transcribed. Many newly forming RNA transcripts (each numbered separately in the diagram) protrude from one of the chromatin fibers. The darker granules on the RNA transcripts represent snRNPs that are beginning the process of spliceosome assembly. In the case of RNA transcript number 28, a mature spliceosome has formed. The higher-magnification electron micrograph on the right shows a single RNA molecule with an attached spliceosome (TEMs).

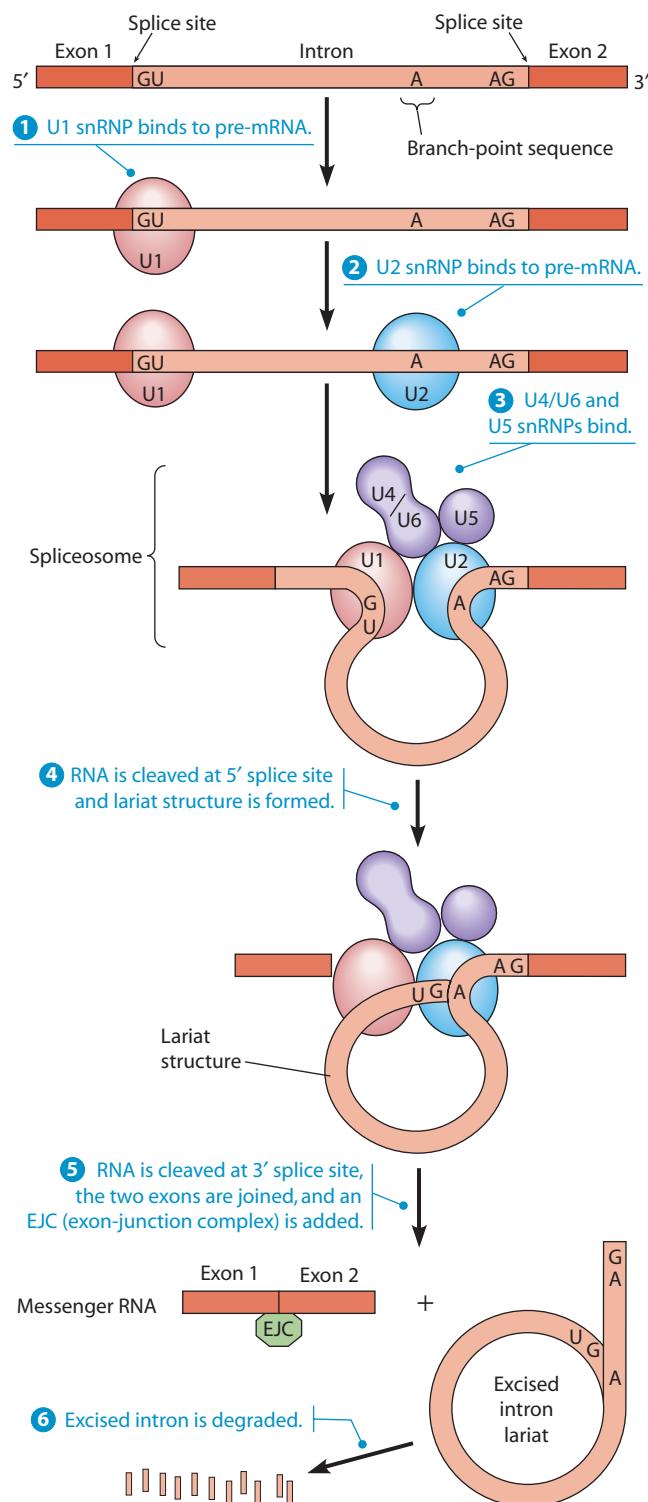

FIGURE 21-22 Intron Removal by Spliceosomes. The spliceosome is an RNA-protein complex that splices intron-containing pre-mRNA in the eukaryotic nucleus. The substrate here is a molecule of pre-mRNA with two exons and one intron. In a stepwise fashion, the pre-mRNA assembles with the U1 snRNP, U2 snRNP, and U4/U6 and U5 snRNPs (along with some non-snRNP splicing factors), forming a mature spliceosome. The pre-mRNA is then cleaved at the 5' splice site and the newly released 5' end is linked to an adenine (A) nucleotide located at the branch-point sequence, creating a looped lariat structure. Finally, the 3' splice site is cleaved and the two ends of the exon are joined together, releasing the intron for subsequent degradation.

Figure 21-22 summarizes how spliceosomes are assembled by the sequential binding of snRNPs to pre-mRNA. The first step is the binding of a snRNP called U1, whose RNA contains a nucleotide sequence that allows it to base-pair with the 5' splice site. A second snRNP, called U2, then binds to the branch-point sequence. Finally, another group of snRNPs (U4/U6 and U5) brings the two ends of the intron together to form a mature spliceosome, a massive complex comparable in size to a ribosome. At this stage the pre-mRNA is cleaved at the 5' splice site, and the newly released 5' end of the intron is covalently joined to an adenine residue located at the branch-point sequence, creating a looped structure called a *lariat*. The 3' splice site is then cleaved, and the two ends of the exon are joined together, releasing the intron for subsequent degradation. A multiprotein complex called an **exon junction complex (EJC)** is deposited near the boundary of each newly formed exon-exon junction. EJCs are required for the efficient export of mRNA from the nucleus. They also influence various regulatory events, including mRNA localization and translation.

In addition to the main class of introns containing GU and AG sequences at their 5' and 3' boundaries, respectively, a second class of introns with AU and AC at these two sites has been identified. These “AU-AC” introns are often excised by a second type of spliceosome that differs in snRNP composition from the spliceosome illustrated in Figure 21-22. But despite the complexities raised by the existence of multiple types of introns and spliceosomes, a unifying principle has emerged: The snRNA molecules present in spliceosomes are directly involved in splice-site recognition, spliceosome assembly, and the catalytic mechanism of splicing. The idea of a catalytic role for snRNAs arose from the discovery of self-splicing RNA introns, our next topic.

Some Introns Are Self-Splicing

Although the participation of spliceosomes is almost always required for intron removal, a few types of genes have *self-splicing RNA introns*. The RNA transcript of such a gene can carry out the entire process of RNA splicing in the absence of any protein (for example, in a test tube); the intron RNA itself catalyzes the process. As we described in Chapter 6, such RNA molecules that function as catalysts in the absence of protein are called *ribozymes*.

There are two classes of introns in which the intron RNA can function as a ribozyme to catalyze its own removal. The first class, called *Group I introns*, is present in the mitochondrial genome of fungi (e.g., yeast) in rRNA genes and in genes coding for components of the electron transport system. Group I introns also occur in plant mitochondrial genes, in some rRNA and tRNA genes of chloroplasts, in nuclear rRNA genes of some unicellular eukaryotes, in some tRNA genes in bacteria, and in a few

bacteriophage genes coding for mRNAs. Group I RNA introns are excised in the form of linear RNA fragments.

In contrast, *Group II introns* are excised as lariats in which an adenine within the intron forms the branch-point, just as in the spliceosome mechanism. Group II introns are found in some mitochondrial and chloroplast genes of plants and unicellular eukaryotes and in the genomes of some archaea and bacteria. Biologists think that today's prevailing splicing mechanism, based on spliceosomes, evolved from Group II introns, with the intron RNA's catalytic role being taken over by the snRNA molecules of the spliceosome. Support for this idea has come from the discovery that protein-free RNA molecules isolated from spliceosomes are capable of catalyzing the first step in the splicing reaction involving the branch-point adenine.

The Existence of Introns Permits Alternative Splicing and Exon Shuffling

The burning questions about introns are: Why do nearly all genes in multicellular eukaryotes have them? Why do cells have so much DNA that seems to serve no coding function? Why, in generation after generation of cells, is so much energy invested in synthesizing segments of DNA—and their RNA transcripts—that appear to serve no useful function and are destined only for the splicing scrap heap?

In fact, it is not true that introns never perform any functions of their own. In a few cases, intron RNAs are processed to yield functional products rather than being degraded. For example, some types of snoRNA—whose role in guiding pre-rRNA methylation and cleavage was discussed earlier in the chapter—are derived from introns that are first removed from pre-mRNA and then processed to form snoRNA. And in a few cases, introns are even translated into proteins.

Despite these exceptions, most introns are destroyed without serving any obvious function. One benefit to such a seemingly wasteful arrangement is that the presence of introns allows each pre-mRNA molecule to be spliced in multiple ways, thereby generating anywhere from 2 or 3 to more than 100 different mRNAs (and hence polypeptides) from the same gene. This phenomenon, called **alternative splicing**, is made possible by mechanisms that allow certain splice sites to be either activated or skipped (**Figure 21-23**). Control over these splice sites is exerted by various molecules, including regulatory proteins and snoRNAs, that bind to *splicing enhancer* or *splicing silencer* sequences in pre-mRNAs. Binding of the appropriate regulatory molecule to a splicing enhancer or silencer leads to activation or skipping of individual splice sites, respectively.

The existence of alternative splicing may help explain how the biological complexity of vertebrates is achieved without a major increase in the number of genes compared to simpler organisms. (Recall from Chapter 18 that humans have barely more genes than a nematode worm does and 12,000 fewer genes than a rice plant does.) Instead of increasing the number of genes, humans transcribe the majority of their genes into pre-mRNAs that can be spliced in more than one way. As a result, the roughly 25,000 human genes produce mRNAs coding for hundreds of thousands of different polypeptides.

Another function of introns is that they allow the evolution of new protein-coding genes through recombination events that bring together new combinations of exons. At least two different mechanisms are involved, both based on the fact that introns are long stretches of DNA where genetic recombination can occur without harming coding sequences. First, genetic recombination between the introns of different genes will produce genes containing new combinations of exons—*exon shuffling*. Second, recombination

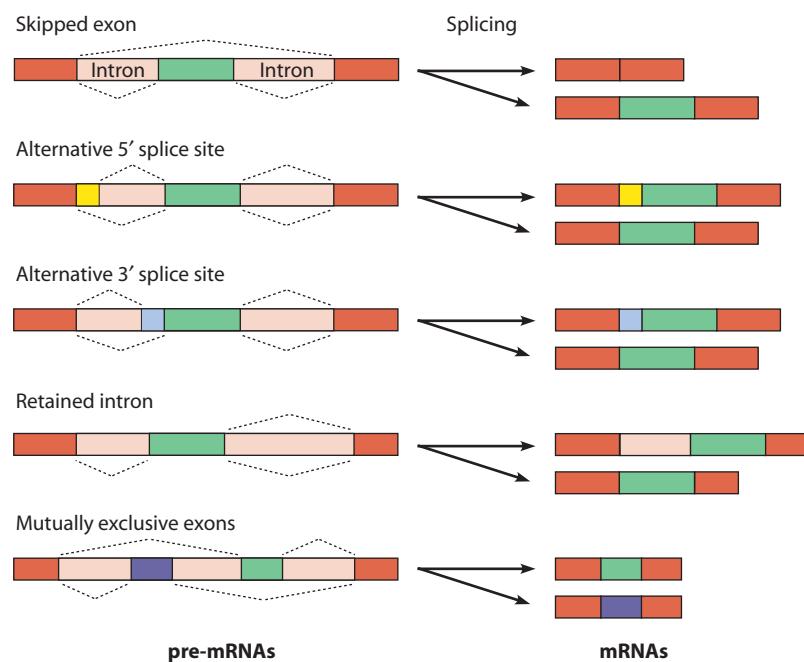

FIGURE 21-23 Some Examples of Alternative Splicing.

This diagram illustrates five alternative splicing mechanisms that allow different mRNAs to be produced from the same pre-mRNA by activating or skipping individual splice sites. The thin dashed lines above and below each pre-mRNA represent the splice sites that are used to generate the two different mRNAs shown for each example.

can also create duplicate copies of an individual exon within a single gene. The two copies could continue as exact duplicates, or one copy might mutate to a sequence that produces a new activity in the polypeptide encoded by that gene.

RNA Editing Allows mRNA Coding Sequences to Be Altered

About a decade after introns and RNA splicing were first discovered, molecular biologists were surprised by the discovery of yet another type of mRNA processing, called **RNA editing**. During RNA editing, anywhere from a single nucleotide to hundreds of nucleotides may be inserted, removed, or chemically altered within the coding sequence of an mRNA. Such changes can create new start or stop codons, or they can alter the reading frame of the message.

Some of the best-studied examples of RNA editing occur in the mitochondrial mRNAs of trypanosomes, which are parasitic protozoa. In these mRNAs, editing involves the insertion and deletion of multiple uracil nucleotides at various points in the mRNA. The information for this editing is located in small RNA molecules called *guide RNAs*, which are encoded by mitochondrial genes separate from the mRNA genes. In one proposed editing mechanism, hydrogen bonding causes short complementary regions of the guide RNA and mRNA to come together, and nearby sequences of U's in the guide RNA are then spliced into the mRNA.

A different type of editing occurs in the mitochondrial and chloroplast mRNAs of flowering plants. In these cases, nucleotides are neither inserted nor deleted, but C's are converted to U's (and vice versa) by deamination (and amidation) reactions. Similar base conversions have also been discovered in mRNAs transcribed from nuclear genes in animal cells. For example, a single codon in the mRNA transcribed from the mammalian apolipoprotein-B gene undergoes a C-to-U conversion during RNA editing. Another type of editing detected in animal cell nuclei converts adenosine (A) to inosine (I), which resembles guanosine (G) in its base-pairing properties. Such A-to-I editing has been detected in mRNAs produced by more than 1600 human genes, mostly in noncoding regions. The reason for putting I's in the untranslated regions of mRNAs is a mystery, but roles in regulating RNA stability, localization, and translation rate have been suggested.

The existence of RNA editing provides a reason to be cautious in inferring either polypeptide or RNA sequences from genomic DNA sequences. For example, many discrepancies were observed when the amino acid sequences of proteins produced by plant mitochondrial genes were first compared with the amino acid sequences that would be predicted based on the base sequence of mitochondrial DNA. Although some of these discrepancies can be explained by nonstandard codon usage in mitochondria (described earlier in the chapter), most of the unexpected amino acids arise because RNA editing alters the base sequence of various mRNA codons, leading to the incor-

poration of amino acids that would not have been expected based on a gene's DNA sequence.

Nucleic acid editing is not restricted to mRNAs. *MicroRNAs*—whose role in regulating gene expression is described in Chapter 23—are another class of RNAs that can be edited. And DNA is also subject to editing. For example, eukaryotes possess a DNA-editing enzyme called *APOBEC3G*, which inactivates retroviruses by catalyzing C-to-U conversions in the initial DNA strand produced when viral RNA is copied by reverse transcriptase (step ② in Figure 21A-1). The C-to-U conversions in the first strand lead to G-to-A conversions in the complementary DNA strand, thereby introducing mutations that debilitate the virus. To defend against this attack, HIV and other retroviruses produce a protein called *Vif*, which targets *APOBEC3G* for destruction. Because suppression of *APOBEC3G* is essential for successful retroviral infection, blocking the action of *Vif* might be a useful strategy for developing novel new treatments for HIV/AIDS.

Key Aspects of mRNA Metabolism

Before ending this chapter, we should note two key aspects of mRNA metabolism that are important to our overall understanding of how mRNA molecules behave within cells. These are the short life span of most mRNAs and the ability of mRNA to amplify genetic information.

Most mRNA Molecules Have a Relatively Short Life Span

Most mRNA molecules have a high *turnover rate*—that is, the rate at which molecules are degraded and then replaced with newly synthesized versions. In this respect, mRNA contrasts with the other major forms of RNA in the cell, rRNA and tRNA, which are notable for their stability. Because of its short life span, mRNA accounts for most of the transcriptional activity in many cells, even though it represents only a small fraction of the total RNA content. Turnover is usually measured in terms of a molecule's *half-life*, which is the length of time required for 50% of the molecules present at any given moment to degrade. The mRNA molecules of bacterial cells generally have half-lives of only a few minutes, whereas the half-lives of eukaryotic mRNAs range from several hours to a few days.

Since the rate at which a given mRNA is degraded determines the length of time it is available for translation, alterations in mRNA life span can affect the amount of protein a given message will produce. As you will learn in Chapter 23, regulation of mRNA life span is one of the mechanisms cells use to exert control over gene expression.

The Existence of mRNA Allows Amplification of Genetic Information

Because mRNA molecules can be synthesized again and again from the same stretch of template DNA, cells are provided with an important opportunity for *amplification*

of the genetic message. If DNA gene sequences were used directly in protein synthesis, the number of protein molecules that could be translated from any gene within a given time period would be strictly limited by the rate of polypeptide synthesis. But in a system using mRNA as an intermediate, multiple copies of a gene's informational content can be made, and each of these can be used in turn to direct the synthesis of the protein product.

As an especially dramatic example of this amplification effect, consider the synthesis of *fibroin*, the major protein of silk. The haploid genome of the silkworm has only one fibroin gene, but about 10^4 copies of fibroin mRNA are transcribed from the two copies of the gene in each diploid cell of the silk gland. Each of these mRNA

molecules, in turn, directs the synthesis of about 10^5 fibroin molecules, resulting in the production of more than 10^9 molecules of fibroin per cell—all within the four-day period it takes the worm to make its cocoon! Without mRNA as an intermediate, the genome of the silkworm would need 10^4 copies of the fibroin gene (or about 40,000 days!) to make a cocoon.

Significantly, most genes that code for proteins occur in only one or a few copies per haploid genome. In contrast, genes that code for rRNA and tRNA are always present in multiple copies. It is advantageous for cells to have many copies of genes whose final products are RNA (rather than protein) because in this case there is no opportunity for amplifying each gene's effect by repeated translation.

SUMMARY OF KEY POINTS

The Directional Flow of Genetic Information

- Instructions stored in DNA are transcribed and processed into molecules of mRNA, rRNA, and tRNA for use in protein synthesis.
- The base sequence of each mRNA molecule dictates the sequence of amino acids in a polypeptide chain.

The Genetic Code

- When guiding the synthesis of a polypeptide chain, mRNA is read in units of three bases called codons.
- The table of the genetic code indicates which amino acid (or stop signal) is specified by each codon. The code is unambiguous, nonoverlapping, degenerate, and nearly universal.

Transcription in Bacterial Cells

- Transcription is the process by which a DNA template strand is copied by RNA polymerase to produce a complementary molecule of RNA.
- The molecular mechanism of transcription involves four stages: (1) binding of RNA polymerase to promoter sequences in the DNA template strand, (2) initiation of RNA synthesis, (3) elongation of the RNA chain, and (4) termination.

Transcription in Eukaryotic Cells

- Transcription in eukaryotes involves the same general principles as in bacteria but is more complex. One major difference is that eukaryotic cells have multiple forms of RNA polymerase that are specialized for synthesizing different types of RNA.
- The three nuclear RNA polymerases recognize different families of DNA promoter sequences. These eukaryotic promoters are usually bound by transcription factors that associate with RNA polymerase rather than by RNA polymerase itself.

RNA Processing

- Newly forming RNA molecules must generally undergo some type of processing, both during and after transcription, before the RNA can perform its normal function. The major exception is bacterial mRNA, whose translation often begins before transcription is completed.
- RNA processing involves chemical alterations such as cleavage of multigene transcription units, removal of non-coding sequences, addition of sequences to the 3' and 5' ends, and insertion, removal, and chemical modification of individual nucleotides.
- Processing of eukaryotic pre-mRNA is especially elaborate, involving the addition of a 5' cap and a 3' poly(A) tail, as well as the removal of introns by spliceosomes or, in some cases, by a process catalyzed by intron RNA.
- The presence of introns and exons allows pre-mRNA molecules to be spliced in more than one way, thereby permitting a single gene to produce multiple mRNAs coding for different polypeptides.
- Various editing mechanisms allow the base sequence of mRNA molecules to be altered, thereby creating mRNAs that code for polypeptides whose amino acid sequences could not have been predicted by knowing the base sequence of the corresponding genes.

Key Aspects of mRNA Metabolism

- Most mRNAs have a relatively short life span.
- Active protein-coding genes are transcribed multiple times to produce many molecules of their corresponding mRNAs, thereby amplifying the amount of protein that each gene can produce.

MAKING CONNECTIONS

How does DNA—whose structure, replication, and sorting into daughter cells during mitosis and meiosis were described in Chapters 18 through 20—perform its role as the source of the genetic information that specifies cellular structure and behavior? In this chapter, you learned that the DNA base sequence of protein-coding genes specifies the amino acid sequence of polypeptide chains using a triplet code. The first step in the decoding process involves transcription of DNA base sequences into molecules of messenger RNA (mRNA). The principle underlying transcription is relatively easy to understand because it involves the transfer of information from one nucleic acid to another by complementary base pairing,

thereby keeping the basic “language” (i.e., nucleotide sequences) the same. But how, you may ask, does the sequence of nucleotides in an mRNA molecule specify the sequence of amino acids in a polypeptide chain? The answer will be provided in Chapter 22, where you will see how nucleotide sequences are translated into amino acid sequences during protein synthesis, a complex process involving ribosomes, transfer RNAs, and dozens of enzymes and protein factors. After Chapter 22 answers the question of how proteins are manufactured, folded, and distributed throughout the cell, the mechanisms responsible for regulating the production of protein molecules will be explored in Chapter 23.

PROBLEM SET

More challenging problems are marked with a •.

21-1 Triplets or Sextuplets? In his Nobel Prize lecture in 1962, Francis Crick pointed out that while the pioneering experiments he performed with Barnett, Brenner, and Watts-Tobin suggested that the DNA “code” is a triplet, their experiments did not rule out the possibility that the code could require six or nine bases.

- (a) Assuming the code is a triplet, what effect would adding or removing six or nine bases have on the reading frame of a piece of DNA?
(b) If the code actually were a sextuplet, how would addition of three, six, or nine nucleotides affect the reading frame of a piece of DNA?

21-2 The Genetic Code in a T-Even Phage. A portion of a polypeptide produced by bacteriophage T4 was found to have the following sequence of amino acids:

...Lys-Ser-Pro-Ser-Leu-Asn-Ala...

Deletion of a single nucleotide from one location in the T4 DNA template strand with subsequent insertion of a different nucleotide nearby changed the sequence to:

...Lys-Val-His-His-Leu-Met-Ala...

- (a) What was the nucleotide sequence of the mRNA segment that encoded this portion of the original polypeptide?
(b) What was the nucleotide sequence of the mRNA encoding this portion of the mutant polypeptide?
(c) Can you determine which nucleotide was deleted and which was inserted? Explain your answer.

21-3 Frameshift Mutations. Each of the mutants listed below this paragraph has a different mutant form of the gene encoding protein X. Each mutant gene contains one or more nucleotide insertions (+) or deletions (−) of the type caused by acridine dyes. Assume that all the mutations are located very near the beginning of the gene for protein X. In each case, indicate with an “OK” if you would expect the mutant protein to be nearly

normal and with a “Not OK” if you would expect it to be obviously abnormal.

- (a) − (b) −/+ (c) −/− (d) +/−/+
(e) +/−/+− (f) +/+/+ (g) +/+/−/+ (h) −/−/+−/−
(i) −/−/−/−/−

21-4 Amino Acid Substitutions in Mutant Proteins.

Although the codon assignments summarized in Figure 21-7 were originally deduced from experiments involving synthetic RNA polymers and triplets, their validity was subsequently confirmed by examining the amino acid sequences of normally occurring mutant proteins. The table below lists some examples of amino acid substitutions seen in mutant forms of hemoglobin, tryptophan synthase, and the tobacco mosaic virus coat protein. For each amino acid alteration, list the corresponding single-base changes in mRNA that could have caused that particular amino acid substitution.

Protein	Amino Acid Substitution
Hemoglobin	Glu → Val His → Tyr Asn → Lys
Coat protein of tobacco mosaic virus	Glu → Gly Ile → Val
Tryptophan synthase	Tyr → Cys Gly → Arg Lys → Stop

• 21-5 Locating Promoters. The following table provides data concerning the effects of various deletions in a eukaryotic gene coding for 5S rRNA on the ability of this gene to be transcribed by RNA polymerase III.

Nucleotides Deleted	Ability of 5S-rRNA Gene to Be Transcribed by RNA Polymerase III
−45 through −1	Yes
+1 through +47	Yes
+10 through +47	Yes
+10 through +63	No
+80 through +123	No
+83 through +123	Yes

- (a) What do these data tell you about the probable location of the promoter for this particular 5S-rRNA gene?
- (b) If a similar experiment were carried out for a gene transcribed by RNA polymerase I, what kinds of results would you expect?
- (c) If a similar experiment were carried out for a gene transcribed by RNA polymerase II, what kinds of results would you expect?

21-6 RNA Polymerases and Promoters. For each of the following statements about RNA polymerases, indicate with a B if the statement is true of the bacterial enzyme and with a I, II, or III if it is true of the respective eukaryotic RNA polymerase. A given statement may be true of any, all, or none (N) of these enzymes.

- (a) The enzyme is insensitive to α -amanitin.
- (b) The enzyme catalyzes an exergonic reaction.
- (c) All the primary transcripts must be processed before being used in translation.
- (d) The enzyme may sometimes be found attached to an RNA molecule that also has ribosomes bound to it.
- (e) The enzyme synthesizes rRNA.
- (f) Transcription factors must bind to the promoter before the polymerase can bind.
- (g) The enzyme adds a poly(A) sequence to mRNA.
- (h) The enzyme moves along the DNA template strand in the $3' \rightarrow 5'$ direction.
- (i) The enzyme synthesizes a product likely to acquire a 5' cap.
- (j) All promoters used by the enzyme lie mostly upstream of the transcriptional startpoint and are only partially transcribed.
- (k) The specificity of transcription by the enzyme is determined by a subunit of the holoenzyme.

21-7 RNA Processing. The three major classes of RNA found in the cytoplasm of a typical eukaryotic cell are rRNA, tRNA, and mRNA. For each, indicate the following:

- (a) Two or more kinds of processing that the RNA has almost certainly been subjected to.
- (b) A processing event unique to that RNA species.
- (c) A processing event that you would also expect to find for the same species of RNA from a bacterial cell.

21-8 Spliceosomes. The RNA processing carried out by spliceosomes in the eukaryotic nucleus involves many different kinds of protein and RNA molecules. For each of the following five components of the splicing process, indicate whether it is protein (P), RNA (R), or both (PR). Then briefly explain how each of the five fits into the process.

- (a) snRNA (b) Spliceosome (c) snRNP
- (d) Splice sites (e) Lariat

• 21-9 Antibiotic Inhibitors of Transcription. Rifamycin and actinomycin D are two antibiotics derived from the bacterium *Streptomyces*. Rifamycin binds to the β subunit of *E. coli* RNA polymerase and interferes with the formation of the first phosphodiester bond in the RNA chain. Actinomycin D binds to double-stranded DNA by intercalation (slipping between neighboring base pairs).

- (a) Which of the four stages in transcription would you expect rifamycin to affect primarily?
- (b) Which of the four stages in transcription would you expect actinomycin D to affect primarily?
- (c) Which of the two inhibitors is more likely to affect RNA synthesis in cultured human liver cells?
- (d) Which of the two inhibitors would be more useful for an experiment that requires the initiation of new RNA chains to be blocked without interfering with the elongation of chains that are already being synthesized?
- (e) When fertilized sea urchin eggs are treated with actinomycin D, they develop for many hours but eventually arrest as hollow balls of several hundred cells (called blastulae). Propose an explanation for why such embryos arrest, but also why they progress as far as they do.

• 21-10 Copolymer Analysis. In their initial attempts to determine codon assignments, Nirenberg and Matthei first used RNA homopolymers and then used RNA copolymers synthesized by the enzyme polynucleotide phosphorylase. This enzyme adds nucleotides randomly to the growing chain but in proportion to their presence in the incubation mixture. By varying the ratio of precursor molecules in the synthesis of copolymers, Nirenberg and Matthei were able to deduce base compositions (but usually not actual sequences) of the codons that code for various amino acids. Suppose you carry out two polynucleotide phosphorylase incubations, with UTP and CTP present in both but in different ratios. In incubation A, the precursors are present in equal concentrations. In incubation B, there is three times as much UTP as CTP. The copolymers generated in both incubation mixtures are then used in a cell-free protein-synthesizing system, and the resulting polypeptides are analyzed for amino acid composition.

- (a) What are the eight possible codons represented by the nucleotide sequences of the resulting copolymers in both incubation mixtures? What amino acids do these codons code for?
- (b) For every 64 codons in the copolymer formed in incubation A, how many of each of the 8 possible codons would you expect on average? How many for incubation B?
- (c) What can you say about the expected frequency of occurrence of the possible amino acids in the polypeptides obtained upon translation of the copolymers from incubation A? What about the polypeptides that result from translation of the incubation B copolymers?
- (d) Explain what sort of information can be obtained by this technique.
- (e) Would it be possible by this technique to determine that codons with 2 U's and 1 C code for phenylalanine, leucine, and serine? Why or why not?
- (f) Would it be possible by this technique to decide which of the three codons with 2 U's and 1 C (UUC, UCU, CUU) correspond to each of the three amino acids mentioned in part e? Why or why not?
- (g) Suggest a way to assign the three codons of part f to the appropriate amino acids of part e.

• 21-11 Introns. To investigate the possible presence of introns in three newly discovered genes (X, Y, and Z), you perform an

experiment in which the restriction enzyme *Hae*III is used to cleave either the DNA of each gene or the cDNA made by copying its mRNA with reverse transcriptase. The resulting DNA fragments are separated by gel electrophoresis, and the presence of fragments in the gels is detected by hybridizing to a radioactive DNA probe made by copying the intact gene with DNA polymerase in the presence of radioactive substrates. The following results are obtained:

Source of DNA	Number of Fragments After Electrophoresis
Gene X DNA	3
cDNA made from mRNA X	2
Gene Y DNA	4
cDNA made from mRNA Y	2
Gene Z DNA	2
cDNA made from mRNA Z	2

Gene Expression: II. Protein Synthesis and Sorting

In the preceding chapter we took gene expression from DNA to RNA, covering DNA transcription followed by processing of the resulting RNA transcripts. For genes encoding ribosomal and transfer RNAs (and some other small RNAs), RNA is the final product of gene expression. But for the thousands of other genes in an organism's genome, the ultimate gene product is protein. This chapter describes how the messenger RNAs (mRNAs) produced by these protein-coding genes are translated into polypeptides, how polypeptides become functional proteins, and how proteins reach the destinations where they carry out their functions.

Translation, the key step in the production of protein molecules, involves a change in language from the nucleotide base sequence of an mRNA molecule to the amino acid sequence of a polypeptide chain. During this process, a sequence of mRNA nucleotides, read as triplet codons, specifies the order in which amino acids are added to a growing polypeptide chain. Ribosomes serve as the intracellular sites for translation, while RNA molecules are the agents that ensure insertion of the correct amino acids at each position in the polypeptide. We will start by surveying the cell's cast of characters for performing translation, and then we will examine each of its steps in detail.

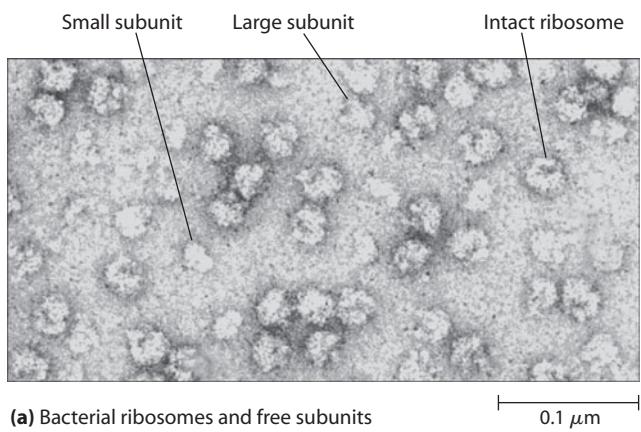

Translation: The Cast of Characters

The cellular machinery for translating mRNAs into polypeptides involves five major components: *ribosomes* that carry out the process of polypeptide synthesis, *tRNA* molecules that align amino acids in the correct order along the mRNA template, *aminoacyl-tRNA synthetases* that attach amino acids to their appropriate tRNA molecules, *mRNA* molecules that encode the amino acid sequence information for the polypeptides being synthesized, and *protein factors* that facilitate several steps in the translation process. In introducing this cast of characters, let's begin with the ribosomes.

The Ribosome Carries Out Polypeptide Synthesis

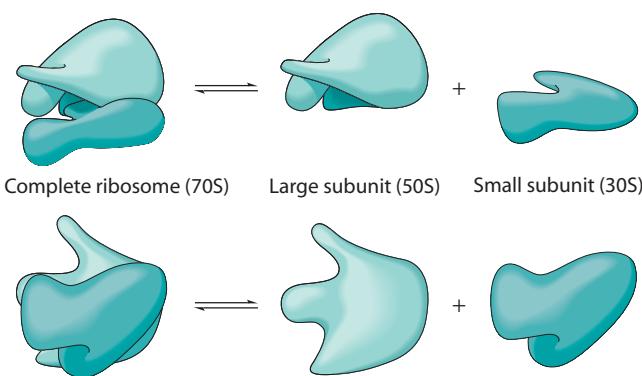

Ribosomes play a central role in protein synthesis, orienting the mRNA and amino acid-carrying tRNAs so the genetic code can be read accurately and catalyzing peptide bond formation to link the amino acids into a polypeptide. As we saw in Chapter 4, **ribosomes** are particles made of ribosomal RNA (rRNA) and protein that reside in the cytoplasm and, in eukaryotes, in the mitochondrial matrix and chloroplast stroma. In the eukaryotic cytoplasm, ribosomes occur both free in the cytosol and bound to membranes of the endoplasmic reticulum and the outer membrane of the nuclear envelope. The ribosomes of prokaryotes (archaea and bacteria) are smaller than those of eukaryotes, although many of the ribosomal proteins, translation factors, and tRNAs used by archaea resemble their eukaryotic counterparts more closely than do the comparable components of bacteria.

The shape of a typical bacterial ribosome revealed by electron microscopy is shown in **Figure 22-1**. Like all ribosomes, it is built from two dissociable subunits called the *large* and *small subunits*. The bacterial ribosome has a sedimentation coefficient of about 70S and is built from a 30S small subunit and a 50S large subunit. Its eukaryotic equivalent is an 80S ribosome consisting of a 40S subunit and a 60S subunit. **Table 22-1** lists some of the properties of bacterial and eukaryotic ribosomes and their subunits. The bacterial ribosome contains fewer proteins, is sensitive to different inhibitors of protein synthesis, and has smaller RNA molecules (and one fewer RNA) than eukaryotic ribosomes have. In Chapter 21, we saw that rRNAs are produced from larger precursor molecules by cleavage and processing reactions that, in eukaryotes, take place within the nucleolus (page 543). During these processing events, the rRNAs become associated with ribosomal proteins and self-assemble into small and large subunits, which come together only after binding to mRNA. X-ray crystallography has allowed the

arrangement of all the individual proteins and RNA molecules of the small and large subunits of bacterial ribosomes to be pinpointed down to the atomic level. Venkatraman Ramakrishnan, Thomas A. Steitz, and Ada E. Yonath were awarded the Nobel Prize in Chemistry in 2009 for their contributions to this monumental achievement.

Functionally, ribosomes have sometimes been called the “workbenches” of protein synthesis, but their active role in polypeptide synthesis makes “machine” a more apt label. In essence, the role of the ribosome in polypeptide synthesis resembles that of a large, complicated enzyme constructed from more than 50 different proteins and several kinds of rRNA. For many years it was thought that the rRNA simply provided a structural scaffold for the ribosomal proteins, with the latter actually carrying out the steps in polypeptide synthesis. But today we know that the reverse is closer to the truth—rRNA performs many of the ribosome’s key functions.

Four sites on the ribosome are particularly important for protein synthesis (**Figure 22-2**). These are an **mRNA-binding site** and three sites where tRNA can bind: an **A (aminoacyl) site** that binds each newly arriving tRNA with its attached amino acid, a **P (peptidyl) site** where the tRNA carrying the growing polypeptide chain resides, and an **E (exit) site**, from which tRNAs leave the ribosome after they have discharged their amino acids. How these sites function in the process of translation will become clear in a few pages.

Transfer RNA Molecules Bring Amino Acids to the Ribosome

Since the sequence of codons in mRNA ultimately determines the amino acid sequence of polypeptide chains, a mechanism must exist that enables codons to arrange amino acids in the proper order. The general nature of this mechanism was first proposed in 1957 by Francis Crick. With remarkable foresight, Crick postulated that amino acids cannot directly recognize nucleotide base sequences and that some kind of hypothetical “adaptor” molecule must therefore mediate the interaction between amino acids and mRNA. He further predicted that each adaptor molecule possesses two sites, one that binds to a specific amino acid and the other that recognizes an mRNA base sequence coding for this amino acid.

In the year following Crick’s adaptor proposal, Mahlon Hoagland discovered a family of adaptor molecules exhibiting these predicted properties. While investigating the process of protein synthesis in cell-free systems, Hoagland found that radioactive amino acids first become

Table 22-1 Properties of Bacterial and Eukaryotic Cytoplasmic Ribosomes

Source	Size of Ribosomes		Subunit	Subunit Size		Subunit Proteins	Subunit RNA	
	S Value*	Mol. Wt.		S Value	Mol. Wt.		S Value	Nucleotides
Bacterial cells	70S	2.5×10^6	Large	50S	1.6×10^6	34	23S	2900
			Small				5S	120
Eukaryotic cells	80S	4.2×10^6	Large	60S	2.8×10^6	About 46	16S	1540
			Small				5.8S	160
				40S	1.43×10^6	About 32	5S	120
							18S	1900

*If you are surprised that the S values of the subunits do not add up to that of the whole ribosome, recall that an S value is a measure of the velocity at which a particle sediments upon centrifugation and is only indirectly related to the mass of the particle.

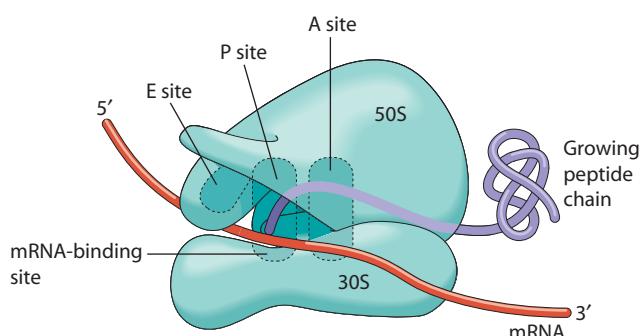

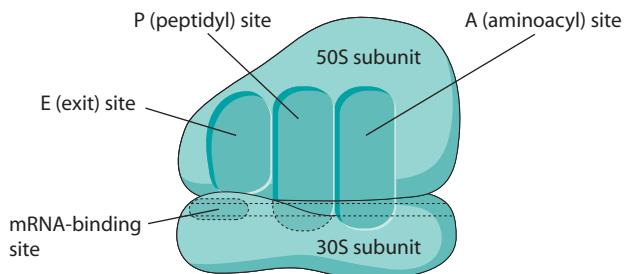

FIGURE 22-2 Binding Sites on a Ribosome. Ribosomes contain A and P sites where amino acid-carrying tRNA molecules bind during polypeptide synthesis, and an E site from which empty tRNAs leave the ribosome. The mRNA-binding site binds a specific nucleotide sequence near the 5' end of mRNA, placing the mRNA in proper position for translation of its first codon. The binding sites are all located at or near the interface between the large and small subunits. In the top diagram, which is a schematic representation of a bacterial ribosome used in this chapter, the pair of horizontal dashed lines indicates where the mRNA molecule lies. The bottom diagram is a more realistic representation.

covalently attached to small RNA molecules. Adding these amino acid–RNA complexes to ribosomes led to the onset of protein synthesis and the incorporation of radioactive amino acids into new proteins. Hoagland therefore concluded that amino acids are initially bound to small RNA molecules, which then bring the amino acids to the ribosome for subsequent insertion into newly forming polypeptide chains.

The small RNA molecules that Hoagland discovered were named **transfer RNAs (tRNAs)**. Appropriate to their role as intermediaries between mRNA and amino acids, tRNA molecules have two kinds of specificity. Each tRNA binds to one specific amino acid, and each recognizes one or more mRNA codons specifying that particular amino acid, as indicated by the genetic code. Transfer RNAs are linked to their corresponding amino acids by an ester bond that joins the amino acid to the 2'- or 3'-hydroxyl group of the adenine (A) nucleotide located at the 3' end of all tRNA molecules (Figure 22-3a). Selection of the correct amino acid for each tRNA is the responsibility of the enzymes that catalyze formation of the ester bond, as we will discuss shortly. By convention, the name of the amino acid that attaches to a given tRNA is indicated by a superscript. For example, tRNA molecules specific for alanine are identified as tRNA^{Ala}. Once the amino acid is

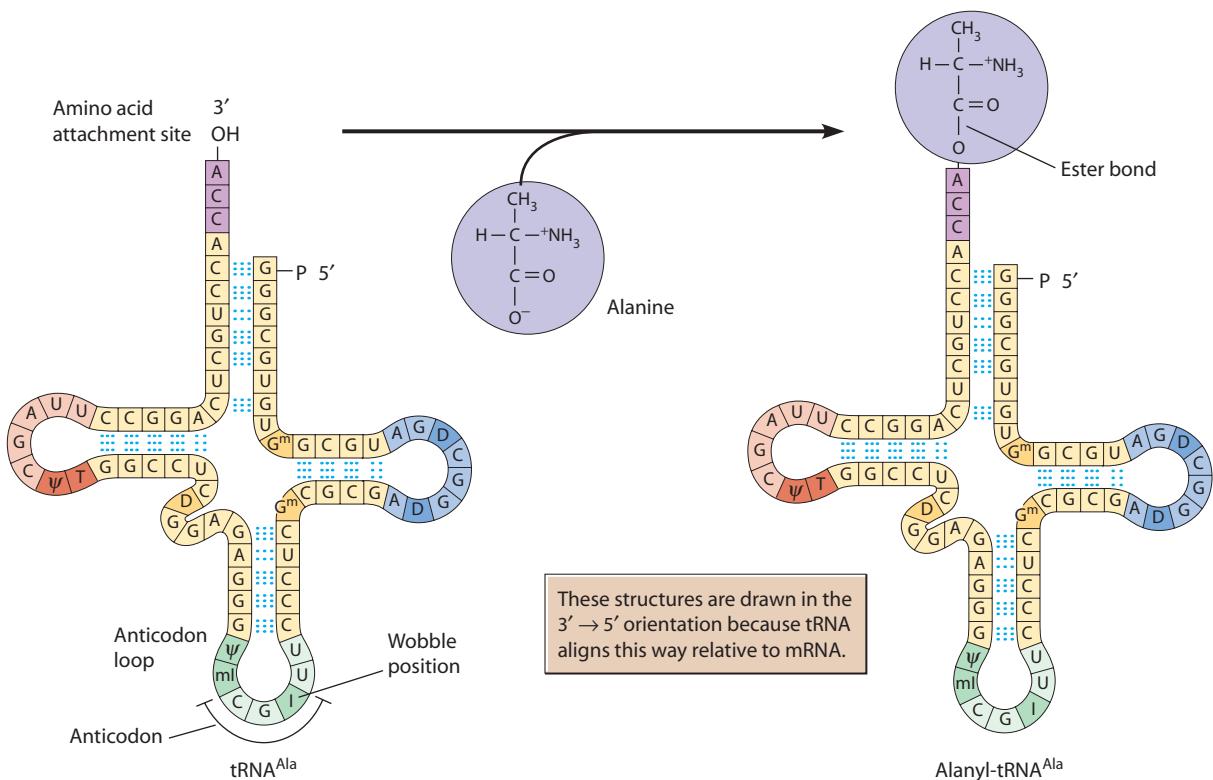

attached, the tRNA is called an **aminoacyl tRNA** (e.g., alanyl tRNA^{Ala}). The tRNA is said to be in its *charged* form, and the amino acid is said to be *activated*.

Transfer RNA molecules can recognize codons in mRNA because each tRNA possesses an **anticodon**, a special trinucleotide sequence located within one of the loops of the tRNA molecule (see Figure 22-3a). The anticodon of each tRNA is complementary to one or more mRNA codons that specify the amino acid being carried by that tRNA. Therefore, *anticodons permit tRNA molecules to recognize codons in mRNA by complementary base pairing*. Take careful note of the convention used in representing codons and anticodons: Codons in mRNA are written in the 5' → 3' direction, whereas anticodons in tRNA are usually represented in the 3' → 5' orientation. Thus, one of the codons for alanine is 5'-GCC-3', and the corresponding anticodon in tRNA is 3'-CGG-5'.

Since the genetic code employs 61 codons to specify amino acids (page 655), you might expect to find 61 different tRNA molecules involved in protein synthesis, each recognizing a different codon. However, the number of different tRNAs is significantly less than 61 because many tRNA molecules recognize more than one codon. You can see why this is possible by examining the table of the genetic code (see Figure 21-6). Codons differing in the third base often code for the same amino acid. For example, UUU and UUC both code for phenylalanine; UCU, UCC, UCA, and UCG all code for serine; and so forth. In such cases, the same tRNA can bind to more than one codon without introducing mistakes. For example, a single tRNA can recognize the codons UUU and UUC because both code for the same amino acid, phenylalanine.

Such considerations led Francis Crick to propose that mRNA and tRNA line up on the ribosome in a way that permits flexibility or “wobble” in the pairing between the third base of the codon and the corresponding base in the anticodon. According to this **wobble hypothesis**, the flexibility in codon-anticodon binding allows some unexpected base pairs to form (Figure 22-4). The unusual base inosine (I), which is extremely rare in other RNA molecules, occurs often in the wobble position of tRNA anticodons (see Figure 22-3a). Inosine is the “wobbliest” of all third-position bases, since it can pair with U, C, or A. For example, a tRNA with the anticodon 3'-UAI-5' can recognize the codons AUU, AUC, and AUA, all of which code for the amino acid isoleucine.

It is because of wobble that fewer tRNA molecules are required for some amino acids than the number of codons that specify those amino acids. In the case of isoleucine, for example, a cell can translate all three codons with a single tRNA molecule containing 3'-UAI-5' as its anticodon. Similarly, the six codons for the amino acid leucine (UUA, UUG, CUU, CUC, CUA, and CUG) require only three tRNAs because of wobble. Although the existence of wobble means that a single tRNA molecule can recognize more than one codon, the different codons recognized by a given tRNA always code for the same amino acid, so wobble does not cause insertion of incorrect amino acids.

(a) Secondary structure of tRNA, before and after amino acid attachment

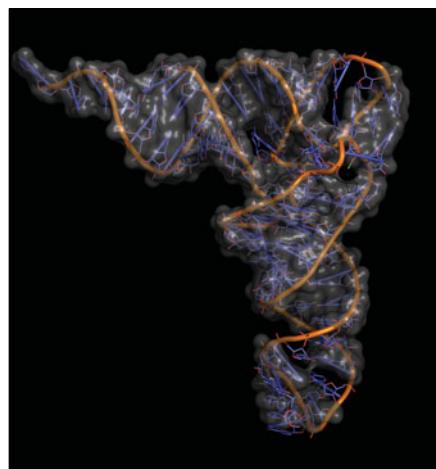

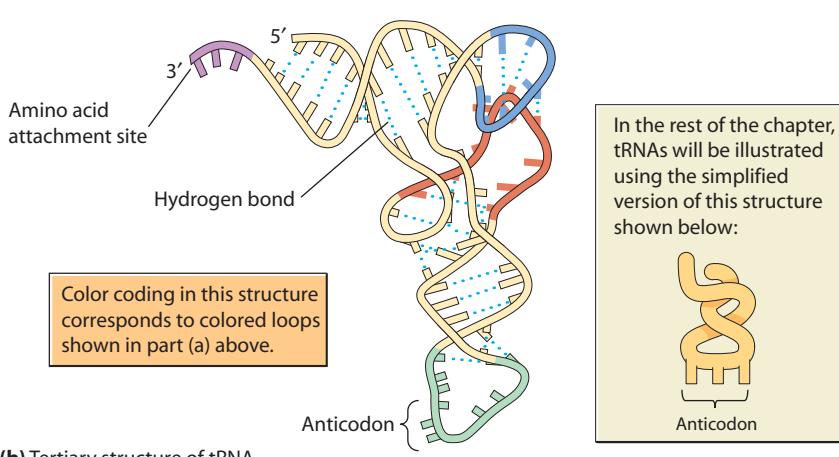

FIGURE 22-3 Structure and Aminoacylation of a tRNA. (a) Yeast alanine tRNA, like all tRNAs, contains three major loops, four base-paired regions, an anticodon triplet, and a 3' terminal sequence of CCA, to which the appropriate amino acid can be attached by an ester bond. Modified bases are dark colored, and their names (as nucleosides) are abbreviated I for inosine, mI for methylinosine, D for dihydrouridine, T for ribothymidine, ψ for pseudouridine, and G^m for methylguanosine. (For the significance of the wobble position in the anticodon, see Figure 22-4.) (b) In the L-shaped tertiary structure of a tRNA the amino acid attachment site is at one end and the anticodon at the other. The image on the right shows a three-dimensional model of the yeast phenylalanine tRNA, with the molecular surface in transparent gray, and the RNA backbone in orange.

Aminoacyl-tRNA Synthetases Link Amino Acids to the Correct Transfer RNAs

Before a tRNA molecule can bring its amino acid to the ribosome, that amino acid must be attached covalently to the tRNA. The enzymes responsible for linking amino

acids to their corresponding tRNAs are called **aminoacyl-tRNA synthetases**. Cells typically have 20 different aminoacyl-tRNA synthetases, one for each of the 20 amino acids commonly used in protein synthesis. Cells that utilize the unusual 21st and 22nd amino acids, *selenocysteine* and

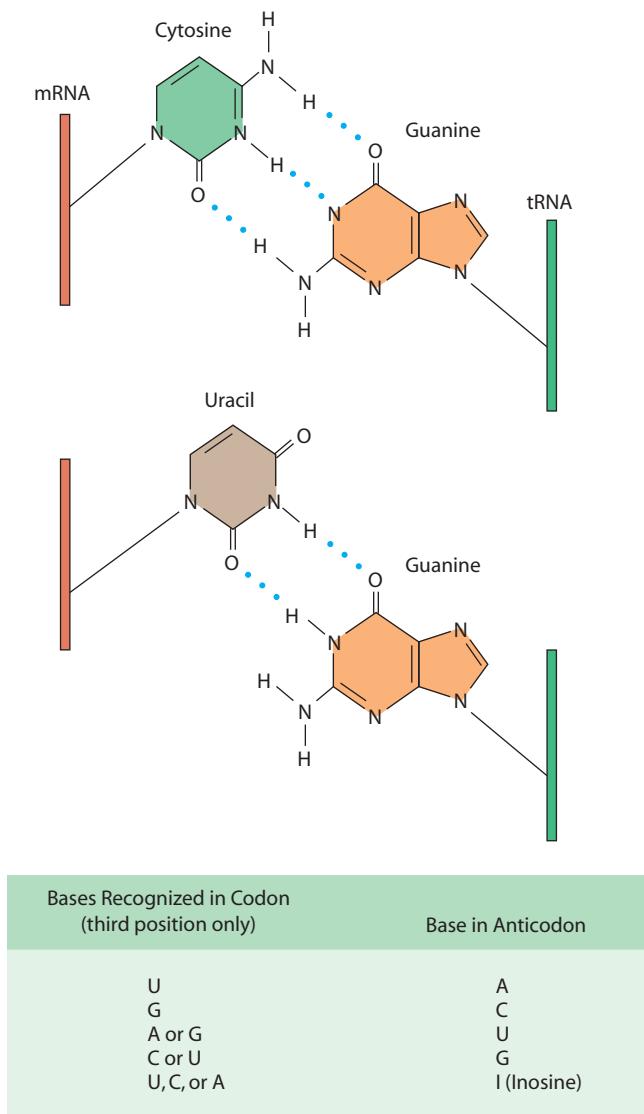

FIGURE 22-4 The Wobble Hypothesis. The two diagrams illustrate how a slight shift or “wobble” in the position of the base guanine in a tRNA anticodon would permit it to pair with uracil (bottom) instead of its normal complementary base, cytosine (top). The table summarizes the base pairs permitted at the third position of a codon by the wobble hypothesis.

pyrrolysine (page 656), contain special tRNAs and aminoacyl-tRNA synthetases for these amino acids as well. When more than one tRNA exists for a given amino acid, the aminoacyl-tRNA synthetase specific for that particular amino acid recognizes each of the tRNAs. Some cells possess less than 20 aminoacyl-tRNA synthetases. In such cases, the same aminoacyl-tRNA synthetase may catalyze the attachment of two different amino acids to their corresponding tRNAs, or it may attach an incorrect amino acid to a tRNA molecule. These latter “errors” are corrected by a second enzyme that alters the incorrect amino acid after it has been attached to the tRNA.

Aminoacyl-tRNA synthetases catalyze the attachment of amino acids to their corresponding tRNAs via an ester bond, accompanied by the hydrolysis of ATP to AMP and pyrophosphate:

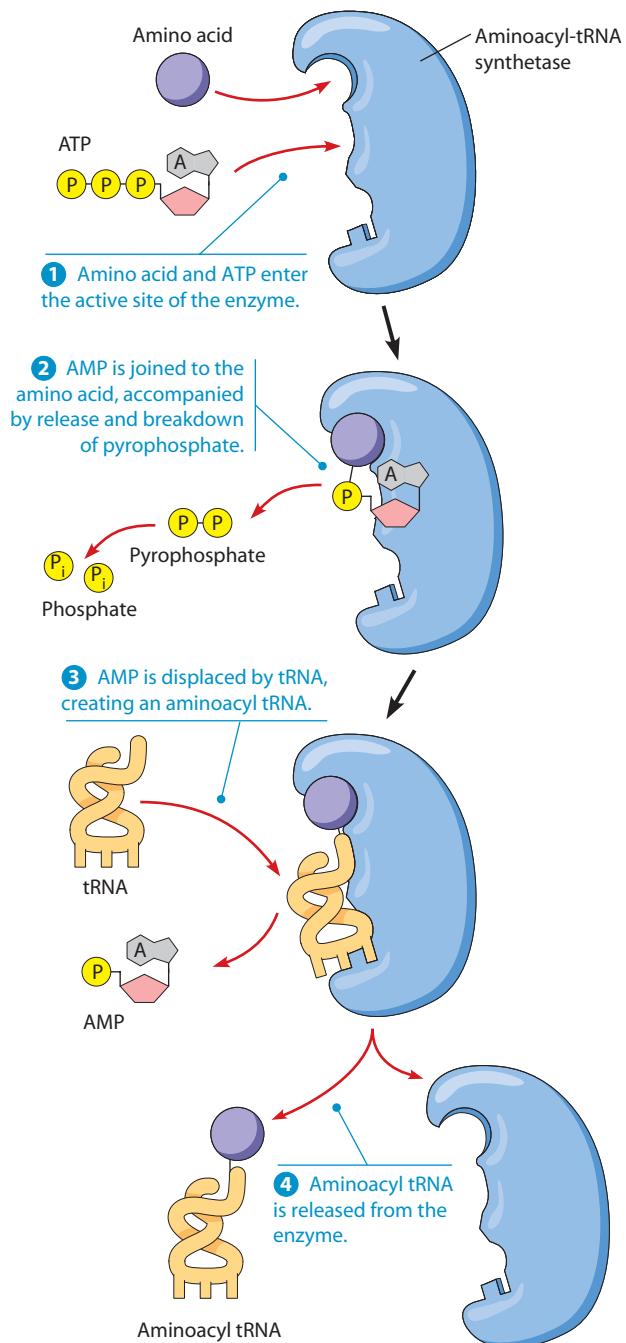

FIGURE 22-5 Amino Acid Activation by Aminoacyl-tRNA Synthetase. This enzyme catalyzes the formation of an ester bond between the carboxyl group of an amino acid and the 3' OH of the appropriate tRNA, generating an aminoacyl tRNA.

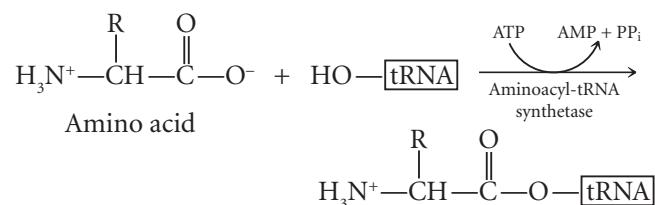

Figure 22-5 outlines the steps by which this reaction occurs. The driving force for the reaction is provided by the hydrolysis of pyrophosphate to 2 P_i.

In the product, aminoacyl tRNA, the ester bond linking the amino acid to the tRNA is said to be a “high-energy” bond. This simply means that hydrolysis of the bond releases sufficient energy to drive formation of the peptide bond that will eventually join the amino acid to a growing polypeptide chain. The process of aminoacylation of a tRNA molecule is therefore also called *amino acid activation* because it links an amino acid to its proper tRNA as well as activates it for subsequent peptide bond formation.

How do aminoacyl-tRNA synthetases identify the correct tRNA for each amino acid? Differences in the base sequences of the various tRNA molecules allow them to be distinguished and, surprisingly, the anticodon is not the only feature to be recognized. Changes in the base sequence of either the anticodon triplet or the 3' end of a tRNA molecule can alter the amino acid that a tRNA attaches to. Thus, aminoacyl-tRNA synthetases recognize nucleotides located in at least two different regions of tRNA molecules when they pick out the tRNA that is to become linked to a particular amino acid. After linking an amino acid to a tRNA molecule, aminoacyl-tRNA synthetases proofread the final product to make sure that the correct amino acid has been used. This proofreading function is performed by a site on the aminoacyl-tRNA synthetase molecule that recognizes incorrect amino acids and releases them by hydrolyzing the bond that links the amino acid to the tRNA.

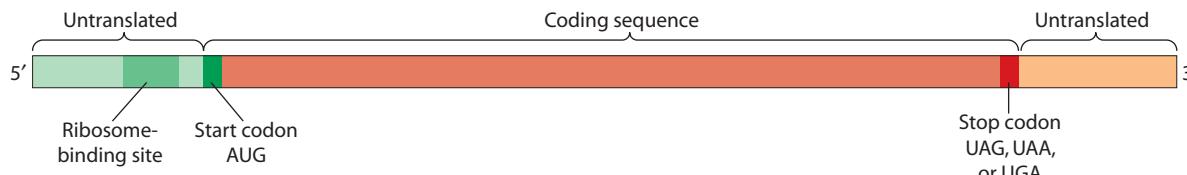

Once the correct amino acid has been joined to its tRNA, it is the tRNA itself (and not the amino acid) that recognizes the appropriate codon in mRNA. The first evidence for this was provided by François Chapeville and Fritz Lipmann, who designed an elegant experiment involving the tRNA that carries the amino acid cysteine. They took the tRNA after its cysteine had been attached and treated it with a nickel catalyst, which converts the attached cysteine into the amino acid alanine. The result was therefore alanine covalently linked to a tRNA molecule that normally carries cysteine. When the researchers added this abnormal aminoacyl tRNA to a cell-free protein-synthesizing system, alanine was inserted into polypeptide chains in locations

normally occupied by cysteine. Such results proved that codons in mRNA recognize tRNA molecules rather than their bound amino acids. Hence, the specificity of the aminoacyl-tRNA synthetase reaction is crucial to the accuracy of gene expression because it ensures that the proper amino acid is linked to each tRNA.

Messenger RNA Brings Polypeptide Coding Information to the Ribosome

As you learned in Chapter 21, the sequence of codons in mRNA directs the order in which amino acids are linked together during protein synthesis. Hence, the mRNA that happens to bind to a given ribosome will determine which polypeptide that ribosome will manufacture. In eukaryotes, where transcription takes place in the nucleus and protein synthesis is mainly a cytoplasmic event, the mRNA must first be exported from the nucleus. Export is mediated by mRNA-binding proteins that contain amino acid sequences called *nuclear export signals (NES)*, which target the protein (and hence its bound mRNA) for transport through the nuclear pores (page 540). This step is not required in prokaryotes, which by definition have no nucleus. As a result, transcription and translation are often coupled in prokaryotic cells—that is, ribosomes can begin translating an mRNA before its transcription from DNA is completed (see Figure 21-16).

At the heart of each messenger RNA molecule is, of course, its message—the sequence of nucleotides that encodes a polypeptide. However, mRNAs also possess sequences at either end that are not translated (Figure 22-6). The untranslated sequence at the 5' end of an mRNA precedes the **start codon**, which is the first codon to be translated. AUG is the most common start codon, although a few other triplets are occasionally used for this purpose. The untranslated sequence at the 3' end follows the **stop codon**, which signals the end of translation and can be UAG, UAA, or UGA. The 5' and 3' untranslated regions range from a few dozen to hundreds of nucleotides in length. Although these

(a) Bacterial mRNA

(b) Eukaryotic mRNA

FIGURE 22-6 Comparison of Bacterial and Eukaryotic Messenger RNA. (a) A bacterial mRNA molecule encoding a single polypeptide has the features shown here. (A polycistronic bacterial mRNA would generally have a set of these features for each gene.) (b) A eukaryotic mRNA molecule has, in addition, a 5' cap and a 3' poly(A) tail. It lacks a ribosome-binding site (a nucleotide sequence also called a Shine-Dalgarno sequence, after its discoverers).

sequences are not translated, their presence is essential for proper mRNA function. Included in the untranslated regions of eukaryotic mRNAs are a 5' cap and a 3' poly(A) tail, both of which were described in Chapter 21. As we will see, the 5' cap is important in initiating translation in eukaryotes.

In eukaryotes, most mRNA molecules are *monocistronic* (i.e., they encode a single polypeptide). In bacteria and archaea, however, some mRNAs are *polycistronic*—meaning they encode several polypeptides, usually with related functions in the cell. The clusters of genes that give rise to polycistronic mRNAs are single transcription units called *operons*, which we will discuss in Chapter 23 in the context of gene regulation. Although most often thought of as a feature of prokaryotes, eukaryotes also produce polycistronic RNAs. In some cases, such as the nematode, *Caenorhabditis elegans*, it is only the pre-mRNA that is polycistronic; subsequent RNA processing results in individual mRNAs that are monocistronic and translated separately. In other eukaryotes, dicistronic RNAs (i.e., RNAs that encode two proteins) remain joined and are translated together.

Protein Factors Are Required for the Initiation, Elongation, and Termination of Polypeptide Chains

In addition to aminoacyl-tRNA synthetases and the protein components of the ribosome, translation requires the participation of several other kinds of protein molecules. Some of these *protein factors* are required for initiating the translation process, others for elongating the growing polypeptide chain, and still others for terminating polypeptide synthesis. The exact roles played by these factors will become apparent as we now proceed to a discussion of the mechanism of translation.

The Mechanism of Translation

The translation of mRNAs into polypeptides is an ordered, stepwise process that begins the synthesis of a polypeptide chain at its amino-terminal end, or *N-terminus*, and sequentially adds amino acids to the growing chain until the carboxyl-terminal end, or *C-terminus*, is reached. The first experimental evidence for such a mechanism was provided in 1961 by Howard Dintzis, who investigated hemoglobin synthesis in developing red blood cells that had been incubated briefly with radioactive amino acids. Dintzis reasoned that if the time of incubation is kept relatively brief, then the radioactivity present in completed hemoglobin chains should be concentrated at the most recently synthesized end of the molecule. He found that the highest concentration of radioactivity in completed hemoglobin chains was at the C-terminal end, indicating that the C-terminus is the last part of the polypeptide chain to be synthesized. This allowed him to conclude that during mRNA translation, *amino acids are added to the growing polypeptide chain beginning at the N-terminus and proceeding toward the C-terminus*.

In theory, mRNA could be read in either the 5' → 3' direction or the 3' → 5' direction during this process. The

first attempts to determine the direction in which mRNA is actually read involved the use of artificial RNA molecules. A typical example is the synthetic RNA that can be made by adding the base C to the 3' end of poly(A), yielding the molecule 5'-AAAAAAAAAA...AAC-3'. When added to a cell-free protein-synthesizing system, this RNA stimulates the synthesis of a polypeptide consisting of a stretch of lysine residues with an asparagine at the C-terminus. Because AAA codes for lysine and AAC codes for asparagine, this means that *mRNA is translated in the 5' → 3' direction*. Confirming evidence has come from many studies in which the base sequences of naturally occurring mRNAs have been compared with the amino acid sequences of the polypeptide chains they encode. In all cases, the amino acid sequence of the polypeptide chain corresponds to the order of mRNA codons read in the 5' → 3' direction.

To understand how translation of mRNA in the 5' → 3' direction leads to the synthesis of polypeptides in the N-terminal to C-terminal direction, it is helpful to subdivide the translation process into three stages, as shown in **Figure 22-7**: ① an *initiation* stage, in which mRNA is bound to the ribosome and positioned for proper translation; ② an *elongation* stage, in which amino acids are sequentially joined together via peptide bonds in an order specified by the arrangement of codons in mRNA; and ③ a *termination* stage, in which the mRNA and the newly formed polypeptide chain are released from the ribosome.

In the following sections we examine each of these stages in detail. Although our discussion focuses mainly on translation in bacterial cells, where the mechanisms are especially well understood, the comparable events in eukaryotic cells are rather similar. The aspects of translation that differ between bacteria and eukaryotes are confined mostly to the initiation stage, as we describe in the next section.

The Initiation of Translation Requires Initiation Factors, Ribosomal Subunits, mRNA, and Initiator tRNA

Bacterial Initiation. The initiation of translation in bacteria is illustrated in **Figure 22-8**, which shows that initiation can be subdivided into three distinct steps. In step ①, three **initiation factors**—called IF1, IF2, and IF3—bind to the small (30S) ribosomal subunit, with GTP attaching to IF2. The presence of IF3 at this early stage prevents the 30S subunit from prematurely associating with the 50S subunit.

In step ②, mRNA and the tRNA carrying the first amino acid bind to the 30S ribosomal subunit. The mRNA is bound to the 30S subunit in its proper orientation by means of a special nucleotide sequence called the mRNA's *ribosome-binding site* (also known as the *Shine-Dalgarno sequence*, after its discoverers). This sequence consists of a stretch of 3–9 purine nucleotides (often AGGA) located slightly upstream of the start codon. These purines in the mRNA form complementary base pairs with a pyrimidine-rich sequence at the 3' end of 16S rRNA, which forms the ribosome's *mRNA-binding site*. The importance of the

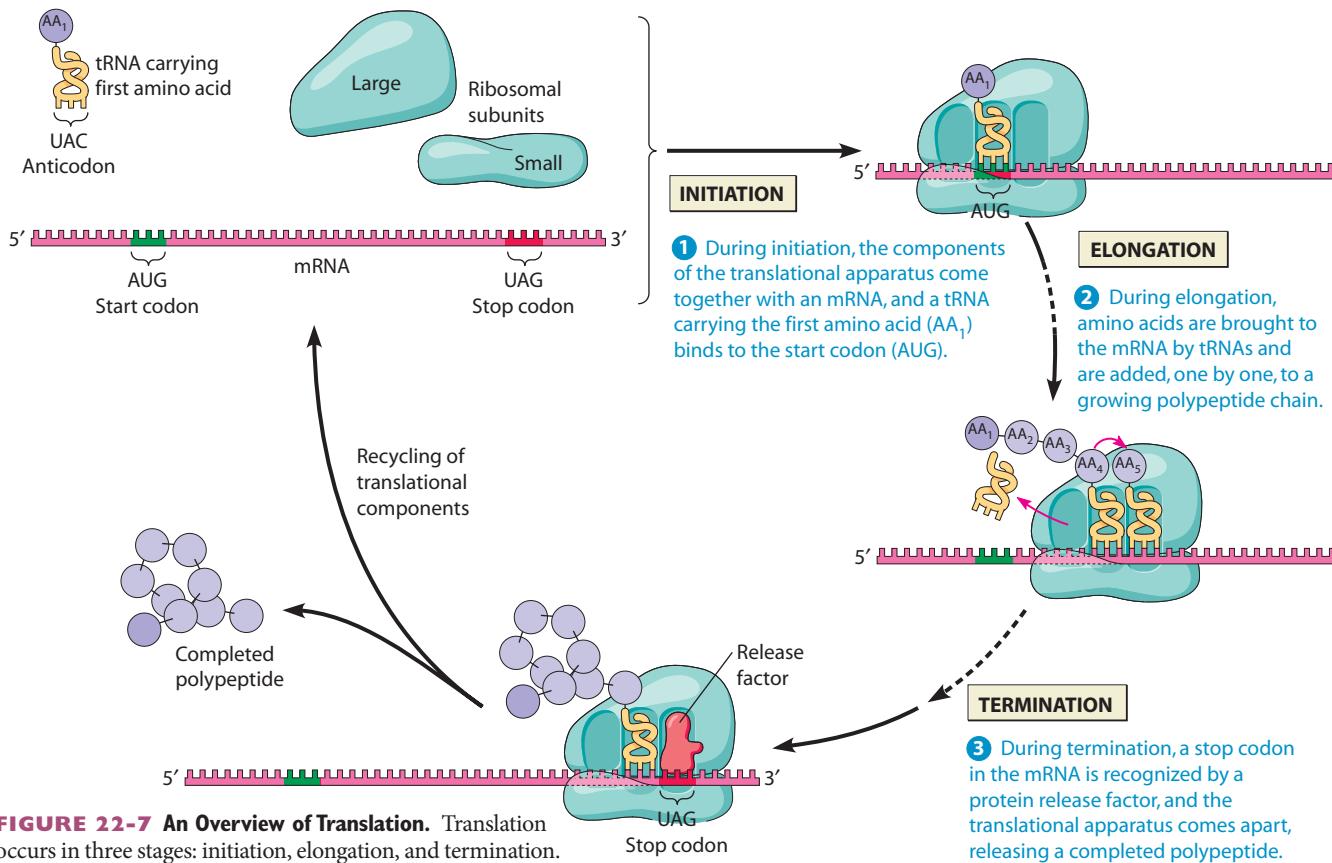

FIGURE 22-7 An Overview of Translation. Translation occurs in three stages: initiation, elongation, and termination.

mRNA-binding site has been shown by studies involving *colicins*, which are proteins produced by certain strains of *Escherichia coli* that can kill other types of bacteria. One such protein, colicin E3, kills bacteria by destroying their ability to synthesize proteins. Upon entering the cytoplasm of susceptible bacteria, colicin E3 catalyzes the removal of a 49-nucleotide fragment from the 3' end of 16S rRNA. This action destroys the mRNA-binding site, thereby creating ribosomes that can no longer initiate polypeptide synthesis.

The binding of mRNA to the mRNA-binding site of the small ribosomal subunit places the mRNA's AUG start codon at the ribosome's P site, where it can bind to the anticodon of the appropriate tRNA. The first clue that a special kind of tRNA is involved in this step emerged when it was discovered that roughly half the proteins in *E. coli* contain methionine at their N-terminal ends. This was surprising because methionine is a relatively uncommon amino acid, accounting for no more than a few percent of the amino acids in bacterial proteins. The explanation for such a pattern became apparent when it was discovered that bacterial cells contain two different methionine-specific tRNAs. One, designated tRNA^{Met}, carries a normal methionine destined for insertion into the internal regions of polypeptide chains. The other, called tRNA^{fMet}, carries a methionine that is converted to the derivative *N-formylmethionine* (*fMet*) after linkage to the tRNA (Figure 22-9). In *N-formylmethionine*, the amino group of methionine is blocked by the addition of a formyl group and so cannot form a peptide bond with another amino acid; only the carboxyl group is available for

bonding to another amino acid. Hence *N-formylmethionine* can be situated only at the N-terminal end of a polypeptide chain—suggesting that tRNA^{fMet} functions as an **initiator tRNA** that starts the process of translation. This idea was soon confirmed by the discovery that bacterial polypeptide chains in the early stages of synthesis always contain *N-formylmethionine* at their N-terminus. Following completion of the polypeptide chain (and in some cases while it is still being synthesized), the formyl group, and often the methionine itself, is enzymatically removed.

During initiation, the initiator tRNA with its attached *N-formylmethionine* is bound to the P site of the 30S ribosomal subunit by the action of initiation factor IF2 (plus GTP), which can distinguish initiator tRNA^{fMet} from other kinds of tRNA. This attribute of IF2 helps explain why AUG start codons bind to the initiator tRNA^{fMet}, whereas AUG codons located elsewhere in mRNA bind to the noninitiating tRNA^{Met}. Once tRNA^{fMet} enters the P site, its anticodon becomes base-paired with the AUG start codon in the mRNA, and IF3 is released. At this point the 30S subunit with its associated IF1, IF2-GTP, mRNA, and *N-formylmethionyl* tRNA^{fMet} is referred to as the **30S initiation complex**.

Once IF3 has been released, the 30S initiation complex can bind to a free 50S ribosomal subunit, generating the **70S initiation complex** (step ③ of Figure 22-8). The 50S subunit then promotes hydrolysis of the IF2-bound GTP, leading to the release of IF2 and IF1. At this stage, all three initiation factors have been released.

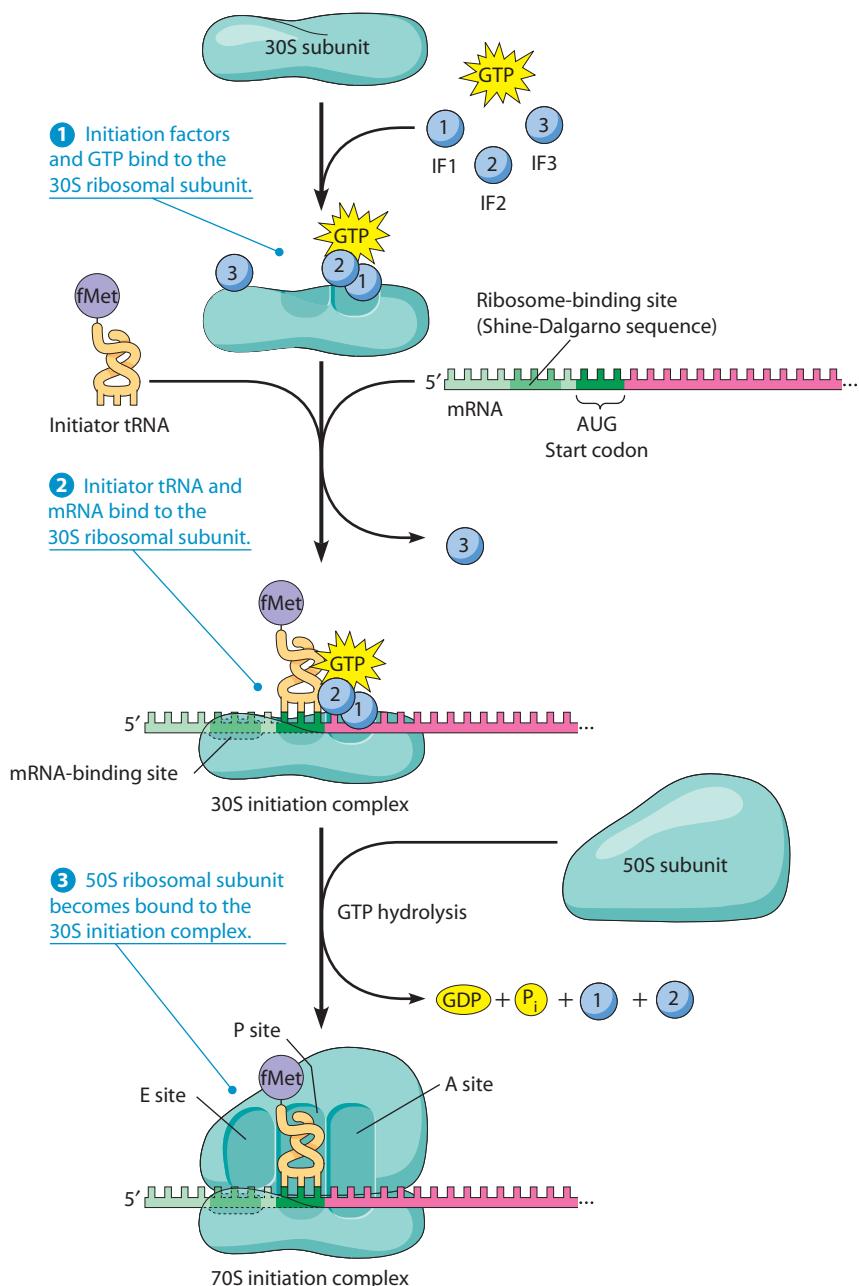

FIGURE 22-8 Initiation of Translation in Bacteria. Assembly of the 70S translation initiation complex occurs in three steps. **1** Three initiation factors (IF1, IF2, and IF3) plus GTP bind to the small ribosomal subunit. **2** The initiator aminoacyl tRNA and mRNA are attached. The mRNA-binding site is composed, at least in part, of a portion of the 16S rRNA of the small ribosomal subunit. **3** The large ribosomal subunit joins the complex. The resulting 70S initiation complex has fMet-tRNA^{fMet} residing in the ribosome's P site.

ACTIVITIES www.thecellplace.com

Initiation of translation

Eukaryotic Initiation. Unlike the situation in bacteria, the AUG start codon in eukaryotes (and archaea) specifies the amino acid methionine rather than N-formylmethionine. Other differences in eukaryotes include the use of a different set of initiation factors known as *eIFs* (roughly

a dozen proteins with names such as eIF1, eIF2, and so forth), a somewhat different pathway for assembling the initiation complex, and a special initiator tRNA^{Met} that—like the normal tRNA for methionine but unlike the initiator tRNA of bacteria—carries methionine that does not become formylated.

At the beginning of eukaryotic initiation, the initiation factor *eIF2* (with GTP attached) binds to the initiator methionyl tRNA^{Met} before the tRNA then binds to the small ribosomal subunit along with other initiation factors, including *eIF1A* (the eukaryotic counterpart of bacterial IF1). The resulting complex next binds to the 5' end of an mRNA, recognizing the 5' cap with the aid of a cap-binding initiation factor, *eIF4F*. (In some cases the complex may instead bind to an *internal ribosome entry sequence*, or *IRES*, which lies directly upstream of the start codon of certain types of mRNA, especially viral mRNAs.)

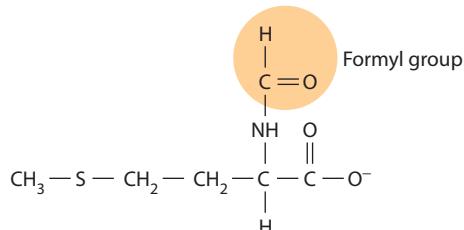

FIGURE 22-9 The Structure of N-Formylmethionine. N-formylmethionine (fMet) is the modified amino acid with which every polypeptide is initiated in bacteria.

After binding to mRNA, the small ribosomal subunit, with the initiator tRNA in tow, scans along the mRNA and usually begins translation at the first AUG triplet it encounters. The nucleotides on either side of the eukaryotic start codon appear to be involved in its recognition. A common start sequence is ACCAUGGG (also called a *Kozak sequence*, after the scientist who discovered that many eukaryotic mRNAs have this sequence), where the underlined triplet is the actual start codon. After the initiator tRNA^{Met} becomes base-paired with the start codon, the large ribosomal subunit joins the complex in a reaction facilitated by the hydrolysis of GTP bound to initiation factor eIF5B.

Chain Elongation Involves Sequential Cycles of Aminoacyl tRNA Binding, Peptide Bond Formation, and Translocation

Once the initiation complex has been completed, a polypeptide chain is synthesized by the successive addition of amino acids in a sequence specified by codons in mRNA. As summarized in **Figure 22-10**, this *elongation stage* of polypeptide synthesis involves a repetitive three-step cycle in which ① *binding of an aminoacyl tRNA* to the ribosome brings a new amino acid into position to be joined to the polypeptide chain, ② *peptide bond formation* links this amino acid to the growing polypeptide, and ③ the mRNA is advanced a distance of three nucleotides by the process of *translocation* to bring the next codon into position for translation. Each of these steps is described in more detail in the following paragraphs.

Binding of Aminoacyl tRNA. At the onset of the elongation stage, the AUG start codon in the mRNA is located at the ribosomal P site and the second codon (the codon immediately downstream from the start codon) is located at the A site. Elongation begins when an aminoacyl tRNA whose anticodon is complementary to the second codon binds to the ribosomal A site (see Figure 22-10, ①). The binding of this new aminoacyl tRNA to the codon in the A site requires two protein **elongation factors**, EF-Tu and EF-Ts, and is driven by the hydrolysis of GTP. From now on, every incoming aminoacyl tRNA will bind first to the A (aminoacyl) site—hence the site's name.

The function of EF-Tu, along with its bound GTP, is to convey the aminoacyl tRNA to the A site of the ribosome. The EF-Tu-GTP complex promotes the binding of all aminoacyl tRNAs *except the initiator tRNA* to the ribosome, thus ensuring that AUG codons located downstream from the start codon do not mistakenly recruit an initiator tRNA to the ribosome. As the aminoacyl tRNA is transferred to the ribosome, the GTP is hydrolyzed and the EF-Tu-GDP complex is released. The role of EF-Ts is to regenerate EF-Tu-GTP from EF-Tu-GDP for the next round of the elongation cycle (see Figure 22-10, ①).

Elongation factors do not recognize individual anticodons, which means that aminoacyl tRNAs of all types (other than initiator tRNAs) are randomly brought to the A site of the ribosome. Some mechanism must therefore

ensure that only the correct aminoacyl tRNA is retained by the ribosome for subsequent use during peptide bond formation. If the anticodon of an incoming aminoacyl tRNA is not complementary to the mRNA codon exposed at the A site, the aminoacyl tRNA does not bind to the ribosome long enough for GTP hydrolysis to take place. When the match is close but not exact, transient binding may occur, and GTP is hydrolyzed. However, the mismatch between the anticodon of the aminoacyl tRNA and the codon of the mRNA creates an abnormal structure at the A site that is usually detected by the ribosome, leading to rejection of the bound aminoacyl tRNA. These mechanisms for selecting against incorrect aminoacyl tRNAs, combined with the proofreading capacity of aminoacyl-tRNA synthetases described earlier, ensure that the final error rate in translation is usually no more than 1 incorrect amino acid per 10,000 incorporated.

Peptide Bond Formation. After the appropriate aminoacyl tRNA has become bound to the ribosomal A site, the next step is formation of a peptide bond between the amino group of the amino acid bound at the A site and the carboxyl group that links the initiating amino acid (or growing polypeptide chain) to the tRNA at the P site. The formation of this peptide bond causes the growing polypeptide chain to be transferred from the tRNA located at the P site to the tRNA located at the A site (see Figure 22-10, ②). Peptide bond formation is the only step in protein synthesis that requires neither nonribosomal protein factors nor an outside source of energy such as GTP or ATP. The necessary energy is provided by cleavage of the high-energy bond that joins the amino acid or peptide chain to the tRNA located at the P site.

For many years, peptide bond formation was thought to be catalyzed by a hypothetical ribosomal protein that was given the name **peptidyl transferase**. However, in 1992 Harry Noller and his colleagues showed that the large subunit of bacterial ribosomes retains peptidyl transferase activity after all ribosomal proteins have been removed. In contrast, peptidyl transferase activity is quickly destroyed when rRNA is degraded by exposing ribosomes to ribonuclease. Such observations suggested that rRNA rather than a ribosomal protein is responsible for catalyzing peptide bond formation. In bacterial ribosomes, peptidyl transferase activity has been localized to the 23S rRNA of the large ribosomal subunit, and high-resolution X-ray data have pinpointed the catalytic site to a specific region of the RNA chain. Hence 23S rRNA is an example of a *ribozyme*, an enzyme made entirely of RNA (see Chapter 6, page 150).

Translocation. After a peptide bond has been formed, the P site contains an empty tRNA and the A site contains a peptidyl tRNA (the tRNA to which the growing polypeptide chain is attached). The mRNA now advances a distance of three nucleotides relative to the small subunit, bringing the next codon into proper position for translation. During this process of **translocation**—which requires that an elongation factor called EF-G plus GTP become

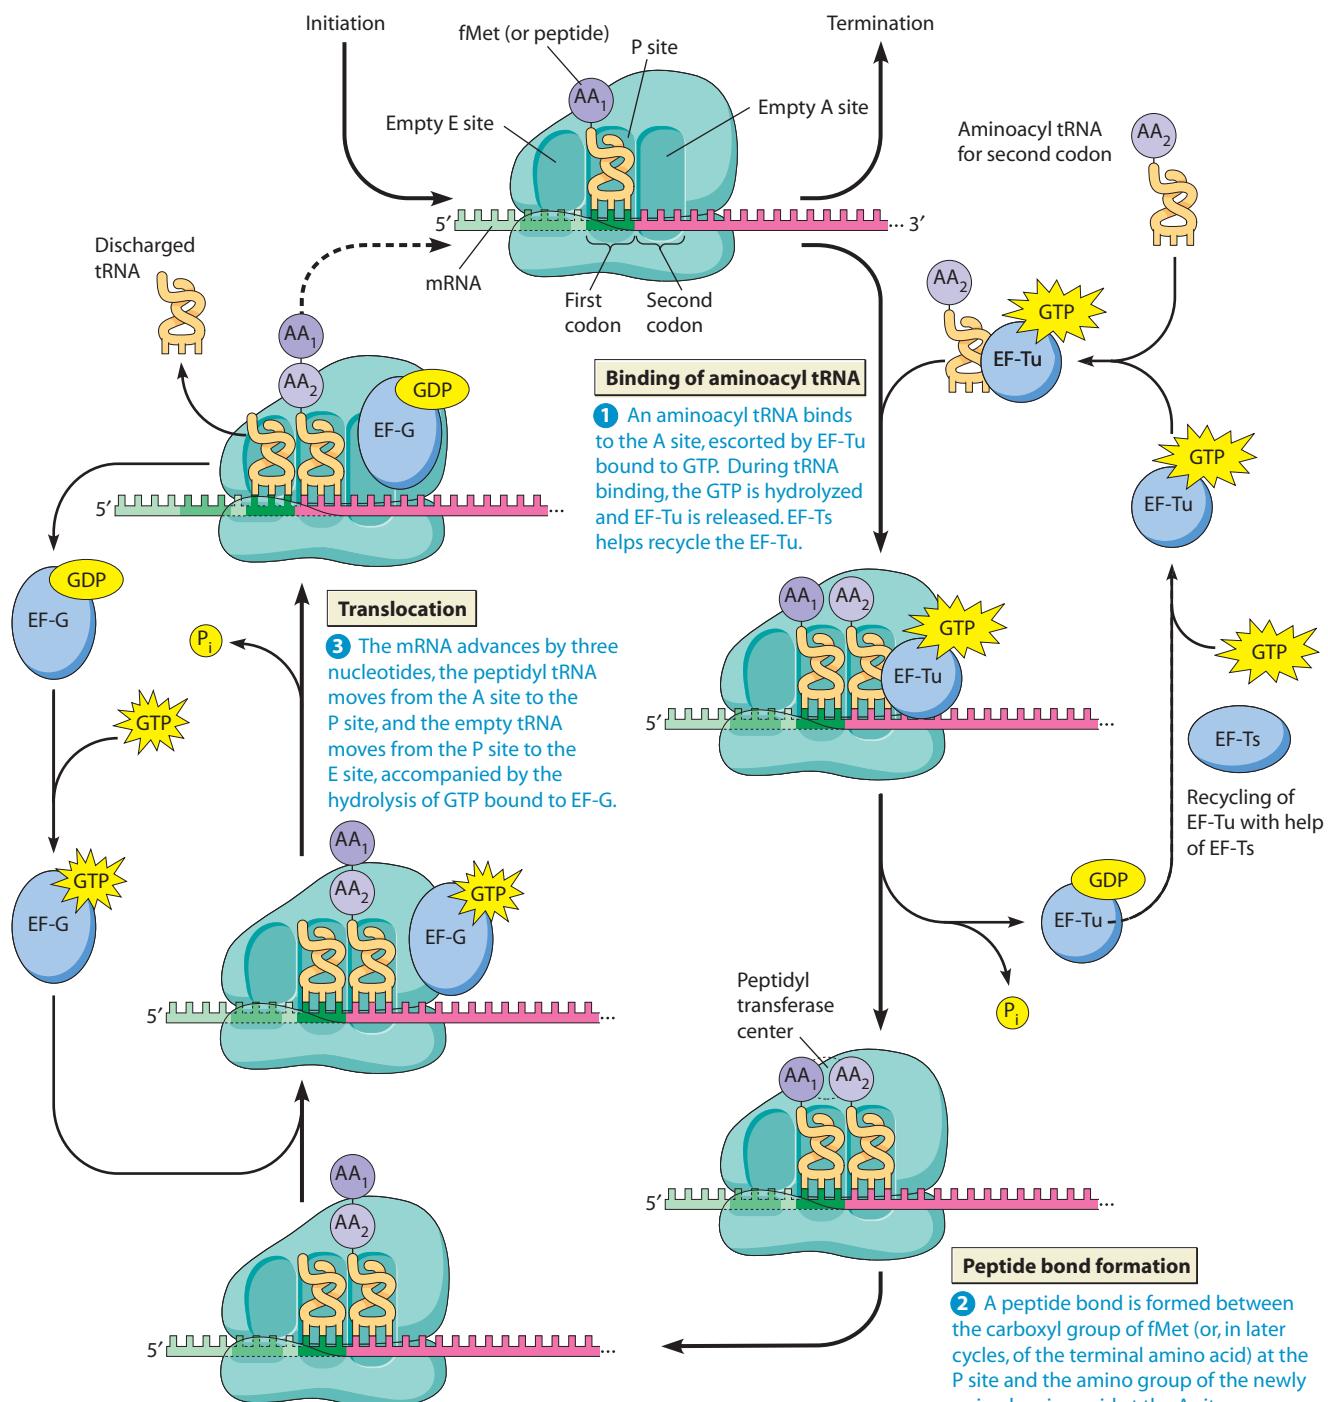

FIGURE 22-10 Polypeptide Chain Elongation in Bacteria. Chain elongation requires the presence of a peptidyl tRNA or, in the first elongation cycle shown here, an fMet-tRNA^{fMet} at the ribosomal P site. Binding of aminoacyl tRNA (1) is followed by peptide bond formation (2) catalyzed by the peptidyl transferase activity of the 23S rRNA of the large ribosomal subunit. During translocation (3), the peptidyl tRNA moves from the A site to the P site, taking the mRNA along with it, and the empty tRNA moves from the P site to the E site and leaves the ribosome. The next mRNA codon is now located in the A site, where the same cycle of events can be repeated for the next amino acid.

ACTIVITIES www.thecellplace.com Elongation of the polypeptide chain

transiently associated with the ribosome—the peptidyl tRNA moves from the A site to the P site and the empty tRNA moves from the P site to the E (exit) site. Although these movements are shown in Figure 22-10 as occurring in a

single step (3), an intermediate “hybrid” state exists in which the anticodon of the peptidyl tRNA still resides at the A site while its aminoacyl end has rotated into the P site, and the anticodon of the empty tRNA still resides at

the P site while its other end has rotated into the E site. Hydrolysis of the GTP bound to EF-G triggers a conformational change in the ribosome that completes the movement of the peptidyl tRNA from the A site to the P site, and the empty tRNA from the P site to the E site.

During translocation, the peptidyl tRNA remains hydrogen-bonded to the mRNA as the mRNA advances by three nucleotides. The central role played by peptidyl tRNA in the translocation process has been demonstrated using mutant tRNA molecules that have *four*-nucleotide anticodons. These tRNAs hydrogen-bond to four nucleotides in mRNA; and, when translocation occurs, the mRNA advances by four nucleotides rather than the usual three. Although this observation indicates that the size of the anticodon loop of the peptidyl tRNA bound to the A site determines how far the mRNA advances during translocation, the physical basis for the mechanism that actually translocates the mRNA over the surface of the ribosome is not well understood.

The net effect of translocation is to bring the next mRNA codon into the A site, so the ribosome is now set to receive the next aminoacyl tRNA and repeat the elongation cycle. The only difference between succeeding elongation cycles and the first cycle is that an initiator tRNA occupies the P site at the beginning of the first elongation cycle, and peptidyl tRNA occupies the P site at the beginning of all subsequent cycles. As each successive amino acid is added, the mRNA is progressively read in the 5' → 3' direction. The amino-terminal end of the growing polypeptide passes out of the ribosome through an *exit tunnel* in the 50S subunit, where it is met by molecular chaperones that help fold the polypeptide into its proper three-dimensional shape. Polypeptide synthesis is very rapid; in a growing *E. coli* cell, a polypeptide of 400 amino acids can be made in 10 seconds.

Termination of Polypeptide Synthesis Is Triggered by Release Factors That Recognize Stop Codons

The elongation process depicted in Figure 22-10 continues in cyclic fashion, reading one codon after another and adding successive amino acids to the polypeptide chain, until one of the three possible stop codons (UAG, UAA, or UGA) in the mRNA arrives at the ribosome's A site (Figure 22-11). Unlike other codons, stop codons are not recognized by tRNA molecules. Instead, the stop codons are recognized by proteins called **release factors**, which possess special regions ("peptide anticodons") that bind to mRNA stop codons present at the ribosomal A site. After binding to the A site along with GTP, the release factors terminate translation by triggering release of the completed polypeptide from the peptidyl tRNA. In essence, the reaction is a hydrolytic cleavage: The polypeptide transfers to a water molecule instead of to an activated amino acid, producing a free carboxyl group at the end of the polypeptide—its C-terminus. After the polypeptide is released accompanied by GTP hydrolysis, the ribosome dissociates into its subunits and the tRNAs

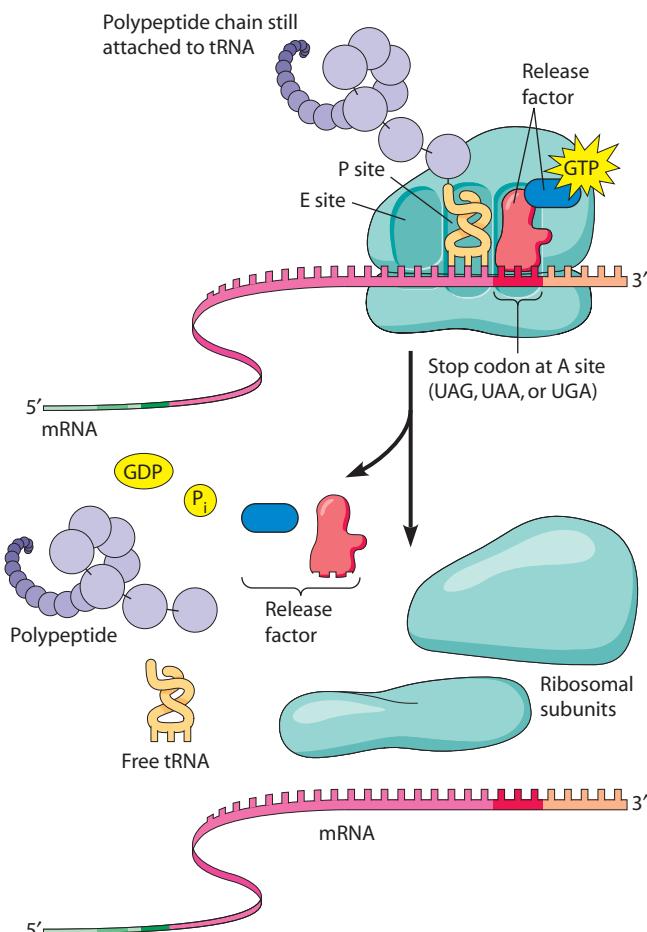

FIGURE 22-11 Termination of Translation. When a stop codon—UAG, UAA, or UGA—arrives at the A site, it is recognized and bound by protein release factors associated with GTP. Hydrolysis of the GTP is accompanied by release of the completed polypeptide, followed by dissociation of the tRNA, mRNA, ribosomal subunits, and release factors.

ACTIVITIES www.thecellplace.com Translation termination

and mRNAs are released. All of these components are now available for reuse in a new cycle of protein synthesis.

Polypeptide Folding Is Facilitated by Molecular Chaperones

Before newly synthesized polypeptides can function properly, they must fold into the correct three-dimensional shape. As discussed in Chapters 2 and 3, the primary sequence of a protein is sufficient to specify its three-dimensional structure, and some polypeptides spontaneously fold into the proper shape in a test tube. However, protein folding inside cells is usually facilitated by proteins called **molecular chaperones** (p. 33). In fact, proper folding often requires the action of several chaperones acting in sequence, beginning when the growing polypeptide chain first emerges from the ribosome's exit tunnel.

A key function of molecular chaperones is to bind to polypeptide chains during the early stages of folding, thereby preventing them from interacting with other

polypeptides before the newly folding chains have acquired the proper conformation. If the folding process goes awry, chaperones can sometimes rescue improperly folded proteins and help them fold properly, or the improperly folded proteins may be destroyed. However, some kinds of incorrectly folded polypeptides tend to bind to each other and form insoluble aggregates that become deposited both within and between cells. Such protein deposits disrupt cell function and may even lead to tissue degeneration and cell death. In **Box 22A**, we discuss how such events can contribute to the development of ailments such as Alzheimer disease and mad cow disease.

Chaperones are found throughout the living world, from archaea and bacteria to the various compartments of eukaryotic cells. Two of the most widely occurring chaperone families are *Hsp70* and *Hsp60*. The “Hsp” comes from the original designation of these proteins as “heat-shock proteins” because cells produce them in response to stressful conditions, such as exposure to high temperatures; under these conditions, chaperones facilitate the refolding of heat-damaged proteins. Members of the *Hsp70* and *Hsp60* chaperone families operate by somewhat different mechanisms, but both involve ATP-dependent cycles of binding and releasing their protein substrates. (It is the release step that requires ATP hydrolysis.) Molecular chaperones are also involved in activities other than protein folding. For example, they help assemble folded polypeptides into multisubunit proteins and—as we will see later in this chapter—they facilitate protein transport into mitochondria and chloroplasts by maintaining polypeptides in an unfolded state prior to their transport into these organelles.

Protein Synthesis Typically Utilizes a Substantial Fraction of a Cell’s Energy Budget

Polypeptide elongation involves the hydrolysis of at least four “high-energy” phosphoanhydride bonds per amino acid added. Two of these bonds are broken in the aminoacyl-tRNA synthetase reaction, where ATP is hydrolyzed to AMP accompanied by the release of two free phosphate groups (see Figure 22-5). The rest are supplied by two molecules of GTP: one used in binding the incoming aminoacyl tRNA at the A site, and the other in the translocation step. Assuming each phosphoanhydride bond has a ΔG° (standard free energy) of 7.3 kcal/mol, the four bonds represent a standard free energy input of 29.2 kcal/mol of amino acid inserted. Thus, the elongation steps required to synthesize a polypeptide 100 amino acids long have a ΔG° value of about 2920 kcal/mol. Moreover, additional GTPs are utilized during formation of the initiation complex, during the transient binding of incorrect aminoacyl tRNAs to the ribosome, and during the termination step of polypeptide synthesis. Clearly, protein synthesis is an expensive process energetically. In fact, it accounts for a substantial fraction of the total energy budget of most cells. When we also consider the energy

required to synthesize messenger RNA and the components of the translational apparatus, as well as the use of ATP by chaperone proteins, the cost of protein synthesis becomes even greater.

It is important to note that during translation, GTP does not function as a typical ATP-like energy donor: Its hydrolysis is not directly linked to the formation of a covalent bond. Instead, GTP appears to induce conformational changes in initiation and elongation factors by binding to them and releasing from them, just as we saw for heterotrimeric and monomeric G proteins in Chapter 14. These shape changes, in turn, allow the factors to bind (noncovalently) to, and be released from, the ribosome. In addition, hydrolysis of the GTP attached to EF-Tu apparently contributes to the accuracy of translation by playing a role in the proofreading mechanism that ejects incorrect aminoacyl tRNAs when they enter the A site.

A Summary of Translation

We have now seen that translation serves as the mechanism that converts information stored in strings of mRNA codons into a chain of amino acids linked by peptide bonds. For a visual summary of the process, refer back to Figure 22-7. As the ribosome reads the mRNA codon by codon in the 5' → 3' direction, successive amino acids are brought into place by complementary base pairing between the codons in the mRNA and the anticodons of aminoacyl-tRNA molecules. When a stop codon is encountered, the completed polypeptide is released, and the mRNA and ribosomal subunits become available for further use.

Most messages are read by many ribosomes simultaneously, each ribosome following closely behind the next on the same mRNA molecule. A cluster of such ribosomes attached to a single mRNA molecule is called a **polyribosome** (see Figure 21-16). By allowing many polypeptides to be synthesized at the same time from a single mRNA molecule, polyribosomes maximize the efficiency of mRNA utilization.

RNA molecules play especially important roles in translation. The mRNA plays a central role, of course, as the carrier of the genetic message. The tRNA molecules serve as the adaptors that bring the amino acids to the appropriate codons. Last but not least, the rRNA molecules have multiple functions. Not only do they serve as structural components of the ribosomes, but one (the 16S rRNA of the small subunit) provides the binding site for incoming mRNA, and another (the 23S rRNA of the large subunit) catalyzes the formation of the peptide bond. The fundamental roles played by RNA may be a vestige of the way that living organisms first evolved on Earth. As we discussed in Chapter 6, the discovery of RNA catalysts (ribozymes) has fostered the idea that the first catalysts on Earth may have been self-replicating RNA molecules rather than proteins. Hence, the present-day ribosome may have evolved from a primitive translational apparatus that was based entirely on RNA molecules.

Protein-Folding Diseases

Polyptide chains must be folded properly before they can perform their normal functions. In humans, more than a dozen diseases have been linked to defects in this folding process. Among the best known is *Alzheimer disease*, the memory disorder that affects one in ten Americans over 65 years old. The symptoms of Alzheimer's are caused by the degeneration of brain cells that exhibit two kinds of structural abnormalities—*intracellular tangles* of a polymerized form of a microtubule accessory protein called *tau*, and *extracellular amyloid plaques* containing fibrils made of a protein fragment 40 to 42 amino acids long called *amyloid-β* ($A\beta$). Evidence that $A\beta$ accumulation is the primary cause of Alzheimer's emerged in the early 1990s, when it was discovered that some forms of Alzheimer's are triggered by inherited mutations in APP, a plasma membrane precursor protein whose cleavage gives rise to $A\beta$. Cleavage of the mutant APP yields a misfolded form of $A\beta$ that aggregates into long fibrils instead of remaining soluble, thereby creating amyloid plaques that accumulate in the brain. Inherited mutations in the enzymes responsible for cleaving APP into $A\beta$ can also produce hereditary forms of Alzheimer's, again characterized by the presence of amyloid plaques. Amyloid accumulation leads to a series of events, including the alteration of tau proteins inside cells, that cause brain cell death and memory loss.

Most people with Alzheimer disease do not inherit mutations in APP or in the enzymes that cleave it, and so they produce a normal version of $A\beta$. Though this normal $A\beta$ usually causes no problems, in some individuals these same $A\beta$ molecules aggregate into fibrils that accumulate and form amyloid plaques. A possible reason for this aberrant behavior is suggested by the discovery that people who inherit different forms of the protein *apolipoprotein E* (*apoE*) have differing risks of developing Alzheimer's. *ApoE* functions primarily in cholesterol transport, but some forms of *apoE* stimulate the accumulation and aggregation of $A\beta$ into the fibrils that form amyloid plaques. Thus any factor that promotes $A\beta$ accumulation may increase a person's risk for Alzheimer's.

Our growing understanding of the relationship between $A\beta$ and Alzheimer's suggests that the disease might eventually be treated using drugs that either inhibit the formation of $A\beta$ or promote its elimination from the brain. It has already been shown that animals can be protected against $A\beta$ buildup by using experimental treatments such as (1) enzyme inhibitors that block the cleavage of $A\beta$ from its precursor APP, (2) small molecules that disrupt amyloid plaques or prevent their formation, and (3) $A\beta$ -containing vaccines that stimulate the immune system to clean up amyloid plaques and/or prevent them from forming. Such vaccines are capable of protecting mice with Alzheimer's symptoms from suffering further memory loss, providing hope that this devastating illness will be conquered in the not-too-distant future.

Abnormalities in protein folding also lie at the heart of a group of brain-destroying infectious diseases that include *scrapie* in sheep and *mad cow disease* in cattle. Stanley Prusiner, who received a Nobel Prize in 1997 for his pioneering work in this field, has proposed that such diseases are transmitted by protein-containing particles called **prions** (briefly discussed in Chapter 4). Because prions do not appear to contain DNA or RNA, Prusiner formulated a unique theory to explain how prions might transmit disease by triggering the infectious spread of abnormal protein folding. According to this theory, a

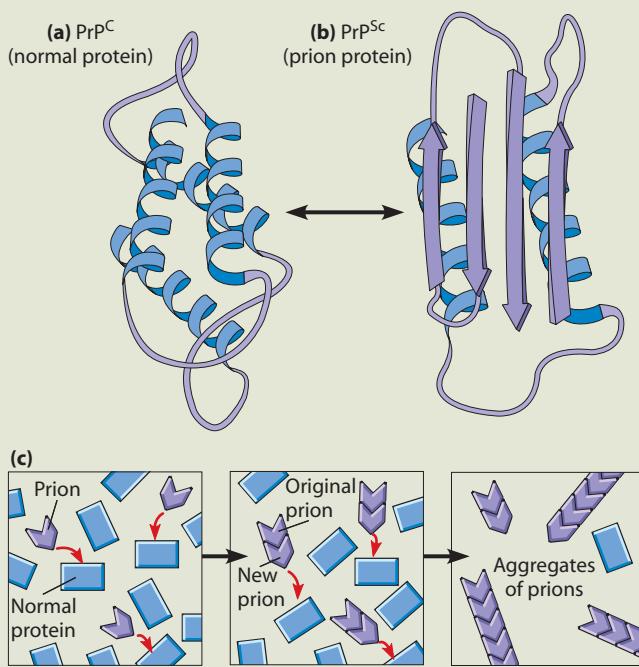

FIGURE 22A-1 A Model for How Prions Promote Their Own Formation. (a) A normal prion protein (PrP^C) contains several α -helices. (b) A misfolded prion protein (PrP^{Sc}) contains β -pleated sheets. (c) The interaction of the prion form of the protein with the normal form can induce the normal protein to misfold. The resulting chain reaction can cause aggregation of the prion form of the protein, leading to degeneration of the brain.

normally folded prion protein (designated PrP^C , Figure 22-A1a) can adopt a misfolded conformation (designated PrP^{Sc} , Figure 22-A1b). When the misfolded PrP^{Sc} encounters a normal PrP^C polypeptide in the process of folding, it causes the normal polypeptide to fold improperly (Figure 22A-1c). The resulting, abnormally folded protein triggers extensive nerve cell damage in the brain, leading to uncontrolled muscle movements and eventual death. The presence of even a tiny bit of prion protein can initiate a chain reaction that causes a cell's normal PrP^C polypeptide chains to fold into more and more of the improperly folded prion protein (PrP^{Sc}). In this way, prion proteins are able to reproduce themselves without the need for nucleic acid.

Even more surprising has been the discovery of different "strains" of prions that cause slightly different forms of disease. When researchers mix tiny quantities of different PrP^{Sc} strains in separate test tubes with large amounts of the same, normal PrP^C polypeptide, each tube produces more of the specific PrP^{Sc} strain than was initially added to that tube. This ability to identify different strains of prions has helped investigators show that almost 200 people in Great Britain were infected with mad cow prions by eating meat derived from diseased cattle, resulting in a fatal, human form of mad cow disease known as *variant Creutzfeldt-Jakob disease* (*vCJD*). More than 1 million cattle have already been destroyed in the United Kingdom in an effort to halt the spread of this disease, but people may continue to die from *vCJD* as a result of having ingested tainted beef over the past two decades.

Mutations and Translation

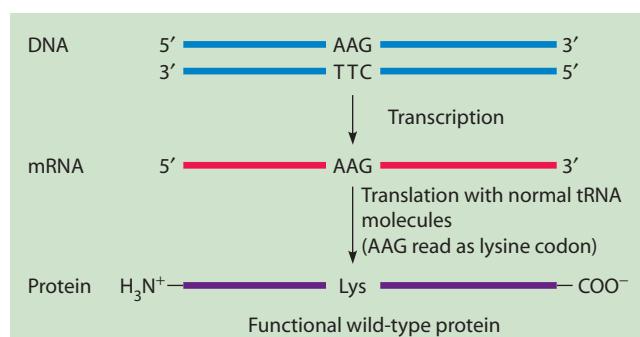

Having described the *normal* process of translation, let us now consider what happens when mRNAs containing *mutant* codons are translated. **Box 22B** provides an overview of the main types of mutations that arise in DNA and their impact on the polypeptide chains produced by mRNAs. Most codon mutations simply alter a single amino acid, and mutations in the third base of a codon frequently do not change the amino acid at all. However, mutations that add or remove stop codons, or alter the reading frame, can severely disrupt mRNA translation. In this section, we will examine some of the ways in which cells can respond to such disruptive mutations.

Suppressor tRNAs Overcome the Effects of Some Mutations

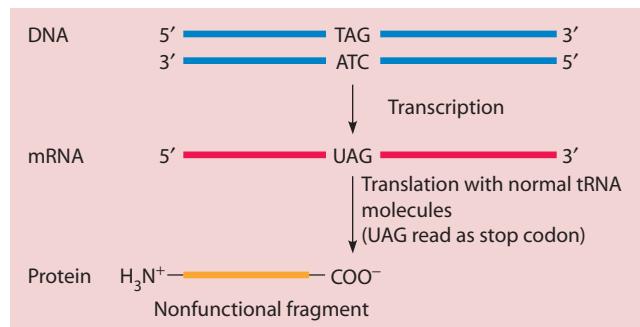

Mutations that convert amino acid-coding codons into stop codons are referred to as **nonsense mutations**. **Figure 22-12** shows a case in which mutation of a single base pair in DNA converts an AAG lysine codon in mRNA to a UAG stop signal. Nonsense mutations like this one typically lead to production of incomplete, nonfunctional polypeptides that have been prematurely terminated at the mutant stop codon.

Nonsense mutations in essential genes are often lethal, but sometimes their detrimental effects can be overcome by an independent mutation affecting a tRNA gene. Such mutant tRNA genes produce mutant tRNAs that recognize what would otherwise be a stop codon and insert an amino acid at that point. In the example shown in Figure 22-12c, a mutant tRNA has an altered anticodon that allows it to read the stop codon UAG as a codon for tyrosine. The inserted amino acid is almost always different from the amino acid that would be present at that position in the wild-type protein, but the important point is that chain termination is averted and a full-length polypeptide can be made.

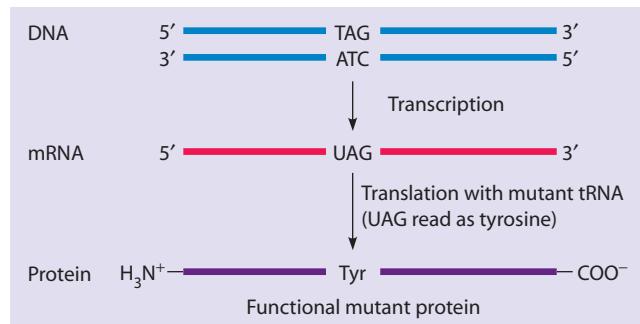

A tRNA molecule that somehow negates the effect of a mutation is called a **suppressor tRNA**. As you might expect, suppressor tRNAs exist that negate the effects of various types of mutations in addition to nonsense mutations (see Problem 22-8 at the end of the chapter). For a cell to survive, suppressor tRNAs must be rather inefficient; otherwise, the protein-synthesizing apparatus would produce too many abnormal proteins. An overly efficient nonsense suppressor, for example, would cause normal stop codons to be read as if they coded for an amino acid, thereby preventing normal termination. In fact, the synthesis of most polypeptides is terminated properly in cells containing nonsense suppressor tRNAs, indicating that a stop codon located in its proper place at the end of an mRNA coding sequence still triggers termination, whereas the same codon in an internal location does not. The most likely explanation is based on the behavior of the release factors that trigger normal termination (page 690). When a stop codon occurs in its proper location near the end of an RNA, release factors trigger termination because they are more efficient than suppressor tRNAs in binding to

(a) Normal gene, normal tRNA molecules

(b) Mutant gene, normal tRNA molecules

(c) Mutant gene, mutant (suppressor) tRNA molecule

FIGURE 22-12 Nonsense Mutations and Suppressor tRNAs. (a) A wild-type (normal) gene is transcribed into an mRNA molecule that contains the codon AAG at one point. Upon translation, this codon specifies the amino acid lysine (Lys) at this point in the functional, wild-type protein. (b) If a DNA mutation occurs that changes the AAG codon in the mRNA to UAG, the UAG codon will be read as a stop signal, and the translation product will be a short, nonfunctional polypeptide. Mutations of this sort are called nonsense mutations. (c) In the presence of a mutant tRNA that reads UAG as an amino acid codon instead of a stop signal, an amino acid will be inserted and polypeptide synthesis will continue. In the example shown, UAG is read as a codon for tyrosine because the mutant tyrosine tRNA has as its anticodon 3'-AUC-5' instead of the usual 3'-AUG-5' (which recognizes the tyrosine codon 5'-UAC-3'). The resulting protein will be mutant because a lysine has been replaced by a tyrosine at one point along the chain. However, the protein may still be functional if its biological activity is not significantly affected by the amino acid substitution.

A Mutation Primer

In its broadest sense, the term *mutation* refers to any change in the nucleotide sequence of a genome. Now that we have examined the processes of transcription and translation, we can understand the effects of several kinds of mutations. Limiting our discussion to protein-coding genes, let's consider some of the main types of mutations and their impact on the polypeptide encoded by the mutant gene.

In this and the previous chapter, we have encountered several types of mutations in which the DNA change involves only one or a few base pairs (**Figure 22B-1a**). At the beginning of Chapter 21, for instance, we mentioned the genetic allele that, when homozygous, causes sickle-cell anemia. This allele originated from a type of mutation called a *base-pair substitution*. In this case, an AT base pair was substituted for a TA base pair in DNA. As a result, a GUA codon replaces a GAA in the mRNA transcribed from the mutant allele, and in the polypeptide (β -globin) a valine replaces a glutamic acid. This single amino acid change, caused by a single base-pair change, is enough to change the conformation of β -globin and, in turn, the hemoglobin tetramer, altering the way hemoglobin molecules pack into red cells and producing abnormally shaped cells that become trapped and damaged when they pass through small blood vessels (see Figure 21-2). Such a base-pair substitution is called a *missense mutation* because the mutated codon continues to code for an amino acid—but the “wrong” one.

Alternatively, a base-pair substitution can create a *nonstop mutation* by converting a normal stop codon into an amino acid codon, or conversely, it can create a *nonsense mutation* by converting an amino acid codon into a stop codon. In the latter case, the translation machinery will terminate the polypeptide prematurely. Unless the nonsense mutation is close to the end of the message or a suppressor tRNA is present, the polypeptide is not likely to be functional. Nonsense, nonstop, and missense codons can also arise from the *base-pair insertions* and *deletions* that cause *frameshift mutations*.

stop codons in this location—perhaps because release factor action is stimulated by a special sequence or three-dimensional configuration near the end of the mRNA.

Nonsense-Mediated Decay and Nonstop Decay Promote the Destruction of Defective mRNAs

In the absence of an appropriate suppressor tRNA, a nonsense stop codon will cause mRNA translation to stop prematurely, thereby generating an incomplete polypeptide chain that cannot function properly and may even harm the cell. To avoid wasting energy on the production of such useless products, eukaryotic cells invoke a quality control mechanism called **nonsense-mediated decay** to destroy mRNAs containing premature stop codons. In mammals, the method for identifying premature stop codons involves the *exon junction complex* (*EJC*), a multiprotein complex deposited during mRNA splicing at each point where an intron is removed from pre-mRNA (see Figure 21-22). Thus, every newly spliced mRNA molecule will have one or more

A single amino acid change (or even a change in several amino acids) does not always affect a protein’s function in a major way. As long as the protein’s three-dimensional conformation remains relatively unchanged, biological activity may be unaffected. Substitution of one amino acid for another of the same type—for example, valine for isoleucine—is especially unlikely to affect protein function. The nature of the genetic code actually reduces the effects of single base-pair alterations because many turn out to be *silent mutations* that change the nucleotide sequence without changing the genetic message. For example, changing the third base of a codon often produces a new codon that still codes for the same amino acid. Here, the “mutant” polypeptide is exactly the same as the wild-type.

In addition to mutations affecting one or a few base pairs, some alterations involve longer stretches of DNA (Figure 22B-1b). A few affect genome segments so large that the DNA changes can be detected by light microscopic examination of chromosomes. Some of these large-scale mutations are created by *insertions* or *deletions* of long DNA segments, but several other mechanisms also exist. In a *duplication*, a section of DNA is tandemly repeated. In an *inversion*, a chromosome segment is cut out and reinserted in its original position but in the reverse direction. A *translocation* involves the movement of a DNA segment from its normal location in the genome to another place, either in the same chromosome or a different one. Because these large-scale mutations may or may not affect the expression of many genes, they have a wide range of phenotypic effects, from no effect at all to lethality.

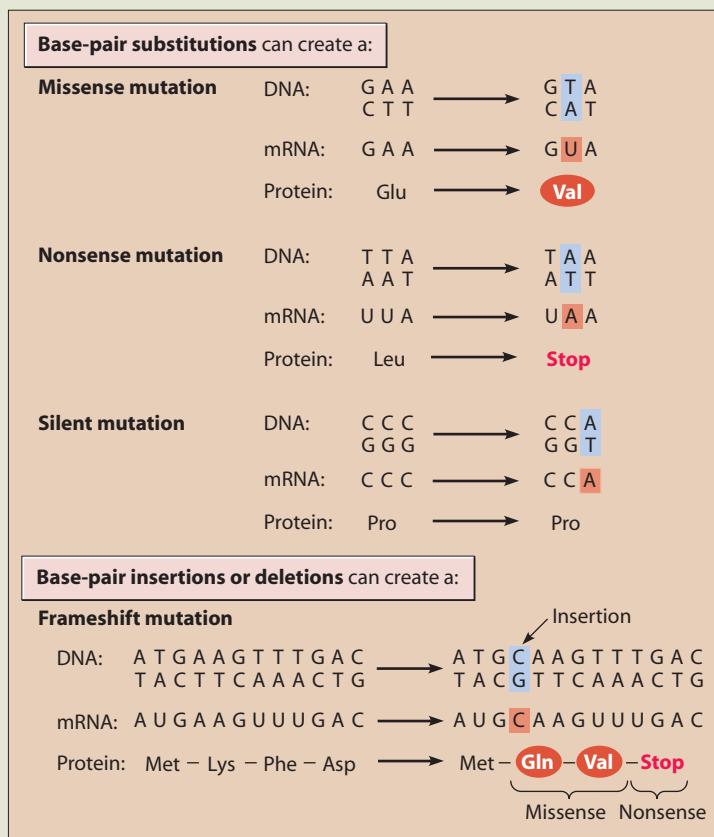

When we think about the potential effects of mutations, it is useful to remember that genes have important noncoding components and that these, too, can be mutated in ways that seriously affect gene products. A mutation in a promoter, for example, can result in more or less frequent transcription of the gene. Even a mutation in an intron can affect the gene product in a major way if it touches a critical part of a splice-site sequence.

EJCs bound to it, one at each exon-exon junction. During translation, the distinction between normal and premature stop codons is made on the basis of their relationship to EJCs. If a stop codon is encountered in an mRNA prior to the last EJC—in other words, before the last exon—it must be a premature stop codon. The presence of such a stop codon will cause translation to be terminated while the mRNA still has one or more EJCs bound to it, and the presence of these remaining EJCs marks the mRNA for degradation.

How do cells handle the opposite situation, namely an mRNA with no stop codons? In eukaryotic cells, translation becomes stalled when a ribosome reaches the end of an mRNA without encountering a stop codon. An RNA-degrading enzyme complex then binds to the empty A site of the ribosome and degrades the defective mRNA in a process called **nonstop decay**. The same problem is handled a bit differently in bacteria. When translation halts at the end of a bacterial mRNA lacking a stop codon, an unusual type of RNA called *tRNA* (“transfer-messenger RNA”) binds to the A site of the ribosome and directs the addition of about a

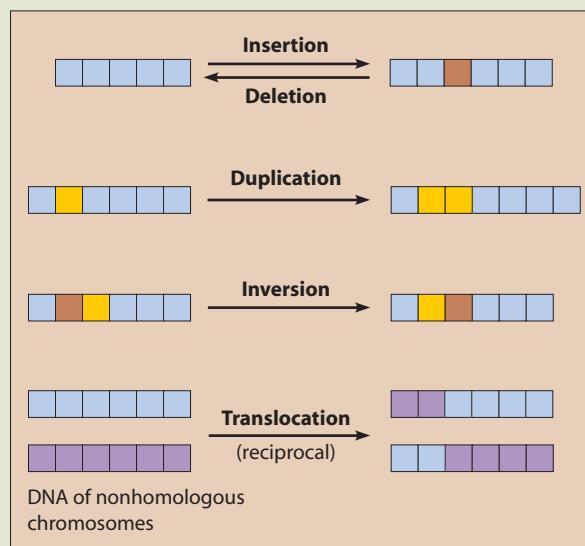

Finally, mutations in genes that encode regulatory proteins—that is, proteins that control the expression of other genes—can

have far-reaching effects on many other proteins. We will discuss this topic in Chapter 23.

(a) Mutations affecting one base pair

FIGURE 22B-1 Types of Mutations. Mutations can affect (a) one base pair or (b) long DNA segments.

(b) Mutations affecting long DNA segments

dozen more amino acids to the growing polypeptide chain. This amino acid sequence creates a signal that targets the protein for destruction. At the same time, the mRNA is degraded by a ribonuclease associated with the tmRNA.

Posttranslational Processing

After polypeptide chains have been synthesized, they often must be chemically modified before they can perform their normal functions. Such modifications are known collectively as **posttranslational modifications**. In bacteria, for example, the *N*-formyl group located at the N-terminus of polypeptide chains is always removed. The methionine it was attached to is often removed also, as is the methionine that starts eukaryotic polypeptides. As a result, relatively few mature polypeptides have methionine at their N-terminus, even though they all started out that way. Sometimes whole blocks of amino acids are removed from the polypeptide. Certain enzymes, for example, are synthesized as inactive precursors that must be activated by the removal of a spe-

cific sequence at one end or the other. The transport of proteins across membranes also may involve the removal of a terminal *signal sequence*, as we will see shortly, and some polypeptides have internal stretches of amino acids that must be removed to produce an active protein. For instance, insulin is synthesized as a single polypeptide and then processed to remove an internal segment; the two end segments remain linked by disulfide bonds between cysteine residues in the active hormone (see Figure 3-7).

Other common processing events include chemical modifications of individual amino acid groups—by methylation, phosphorylation, or acetylation reactions, for example. In addition, a polypeptide may undergo glycosylation (the addition of carbohydrate side chains; see Chapter 12) or binding to prosthetic groups. Finally, in the case of proteins composed of multiple subunits, individual polypeptide chains must bind to one another to form the appropriate multisubunit proteins or multiprotein complexes.

In addition to the preceding posttranslational events, some proteins undergo a relatively unusual type of

processing called *protein splicing*, which is analogous to the phenomenon of *RNA splicing* discussed in Chapter 21. As we saw, intron sequences are removed from RNA molecules during RNA splicing, and the remaining exon sequences are simultaneously spliced together. Likewise, during protein splicing, specific amino acid sequences called *inteins* are removed from a polypeptide chain and the remaining segments, called *exteins*, are spliced together to form the mature protein. Protein splicing is usually intramolecular, involving the excision of an intein from a single polypeptide chain by a self-catalytic mechanism. However, splicing can also take place between two polypeptide chains arising from two different mRNAs. For example, in some photosynthetic bacteria a subunit of DNA polymerase III is produced from two separate genes, each coding for an intein-containing polypeptide that includes part of the DNA polymerase subunit. In some cases, the inteins removed by protein splicing reactions turn out to be stable proteins exhibiting their own biological functions (usually endonuclease activity). Once considered to be an oddity of nature, protein splicing has now been detected in dozens of different organisms, prokaryotes as well as eukaryotes.

Protein Targeting and Sorting

Now that we have seen how proteins are synthesized, we are ready to explore the mechanisms that route each newly made protein to its correct destination. Think for a moment about a typical eukaryotic cell with its diversity of organelles, each containing its own unique set of proteins. Such a cell is likely to have billions of protein molecules, representing at least 10,000 kinds of polypeptides. And each polypeptide must find its way to the appropriate location within the cell, or even out of the cell altogether. A limited number of these polypeptides are encoded by the genome of the mitochondrion (and, for plant cells, by the chloroplast genome as well), but most are encoded by nuclear genes and are synthesized by a process beginning in the cytosol. Each of these polypeptides must then be directed to its proper destination and must therefore have some sort of molecular “zip code” ensuring its delivery to the correct place. As our final topic for this chapter, we will consider this process of protein targeting and sorting.

We can begin by grouping the various compartments of eukaryotic cells into three categories: (1) the endomembrane system, the interrelated system of membrane compartments that includes the endoplasmic reticulum (ER), the Golgi complex, lysosomes, secretory vesicles, the nuclear envelope, and the plasma membrane; (2) the cytosol; and (3) mitochondria, chloroplasts, peroxisomes (and related organelles), and the interior of the nucleus.

Polypeptides encoded by nuclear genes are routed to these compartments using several different mechanisms. The process begins with transcription of DNA into RNAs that are processed in the nucleus and then transported through nuclear pores for translation in the cytoplasm, where most ribosomes occur. Although translation is

largely a cytoplasmic process, some evidence suggests that up to 10% of a cell’s ribosomes may actually reside in the nucleus, where they can translate newly synthesized RNAs. Nuclear translation appears to function mainly as a quality control mechanism that checks new mRNAs for the presence of errors (see the discussion of nonsense-mediated decay on page 694).

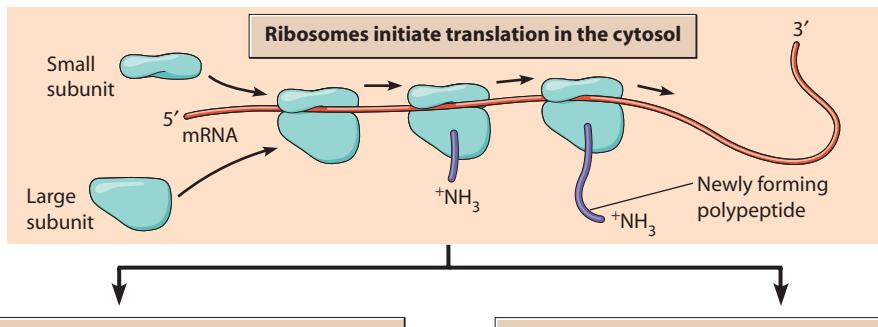

Despite the existence of these functioning nuclear ribosomes, it is clear that most polypeptide synthesis occurs on cytoplasmic ribosomes after mRNAs have been exported through the nuclear pores. Upon arriving in the cytoplasm, these mRNAs become associated with *free ribosomes* (ribosomes not attached to any membrane). Shortly after translation begins, two main pathways for routing the newly forming polypeptide products begin to diverge (**Figure 22-13**). The first pathway is utilized by ribosomes synthesizing polypeptides destined for the endomembrane system or for export from the cell. Such ribosomes become attached to ER membranes early in the translational process, and the growing polypeptide chains are then transferred across (or, in the case of integral membrane proteins, inserted into) the ER membrane as synthesis proceeds (Figure 22-13a). This transfer of polypeptides into the ER is called **cotranslational import** because movement of the polypeptide across or into the ER membrane is directly coupled to the translational process. The subsequent conveyance of such proteins from the ER to their final destinations is carried out by various membrane vesicles and the Golgi complex, as discussed in Chapter 12 (see Figure 12-8).

An alternative pathway is employed for polypeptides destined for either the cytosol or for mitochondria, chloroplasts, peroxisomes, and the nuclear interior (Figure 22-13b). Ribosomes synthesizing these types of polypeptides remain free in the cytosol, unattached to any membrane. After translation has been completed, the polypeptides are released from the ribosomes and either remain in the cytosol as their final destination or are taken up by the appropriate organelle. The uptake by organelles of such completed polypeptides requires the presence of special targeting signals and is called **posttranslational import**. In the case of the nucleus, polypeptides enter through the nuclear pores, as discussed in Chapter 18 (see Figure 18-31). Polypeptide entrance into mitochondria, chloroplasts, and peroxisomes involves a different kind of mechanism, as we will see shortly.

With this general overview in mind, we are now ready to examine the mechanisms of cotranslational import and posttranslational import in detail.

Cotranslational Import Allows Some Polypeptides to Enter the ER as They Are Being Synthesized

Cotranslational import into the ER is the first step in the pathway for delivering newly synthesized proteins to various locations within the endomembrane system. Proteins handled in this way are synthesized on ribosomes that become attached to the ER shortly after translation begins.

(a) Ribosomes attach to ER membranes if they are synthesizing polypeptides destined for the endomembrane system or for export from the cell. As synthesis continues, the newly forming polypeptide is transferred across the ER membrane by **COTRANSLATIONAL IMPORT**. The completed polypeptide either remains in the ER or is transported via various vesicles to another compartment of the endomembrane system. (Integral membrane proteins are inserted into the ER membrane as they are made, rather than being released into the ER lumen.)

OR

(b) Ribosomes remain free in the cytosol if they are synthesizing polypeptides destined for the cytosol or for import into the nucleus, mitochondria, chloroplasts, or peroxisomes. When the polypeptide is complete, it is released from the ribosome and either remains in the cytosol or is transported into the appropriate organelle by **POSTTRANSLATIONAL IMPORT**. Polypeptide uptake by the nucleus occurs via the nuclear pores, using a mechanism different from that involved in posttranslational uptake by other organelles.

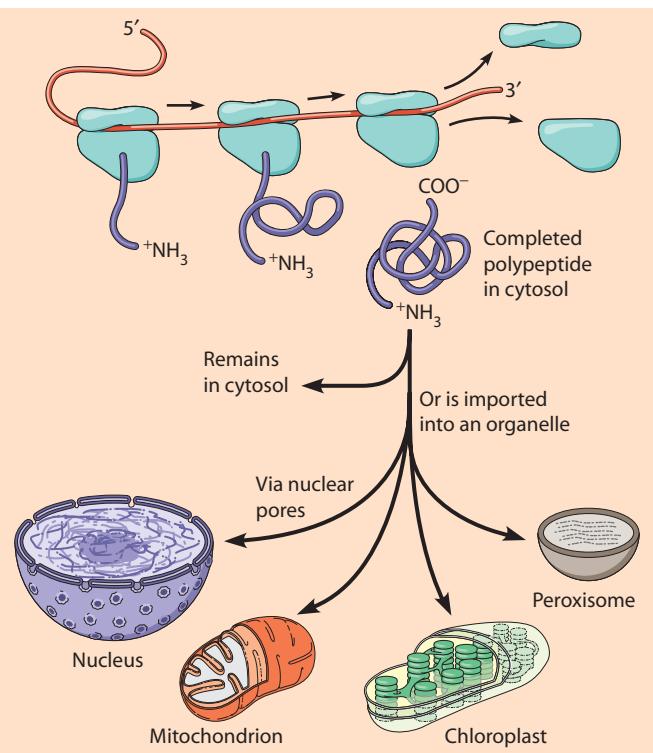

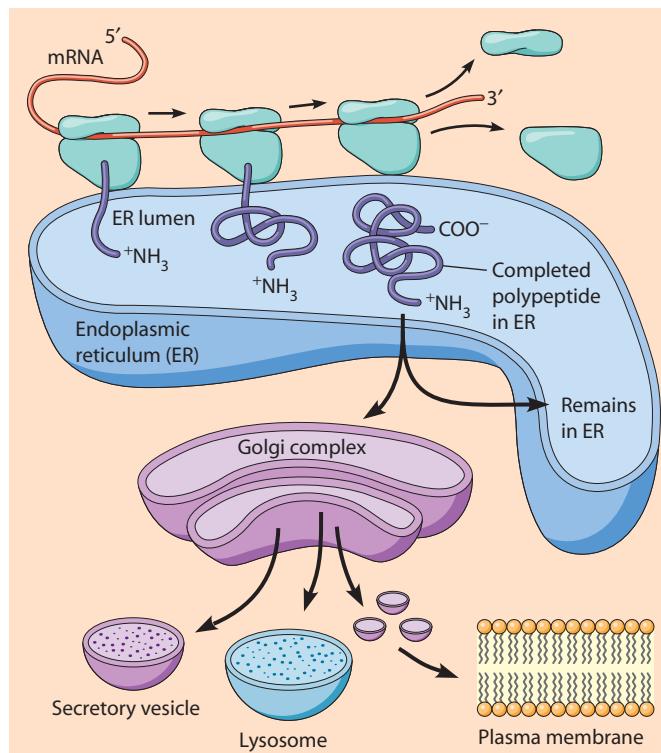

FIGURE 22-13 Intracellular Sorting of Proteins. Polypeptide synthesis begins in the cytosol but takes one of two alternative routes when the polypeptide is about 30 amino acids long. **(a)** Polypeptides destined for the endomembrane system, or for export from the cell, are transferred across the ER membrane by cotranslational import as they are being made. **(b)** Other polypeptides are synthesized in the cytosol and either remain there or are transferred by posttranslational import into the nucleus, mitochondria, chloroplasts, or peroxisomes.

The role of the ER in this process was first suggested by experiments in which Colvin Redman and David Sabatini studied protein synthesis in isolated vesicles of rough ER (ER vesicles with attached ribosomes). Such vesicles, known as *microsomes*, can be isolated using subcellular fractionation and centrifugation (see Box 12A). After briefly incubating the rough ER vesicles in the presence of radioactive amino acids and other components needed for protein synthesis, they stopped the reaction by adding *puromycin*,

an antibiotic that causes partially completed polypeptide chains to be released from ribosomes. When the ribosomes and membrane vesicles were then separated and analyzed to see where the newly made, radioactive polypeptide chains were located, a substantial fraction of the radioactivity was found inside the ER lumen (**Figure 22-14**). Such results suggested that newly forming polypeptides pass into the lumen of the ER *as they are being synthesized*, allowing them to be routed through the ER to their correct destinations.

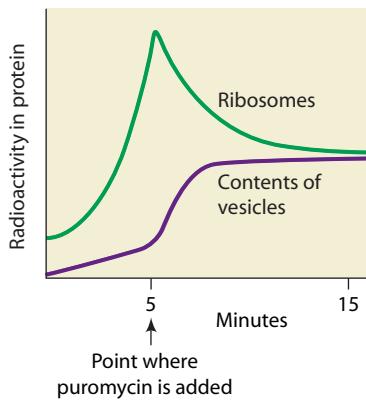

FIGURE 22-14 Evidence That Proteins Synthesized on Ribosomes Attached to ER Membranes Pass Directly into the ER Lumen. ER vesicles containing attached ribosomes were isolated and incubated with radioactive amino acids to label newly made polypeptide chains. Next, protein synthesis was halted by adding puromycin, which also causes the newly forming polypeptide chains to be released from the ribosomes. The ribosomes were then removed from the membrane vesicles, and the amount of radioactive protein associated with the ribosomes and in the membrane vesicles was measured. The graph shows that after the addition of puromycin, radioactivity is lost from the ribosomes and appears inside the vesicles. This observation suggests that the newly forming polypeptide chains are inserted through the ER membrane as they are being synthesized, and puromycin causes the chains to be prematurely released into the vesicle lumen.

If some polypeptides move directly into the lumen of the ER as they are being synthesized, how does the cell determine which polypeptides are to be handled in this way? An answer was first suggested in 1971 by Günter Blobel and David Sabatini, whose model was called the *signal hypothesis* because it proposed that some sort of intrinsic molecular signal distinguishes such polypeptides from the many polypeptides destined to be released into the cytosol. This hypothesis has so profoundly influenced the field of cell biology that Blobel was awarded the Nobel Prize in 1999 for his work in demonstrating that proteins have intrinsic signals governing their transport and localization within the cell. The signal hypothesis stated that for polypeptides destined for the ER, the first segment of the polypeptide to be synthesized, the N-terminus, contains an **ER signal sequence** that directs the ribosome-mRNA-polypeptide complex to the surface of the rough ER, where the complex anchors at a protein “dock” on the ER surface. Then, as the polypeptide chain elongates during mRNA translation, it progressively crosses the ER membrane and enters the ER lumen.

Shortly after the signal hypothesis was first proposed, evidence for the actual existence of ER signal sequences was obtained by César Milstein and his associates, who were studying the synthesis of the small subunit, or *light chain*, of the protein *immunoglobulin G*. In cell-free systems containing purified ribosomes and the components required for protein synthesis, the mRNA coding for the immunoglobulin light chain directs the synthesis of a polypeptide product that is 20 amino acids longer at its

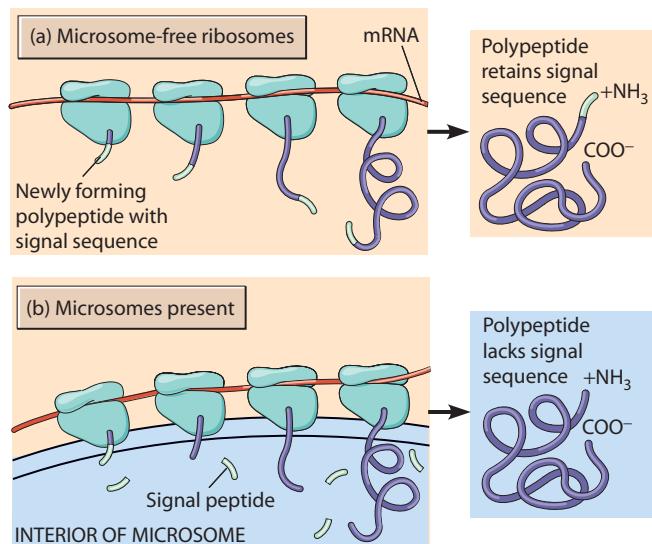

FIGURE 22-15 Evidence That Cotranslational Insertion into the ER Is Required for Normal Processing of Secreted Proteins. (a) Protein synthesis can be carried out in a cell-free system that includes ribosomes and other components but no membranes. When a messenger RNA encoding a protein that is normally secreted is added, the resulting protein is abnormally large because it retains its signal sequence. (b) When microsomes, which consist of ER membranes and attached ribosomes, are isolated and the same mRNA is added, the resulting protein is transported across the vesicle membrane and the signal sequence is cleaved.

N-terminal end than the authentic light chain itself. Adding ER membranes (microsomes) to this system leads to the production of an immunoglobulin light chain of the correct size (Figure 22-15). Such findings suggested that the extra 20-amino acid segment is functioning as an ER signal sequence and that this signal sequence is removed when the polypeptide moves into the ER. Subsequent studies revealed that other polypeptides destined for the ER also possess an N-terminal sequence that is required for targeting the protein to the ER and that is removed as the polypeptide moves into the ER. Proteins containing such ER signal sequences at their N-terminus are often referred to as *preproteins* (e.g., prelysozyme, preproinsulin, pretrypsinogen, and so forth).

Sequencing studies have revealed that the amino acid compositions of ER signal sequences are surprisingly variable, but several unifying features have been noted. ER signal sequences are typically 15–30 amino acids long and consist of three domains: a positively charged N-terminal region, a central hydrophobic region, and a polar region adjoining the site where cleavage from the mature protein will take place. The positively charged end may promote interaction with the hydrophilic exterior of the ER membrane, and the hydrophobic region may facilitate interaction of the signal sequence with the membrane’s lipid interior. In any case, it is now established that only polypeptides with ER signal sequences can be inserted into or across the ER membrane as their synthesis proceeds. In fact, when recombinant DNA methods are used to add ER

signal sequences to polypeptides that do not usually have them, the recombinant polypeptides are directed to the ER.

The Signal Recognition Particle (SRP) Binds the Ribosome-mRNA-Polypeptide Complex to the ER Membrane

Once the existence of ER signal sequences was established, it quickly became clear that newly forming polypeptides must become attached to the ER membrane before very much of the polypeptide has emerged from the ribosome. If translation were to continue without attachment to the ER, the folding of the growing polypeptide chain might bury the signal sequence. To understand what prevents this from happening, we need to look at the signal mechanism in further detail.

Contrary to the original signal hypothesis, the ER signal sequence does not itself initiate contact with the ER. Instead, the contact is mediated by a **signal recognition particle (SRP)**, which recognizes and binds to the ER signal sequence of the newly forming polypeptide and then binds to the ER membrane (**Figure 22-16**). At first the SRP was thought to be purely protein (the *P* in its name originally stood for protein). Later, however, the SRP was shown to consist of six different polypeptides complexed with a 300-nucleotide (7S) molecule of RNA. The protein components have three main active sites: one that recognizes and binds to the ER signal sequence, one that interacts with the ribosome to block further translation, and one that binds to the ER membrane.

Figure 22-16 illustrates the role played by the SRP in cotranslational import. The process begins when an mRNA coding for a polypeptide destined for the ER starts to be translated on a free ribosome. Polypeptide synthesis proceeds until the ER signal sequence has been formed and emerges from the surface of the ribosome. At this stage, SRP (shown in orange) binds to the signal sequence and blocks further translation (step **①**). The SRP then binds the ribosome to a special structure in the ER membrane called a **translocon** because it carries out the translocation of polypeptides across the ER membrane. (Note that the term *translocation*, which literally means “a change of location,” is used to describe both the movement of proteins through membranes and, earlier in the chapter, the movement of mRNA across the ribosome.)

The translocon is a protein complex composed of several components involved in cotranslational import, including an *SRP receptor* to which the SRP binds, a *ribosome receptor* that holds the ribosome in place, a *pore protein* that forms a channel through which the growing polypeptide can enter the ER lumen, and *signal peptidase*, an enzyme that removes the ER signal sequence. As **②** shows, SRP (bringing an attached ribosome) first binds to the SRP receptor, allowing the ribosome to become attached to the ribosome receptor. Next, GTP binds to both SRP and the SRP receptor, unblocking translation and causing transfer of the signal sequence to the pore protein,

whose central channel opens as the signal sequence is inserted (**③**). GTP is then hydrolyzed, accompanied by release of the SRP (**④**). As the polypeptide elongates, it passes into the ER lumen and signal peptidase cleaves the signal sequence, which is quickly degraded (**⑤**). After polypeptide synthesis is completed, the final polypeptide is released into the ER lumen, the translocon channel is closed, and the ribosome detaches from the ER membrane and dissociates into its subunits, releasing the mRNA (**⑥**).

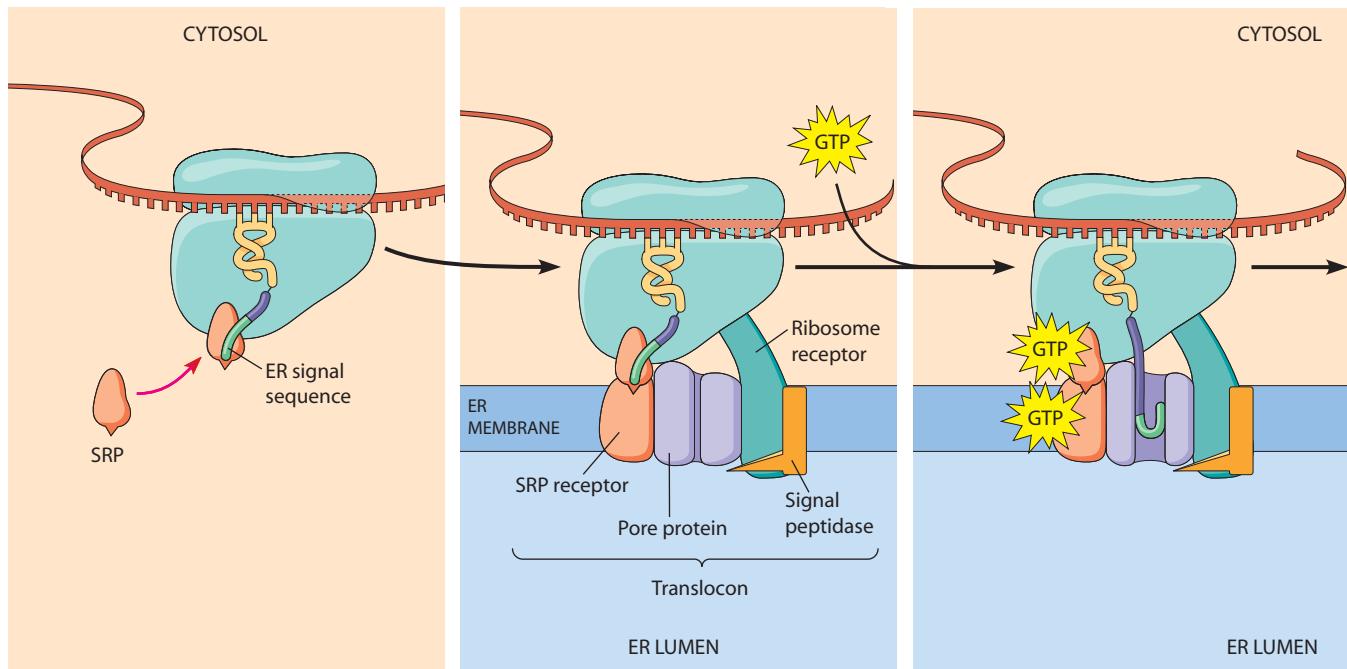

Protein Folding and Quality Control Take Place Within the ER

After polypeptides are released into the ER lumen, they fold into their final shape and, in some cases, assemble with other polypeptides to form multisubunit proteins. As we mentioned earlier in the chapter, molecular chaperones facilitate these folding and assembly events. The most abundant chaperone in the ER lumen is a member of the Hsp70 family of chaperones known as BiP (an abbreviation for *Binding Protein*). BiP acts by binding to *hydrophobic regions* of polypeptide chains, especially to regions enriched in the amino acids tryptophan, phenylalanine, and leucine.

In a mature, fully folded protein, such hydrophobic regions are buried in the interior of the protein molecule. In an unfolded polypeptide, these same hydrophobic regions are exposed to the surrounding aqueous environment, creating an unstable situation in which polypeptides tend to aggregate with one another. BiP prevents this aggregation by transiently binding to the hydrophobic regions of unfolded polypeptides as they emerge into the ER lumen, stabilizing them and preventing them from interacting with other unfolded polypeptides. BiP then releases the polypeptide chain, accompanied by ATP hydrolysis, giving the polypeptide a brief opportunity to fold (perhaps aided by other chaperones). If the polypeptide folds correctly, its hydrophobic regions become buried in the molecule’s interior and can no longer bind to BiP. But if the hydrophobic segments fail to fold properly, BiP binds again to the polypeptide and the cycle is repeated. In this way, BiP uses energy released by ATP hydrolysis to promote proper protein folding.

Folding is often accompanied by the formation of disulfide bonds between cysteines located in different regions of a polypeptide chain. This reaction is facilitated by **protein disulfide isomerase**, an enzyme present in the ER lumen that catalyzes the formation and breakage of disulfide bonds between cysteine residues. Protein disulfide isomerase starts acting before the synthesis of a newly forming polypeptide has been completed, allowing various disulfide bond combinations to be tested until the most stable arrangement is found.

Proteins that repeatedly fail to fold properly can activate several types of quality control mechanisms. One such mechanism, called the **unfolded protein response (UPR)**, uses sensor molecules in the ER membrane to detect misfolded proteins. These sensors activate signaling

① SRP binds to ER signal sequence and blocks translation.

② SRP binds to SRP receptor; ribosome docks on membrane.

③ GTP binds to SRP and SRP receptor; pore opens and polypeptide is inserted.

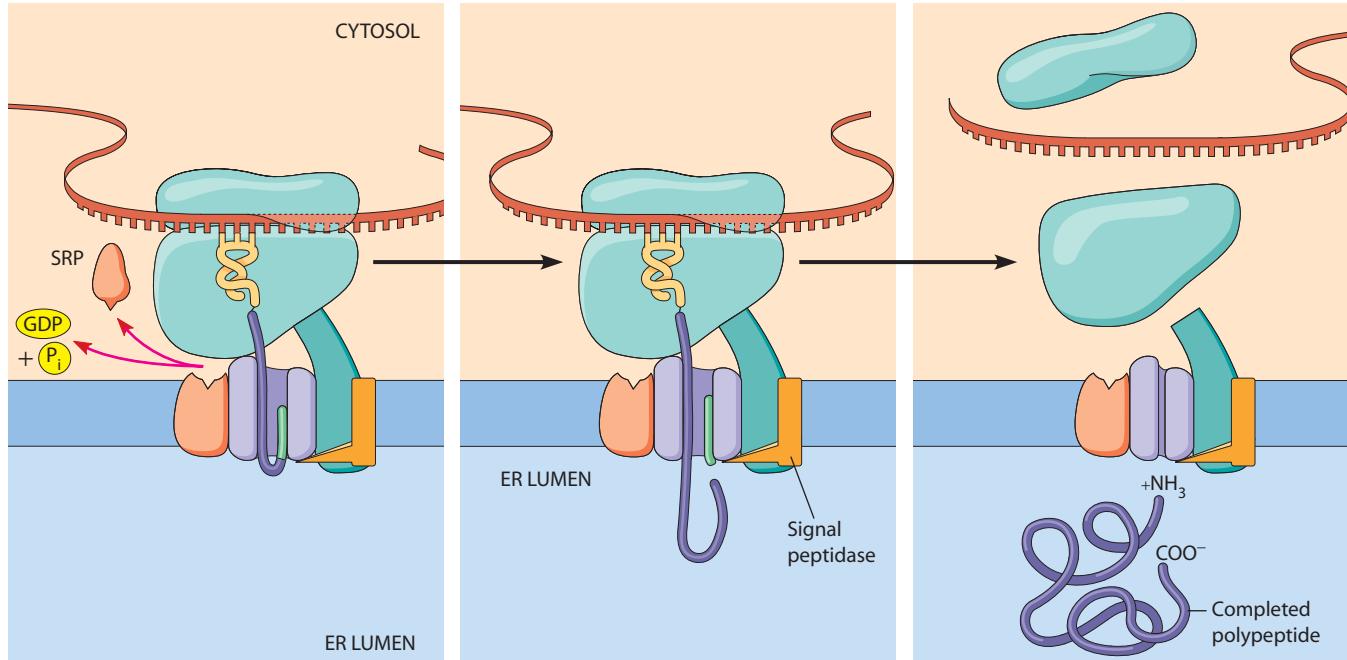

FIGURE 22-16 A Model for the Signal Mechanism of Cotranslational Import. This figure shows a schematic model for the signal mechanism. It is now well established that the growing polypeptide translocates through a hydrophilic pore created by one or more membrane proteins. The complex of membrane proteins that carry out translocation is called the *translocon*.

pathways that shut down the synthesis of most proteins while enhancing the production of those required for protein folding and degradation. Another type of quality control, known as **ER-associated degradation (ERAD)**, recognizes misfolded or unassembled proteins and exports or “retrotranslocates” them back across the ER membrane to the cytosol, where they are degraded by *proteasomes* as described in Chapter 23.

Proteins Released into the ER Lumen Are Routed to the Golgi Complex, Secretory Vesicles, Lysosomes, or Back to the ER

Most of the proteins synthesized on ribosomes attached to the ER are *glycoproteins*—that is, proteins with covalently bound carbohydrate groups. As you learned in Chapter 12, the initial glycosylation reactions that add these carbohydrate side chains take place in the ER, often while the growing polypeptide is still being synthesized. After polypeptides have been released into the ER lumen, glycosylated, and folded, they are delivered by various types of transport vesicles to their destinations within the cell (see Figure 12-8). The first stop in this transport pathway is the Golgi complex, where further glycosylation and processing of carbohydrate side chains may occur. The Golgi complex then serves as a site for sorting and distributing proteins to other locations.

For soluble proteins, the default pathway takes them from the Golgi complex to secretory vesicles that move to the cell surface and fuse with the plasma membrane, leading to secretion of such proteins from the cell. Soluble proteins entering the Golgi complex and that are not destined for secretion from the cell possess specific carbohydrate side chains and/or short amino acid signal sequences that target each protein to its appropriate location within the endomembrane system. For example, we saw in Chapter 12 that many lysosomal enzymes possess carbohydrate side chains exhibiting the unusual sugar *mannose-6-phosphate*. This sugar serves as a recognition device that allows the Golgi complex to selectively package such proteins into newly forming lysosomes (see Figure 12-9). As we also saw in Chapter 12, a different signaling mechanism is used for proteins whose final destination is the ER. The C-terminus of these proteins usually contains a *KDEL sequence*, which consists of the amino acids Lys-Asp-Glu-Leu or a closely related sequence. The Golgi complex employs a receptor protein that binds to the KDEL sequence and delivers the targeted protein back to the ER. Protein disulfide isomerase—the ER-resident enzyme whose role in protein folding was described in the preceding section—is an example of a protein possessing a KDEL sequence that confines the molecule to the ER.

Stop-Transfer Sequences Mediate the Insertion of Integral Membrane Proteins

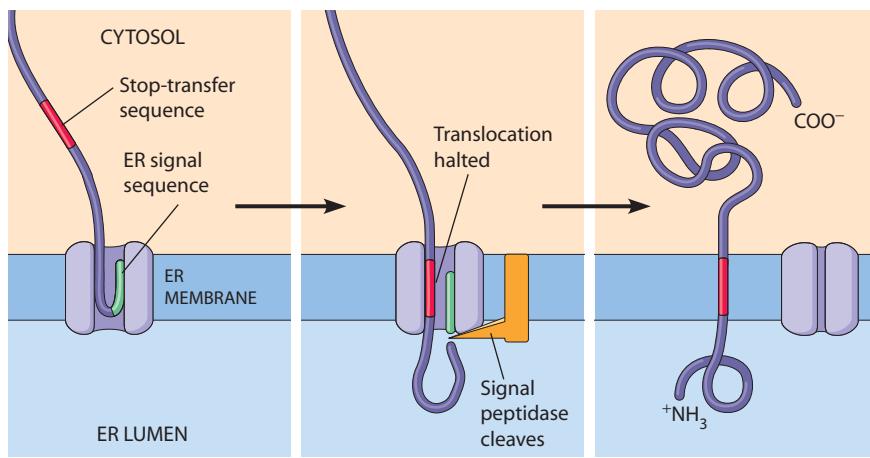

So far, we have focused on the cotranslational import and sorting of *soluble proteins* that are destined either for secretion from the cell or for the lumen of endomembrane components, such as the ER, the Golgi complex, lysosomes, and related vesicles. The other major group of polypeptides synthesized on ER-attached ribosomes consists of molecules destined to become integral *membrane proteins*. Polypeptides of this type are synthesized by a mechanism similar to the one illustrated in Figure 22-16 for soluble proteins except that the completed polypeptide chain remains embedded in the ER membrane rather than being released into the ER lumen.

Recall from Chapter 7 that integral membrane proteins are typically anchored to the lipid bilayer by one or more α -helical *transmembrane segments* consisting of 20–30 hydrophobic amino acids. In considering the mechanism that allows such proteins to be retained as part of the ER membrane after synthesis rather than being released into the ER lumen, we focus here on the simplest case: proteins with only a single such transmembrane segment. The principles involved, however, extend to proteins with more complicated configurations. Researchers postulate two main mechanisms by which hydrophobic transmembrane segments anchor newly forming polypeptide chains to the lipid bilayer of the ER membrane.

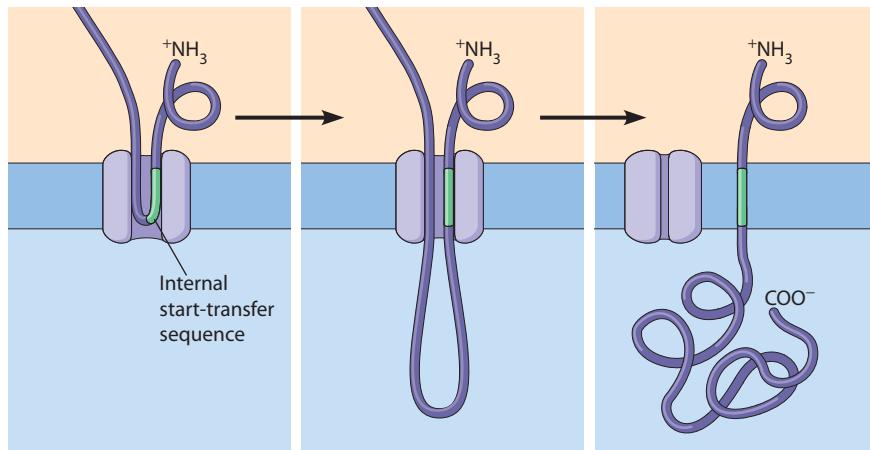

The first of these mechanisms involves polypeptides with a typical ER signal sequence at their N-terminus, which allows an SRP to bind the ribosome-mRNA complex to the ER membrane. Elongation of the polypeptide chain then continues until the hydrophobic transmembrane segment of the polypeptide is synthesized. As shown in **Figure 22-17a**, this stretch of amino acids functions as a **stop-transfer sequence** that halts translocation of the polypeptide through the ER membrane. Translation continues, but the rest of the polypeptide chain remains on the cytosolic side of the ER membrane, resulting in a transmembrane protein with its N-terminus in the ER lumen and its C-terminus in the cytosol. Meanwhile, the hydrophobic stop-transfer signal moves laterally out through a side opening in the translocon and into the lipid bilayer, forming the permanent transmembrane segment that anchors the protein to the membrane.

The second mechanism involves membrane proteins that lack a typical signal sequence at their N-terminus and instead possess an *internal start-transfer sequence* that performs two functions: It first acts as an ER signal sequence that allows an SRP to bind the ribosome-mRNA complex to the ER membrane, and then its hydrophobic region functions as a membrane anchor that moves out through a side opening in the translocon and permanently attaches the polypeptide to the lipid bilayer (Figure 22-17b). The orientation of the start-transfer sequence at the time of insertion determines which terminus of the polypeptide ends up in the ER lumen and which in the cytosol. Transmembrane proteins with multiple membrane-spanning regions are formed in a similar way, except that an alternating pattern of start-transfer and stop-transfer sequences creates a polypeptide containing multiple transmembrane segments that pass back and forth across the membrane.

Once a newly formed polypeptide has been incorporated into the ER membrane by one of the preceding

(a) Polypeptide with an internal stop-transfer sequence and a terminal ER signal sequence. The stop-transfer sequence halts the process of translocation and moves out through a side opening in the translocon to anchor the polypeptide in the membrane, creating a transmembrane protein with its N-terminus in the ER lumen and its C-terminus in the cytosol.

(b) Polypeptide with only a single, internal start-transfer sequence. This single start-transfer sequence starts polypeptide transfer and then moves through a side opening in the translocon to anchor itself in the membrane. (If this polypeptide also had a stop-transfer sequence that prevented complete transfer of the polypeptide through the translocon, the result would be a transmembrane protein with both its N-terminus and its C-terminus in the cytosol.)

FIGURE 22-17 Cotranslational Insertion of Transmembrane Proteins into the ER Membrane. This figure shows two mechanisms for inserting integral membrane proteins containing a single transmembrane segment. For clarity, the SRP, ribosome, and most other parts of the translocational apparatus have been omitted. Transmembrane proteins whose N- and C-termini are oriented in opposite directions from those shown here can be created using a start-transfer sequence that has the opposite orientation when it first inserts into the translocation apparatus.

mechanisms, it can either remain in place to function as an ER membrane protein or be transported to other components of the endomembrane system, such as the Golgi complex, lysosomes, nuclear envelope, or plasma membrane. Transport is carried out by a series of membrane budding and fusing events in which membrane vesicles pinch off from one compartment of the endomembrane system and fuse with another compartment, as we described in Figure 12-8.

Posttranslational Import Allows Some Polypeptides to Enter Organelles After They Have Been Synthesized

In contrast to the cotranslational import of proteins into the ER discussed in the preceding several pages, proteins destined for the nuclear interior, mitochondrion, chloroplast, or peroxisome are imported into these organelles *after* translation has been completed. Because such proteins are synthesized on free ribosomes and released into the cytosol, each protein must carry a targeting signal that directs it to

the correct organelle. In Chapter 12, you learned that a serine-lysine-leucine sequence (SKL in single-letter code) located near the C-terminus of a protein targets it for uptake into peroxisomes. And in Chapter 18, you learned that posttranslational import of proteins into the nucleus depends on *nuclear localization signals* that target proteins for transport through nuclear pore complexes (see Figure 18-31). Here, we focus on protein import into mitochondria and chloroplasts, which involves signal sequences similar to those used in cotranslational import.

Importing Polypeptides into Mitochondria and Chloroplasts. Although mitochondria and chloroplasts contain their own DNA and protein-synthesizing machinery, they synthesize few of the polypeptides they require. More than 95% of the proteins residing in these two organelles, like all proteins found in the nucleus and peroxisomes, are encoded by nuclear genes and synthesized on cytosolic ribosomes. The small number of polypeptides synthesized within mitochondria are targeted mainly to the inner mitochondrial membrane, and the polypeptides

synthesized within chloroplasts are targeted mainly to thylakoid membranes. Almost without exception, such polypeptides encoded by mitochondrial or chloroplast genes are subunits of multimeric proteins, with one or more of the other subunits being encoded by nuclear genes and imported from the cytosol. For example, mammalian cytochrome *c* oxidase consists of 13 polypeptides, 3 of which are encoded by the mitochondrial genome and synthesized within mitochondria. The other 10 subunits are synthesized in the cytosol and imported into mitochondria.

Most mitochondrial and chloroplast polypeptides are synthesized on cytosolic ribosomes, released into the cytosol, and taken up by the appropriate organelle (mitochondrion or chloroplast) within a few minutes. The targeting signal for such polypeptides is a special sequence called a **transit sequence**. Like the ER signal sequence of ER-targeted polypeptides, the transit sequence is located at the N-terminus of the polypeptide. Once inside the mitochondrion or chloroplast, the transit sequence is removed by a *transit peptidase* located within the organelle. Removal of the transit sequence often occurs before transport is complete.

The transit sequences of mitochondrial or chloroplast polypeptides typically contain both hydrophobic and hydrophilic amino acids. The presence of positively charged amino acids is critical, although the secondary structure of the sequence may be more important than the specific amino acids. For example, some mitochondrial transit sequences have positively charged amino acids interspersed with hydrophobic amino acids in such a way that, when the sequence is coiled into an α helix, most of the positively charged amino acids are on one side of the helix and the hydrophobic amino acids are on the other.

The uptake of polypeptide chains possessing transit sequences is mediated by specialized transport complexes located in the outer and inner membranes of mitochondria and chloroplasts. As shown in **Figure 22–18**, the mitochondrial transport complexes are called **TOM** (translocase of the outer mitochondrial membrane) and **TIM** (translocase of the inner mitochondrial membrane). The comparable chloroplast complexes are **TOC** (translocase of the outer chloroplast membrane) and **TIC** (translocase of the inner chloroplast membrane). Polypeptides are initially selected for transport into mitochondria or chloroplasts by components of TOM or TOC known as *transit sequence receptors*. After a transit sequence has bound to its receptor, the polypeptide containing this sequence is translocated across the outer membrane through a *pore* in the TOM or TOC complex. If the polypeptide is destined for the interior of the organelle, movement through the TOM or TOC complex is quickly followed by passage through the TIM or TIC complex of the inner membrane, presumably at a *contact site* where the outer and inner membranes lie close together.

Evidence supporting this model has come both from electron microscopy, which reveals many sites of close contact between outer and inner membranes, and from

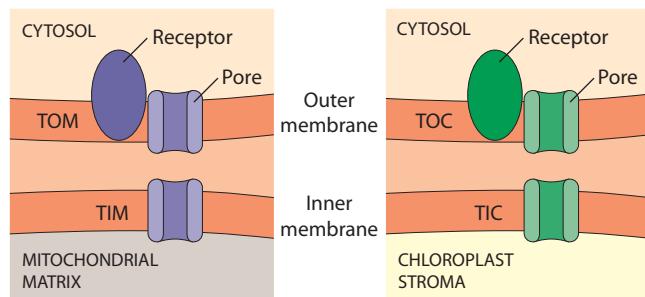

FIGURE 22–18 Polypeptide Transport Complexes of the Outer and Inner Mitochondrial and Chloroplast Membranes.

Mitochondrial and chloroplast polypeptides synthesized in the cytosol are transported into these organelles by specialized transport complexes located in their outer and inner membranes. In mitochondria, the outer and inner membrane complexes are called **TOM** and **TIM**, respectively. The comparable chloroplast structures are **TOC** and **TIC**. The transport complexes of the outer membranes (TOM and TOC) consist of two types of components: receptor proteins that recognize and bind to polypeptides targeted for uptake and pore proteins that form channels through which the polypeptides are translocated.

biochemical experiments, in which cell-free mitochondrial import systems are incubated on ice to trap polypeptides in the act of being translocated (**Figure 22–19**). The low temperature causes polypeptide movement across the membranes to halt shortly after it starts. At this point the polypeptides have already had their transit sequences removed by the transit peptidase enzyme located in the mitochondrial matrix, but they can still be attacked by externally added proteolytic enzymes. Such results indicate that polypeptides can transiently span both membranes during import. In other words, the N-terminus can enter the matrix of the mitochondrion while the rest of the molecule is still outside the organelle.

Polypeptides entering mitochondria and chloroplasts must generally be in an unfolded state before they can pass across the membranes bounding these organelles. This requirement has been demonstrated experimentally by attaching polypeptides containing a mitochondrial transit sequence to agents that maintain the polypeptide chain in a tightly folded state. Such polypeptides bind to the outer surface of mitochondria but will not move across the membrane, apparently because the size of the folded polypeptide exceeds the diameter of the membrane pore it must pass through.

To maintain the necessary unfolded state, polypeptides targeted for mitochondria and chloroplasts are usually bound to *chaperone proteins* similar to those that help newly synthesized polypeptides fold correctly. **Figure 22–20** shows a current model for this chaperone-mediated import of polypeptides into the mitochondrial matrix. To start the process, chaperones of the Hsp70 class bind to a newly forming polypeptide that is still in the process of being synthesized in the cytosol, keeping it in a loosely folded state (step ①). Next, the transit sequence at the N-terminus of the

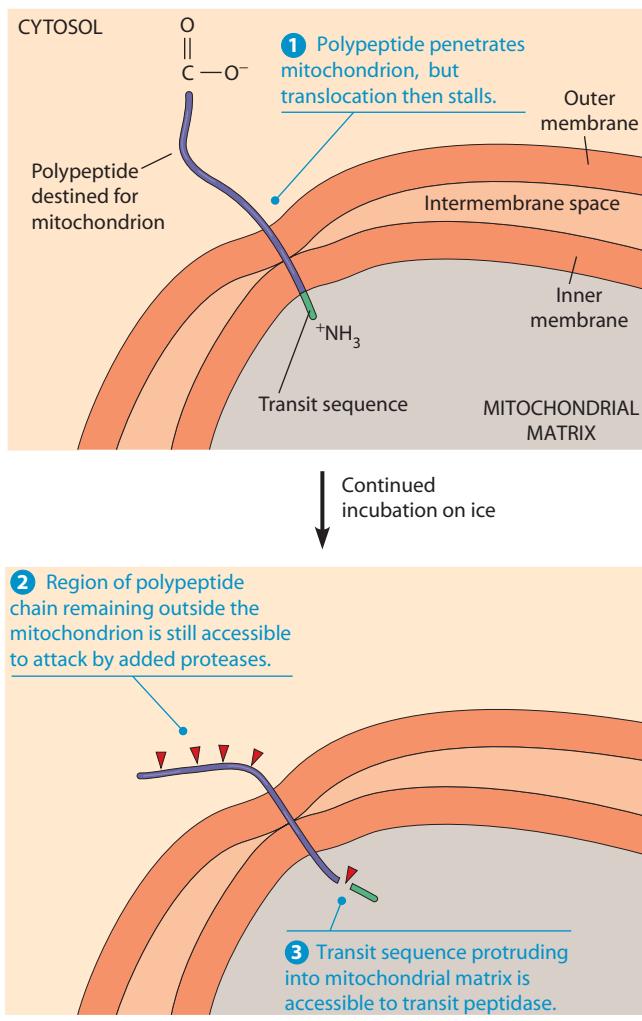

FIGURE 22-19 Experiment Showing That Polypeptides Span Both Mitochondrial Membranes During Import. To demonstrate that polypeptides being imported into mitochondria span both membranes at the same time, a cell-free import system was incubated on ice instead of at the usual temperature of 37°C. At low temperature, polypeptides start to enter the mitochondrion, but their translocation soon stalls. Under these conditions, the transit sequence is cleaved by transit peptidase in the matrix, indicating that the N-terminus of the polypeptide is inside the mitochondrion. At the same time, most of the polypeptide chain is accessible to attack by proteolytic enzymes added to the outside of the mitochondrion. This means that the polypeptide must span both membranes during import, presumably at a contact site between the two membranes.

polypeptide binds to the receptor component of TOM, which protrudes from the surface of the outer mitochondrial membrane (2). The chaperone proteins then are released, accompanied by ATP hydrolysis, as the polypeptide is translocated through the TOM and TIM pores and into the mitochondrial matrix (3). When the transit sequence emerges into the matrix, it is removed by transit peptidase (4). As the rest of the polypeptide subsequently enters the matrix, mitochondrial Hsp70 molecules bind to it temporarily. The subsequent release of Hsp70 requires ATP hydrolysis (5), which is thought to drive the translocation process. Finally, in many cases mitochondrial Hsp60 chaper-

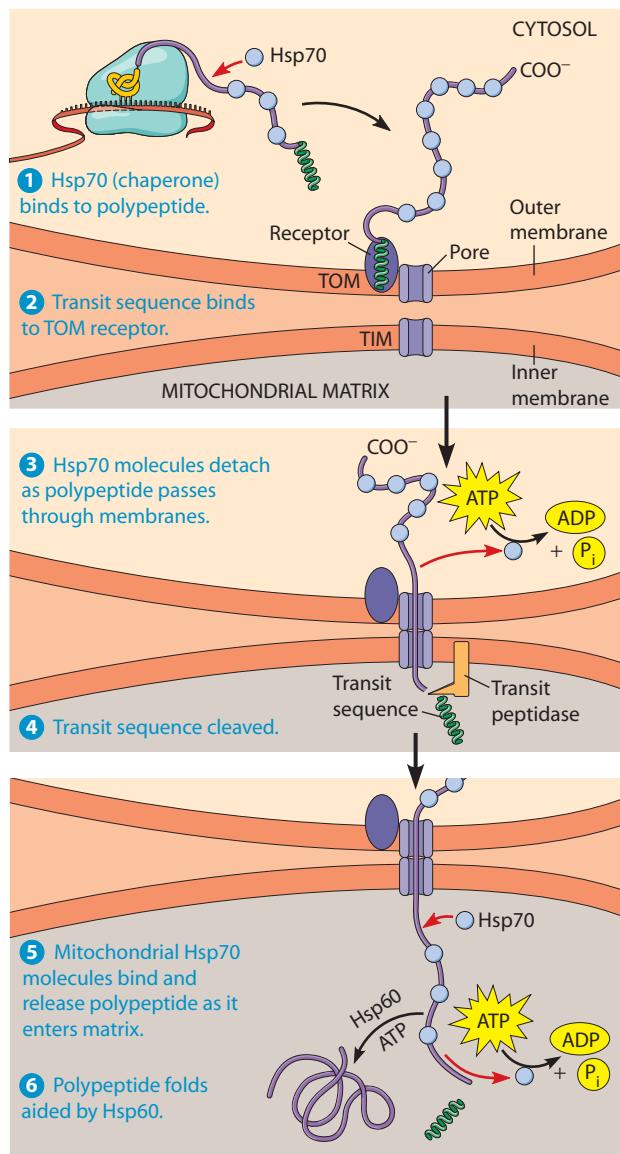

FIGURE 22-20 Posttranslational Import of Polypeptides into the Mitochondrion. Like cotranslational import into the ER, posttranslational import into a mitochondrion involves a signal sequence (called a transit sequence in this case), a membrane receptor, pore-forming membrane proteins, and a peptidase. However, in the mitochondrion, the membrane receptor recognizes the signal sequence directly, without the intervention of a cytosolic SRP. Furthermore, chaperone proteins play several crucial roles in the mitochondrial process: They keep the polypeptide partially unfolded after synthesis in the cytosol so that binding of the transit sequence and translocation can occur (steps 1–3); they drive the translocation itself by binding to and releasing from the polypeptide *within* the matrix, which is an ATP-requiring process (step 5); and they help the polypeptide fold into its final conformation (step 6). The chaperones included here are cytosolic and mitochondrial versions of Hsp70 (light blue) and a mitochondrial Hsp60 (not illustrated).

erone molecules bind to the polypeptide and help it achieve its fully folded conformation (6).

Both chloroplasts and mitochondria require energy for the import of polypeptides. Mitochondrial import is driven both by ATP hydrolysis and by the electrochemical

gradient across the inner membrane. The electrochemical gradient seems to be necessary only for the binding and penetration of the transit sequence. Once this step has occurred, experimental abolition of the membrane potential does not interfere with the rest of the transfer process. Chloroplasts, on the other hand, maintain an electrochemical gradient across the thylakoid membrane but not across the inner membrane. Presumably the energy requirement for import into the chloroplast stroma is met by ATP alone.

Targeting Polypeptides to the Proper Compartments

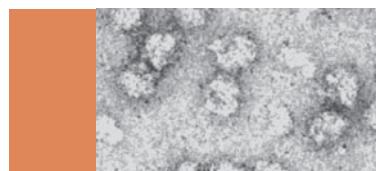

Within Mitochondria and Chloroplasts. Due to the structural complexity of mitochondria and chloroplasts, proteins to be imported from the cytosol must be targeted not only to the right organelle but also to the appropriate compartment within the organelle. Mitochondria have four compartments: the outer membrane, the intermembrane space, the inner membrane, and the matrix. Chloroplasts have four similar compartments (with the stroma substituted for matrix) plus two additional compartments: the thylakoid membrane and the thylakoid lumen. Thus, a polypeptide may have to cross one, two, or even three membranes to reach its final destination.

Given the structural complexity of both organelles, it is perhaps not surprising that many mitochondrial and chloroplast polypeptides require more than one signal to arrive at their proper destinations. For example, targeting a polypeptide to the outer or inner mitochondrial membrane requires an N-terminal transit sequence to direct the polypeptide to the mitochondrion, plus an additional internal sequence, called a *hydrophobic sorting signal*, to target the polypeptide to its final destination. In such cases the hydrophobic sorting signal acts as a stop-transfer sequence that halts translocation of the polypeptide through either the outer or inner membrane translocase and promotes its lateral movement out through a side opening in the translocase and into the lipid bilayer of the membrane. The hydrophobic signal sequence then remains embedded in the membrane, anchoring the polypeptide to the lipid bilayer, while the N-terminal transit sequence is usually

removed. A combination of transit and hydrophobic sorting sequences is also used for targeting polypeptides to the intermembrane space. In this case the polypeptide passes through the outer membrane and the signal sequences are then removed, leaving the polypeptide in the space between the two membranes.

Multiple signals are also involved in directing some chloroplast polypeptides to their final destination. Polypeptides intended for insertion into (or transport across) the thylakoid membrane, for example, must first be targeted to the chloroplast and transported into the stroma, presumably crossing the inner and outer membranes at a contact site. In the stroma, the transit sequence used for this first step is cleaved from the polypeptide, unmasking a hydrophobic *thylakoid signal sequence* that targets the polypeptide for either the thylakoid membrane or thylakoid lumen. For polypeptides destined for the thylakoid membrane, the hydrophobic signal sequence may spontaneously insert and anchor the polypeptide within the lipid bilayer of the thylakoid membrane. Alternatively, the insertion of some polypeptides into thylakoid membranes requires the participation of a GTP-dependent protein resembling the signal recognition particle (SRP) that directs and binds polypeptides to ER membranes.

Polypeptides destined for the thylakoid lumen are translocated completely across the thylakoid membrane, accompanied by cleavage of the thylakoid signal sequence as the polypeptide is released into the lumen. Most polypeptides targeted to the lumen are translocated across the thylakoid membrane in an unfolded state by an ATP-dependent process that resembles the mechanism employed for translocating polypeptides across the outer chloroplast or mitochondrial membranes. However, some extensively folded proteins can also be transported across thylakoid membranes using an alternative mechanism driven by energy derived from the proton gradient. Although translocation of extensively folded proteins across membranes is relatively unusual, similar mechanisms have been detected in peroxisomes and in the bacterial plasma membrane.

SUMMARY OF KEY POINTS

Translation: The Cast of Characters

- Translation refers to the synthesis of polypeptide chains on ribosomes using a process that employs mRNA to determine the amino acid sequence.
- The rRNA component of the ribosome helps position the mRNA and catalyzes peptide bond formation; aminoacyl-tRNA synthetases link amino acids to the tRNA molecules that bring amino acids to the ribosome; and various protein factors trigger specific events associated with the translation cycle.

The Mechanism of Translation

- Translation involves initiation, elongation, and termination stages.
- During the initiation stage, initiation factors trigger the assembly of mRNA, ribosomal subunits, and initiator aminoacyl tRNA into an initiation complex.
- Chain elongation involves sequential cycles of aminoacyl tRNA binding, peptide bond formation, and translocation,

with each cycle driven by the action of elongation factors. The net result is that aminoacyl tRNAs add their amino acids to the growing polypeptide chain in an order specified by the codon sequence in mRNA.

- Chain termination occurs when a stop codon in mRNA is recognized by release factors, which cause the mRNA and newly formed polypeptide to be released from the ribosome.
- GTP binding and hydrolysis are required for the action of several initiation, elongation, and release factors.
- Proper folding of newly produced polypeptide chains is assisted by molecular chaperones. Abnormalities in protein folding can lead to various health problems, including Alzheimer disease and mad cow disease.

Mutations and Translation

- Nonsense mutations, which change an amino acid codon to a stop codon, can be overcome by suppressor mutations that allow a tRNA anticodon to read the stop codon as an amino acid.
- Defective mRNAs containing premature stop codons are destroyed by nonsense-mediated decay; defective mRNAs containing no stop codon are destroyed by nonstop decay.

Posttranslational Processing

- Newly made polypeptide chains often require chemical modification before they can function properly. Such modifications include cleavage of peptide bonds, phosphorylation, acetylation, methylation, glycosylation, and protein splicing.

MAKING CONNECTIONS

In this chapter you learned how mRNA molecules determine the amino acid sequence of newly forming polypeptide chains, which are then folded and assembled into functional proteins destined for various subcellular locations. The protein molecules produced and delivered by the mechanisms described in this chapter are responsible for most of the properties we associate with living cells. The events responsible for creating the mRNAs that

Protein Targeting and Sorting

- Many polypeptides possess special amino acid sequences that target them to their appropriate location.
- Polypeptides destined for the endomembrane system, or for secretion from the cell, have an N-terminal ER signal sequence that causes them to enter translocon channels in the ER membrane while the polypeptide chain is still being synthesized.
- Some of these polypeptides pass completely through the translocon and are released into the ER lumen. Others possess one or more internal stop-transfer sequences that cause the polypeptide to remain anchored to the membrane. In either case the resulting proteins may stay in the ER or be transported to other locations within the endomembrane system, such as the Golgi complex, lysosomes, plasma membrane, or secretory vesicles that expel the protein from the cell.
- The unfolded protein response (UPR) and ER-associated degradation (ERAD) help prevent the endomembrane system from accumulating unfolded proteins.
- Polypeptides destined for the nuclear interior, mitochondria, chloroplasts, or peroxisomes are synthesized on cytosolic ribosomes (as are polypeptides that remain in the cytosol) and are then imported posttranslationally into the targeted organelle. Polypeptides destined for peroxisomes contain a special targeting sequence near the C-terminus, whereas those targeted to the nucleus contain nuclear localization signals that promote their uptake through the nuclear pores.
- Some mitochondrial and chloroplast polypeptides require more than one signal to arrive at their proper destinations. Such polypeptides usually possess an N-terminal transit sequence to direct the polypeptide into mitochondria or chloroplasts plus a hydrophobic sorting signal to target the polypeptide to its final destination within each organelle.

PROBLEM SET

More challenging problems are marked with a •.

22-1 The Genetic Code and Two Human Hormones. The following is the actual sequence of a small stretch of human DNA:

3' AATTATACACGATGAAGCTTGTGACAGGGTTCCAATCATTAA 5'
5' TTAATATGTGCTACTTCGAACACTGTCCCAAAGGTTAGTAATT 3'

(a) What are the two possible RNA molecules that could be transcribed from this DNA?

guide polypeptide synthesis were described in Chapter 21, and the role of the endomembrane system in delivering the resulting proteins to their appropriate subcellular locations was covered in Chapter 12. Now that you understand how a cell's protein molecules are produced and distributed, the next chapter will describe how the production of specific proteins is regulated to meet the changing needs of individual cells.

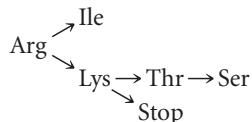

- (b) Only one of these two RNA molecules can actually be translated. Explain why.
- (c) The RNA molecule that can be translated is the mRNA for the hormone vasopressin. What is the apparent amino acid sequence for vasopressin? (The genetic code is given in Figure 21-6.)
- (d) In its active form, vasopressin is a nonapeptide (that is, it has nine amino acids) with cysteine at the N-terminus. How can you explain this in light of your answer to part c?

- (e) A related hormone, oxytocin, has the following amino acid sequence:

Cys-Tyr-Ile-Glu-Asp-Cys-Pro-Leu-Gly

Where and how would you change the DNA that codes for vasopressin so that it would code for oxytocin instead? Does your answer suggest a possible evolutionary relationship between the genes for vasopressin and oxytocin?

- 22-2 Tracking a Series of Mutations.** The following diagram shows the amino acids that result from mutations in the codon for a particular amino acid in a bacterial polypeptide:

Assume that each arrow denotes a single base-pair substitution in the bacterial DNA.

- (a) Referring to the genetic code table in Figure 21-6, determine the most likely codons for each of the amino acids and the stop signal in the diagram.
 (b) Starting with a population of mutant cells carrying the non-sense mutation, another mutant is isolated in which the premature stop signal is suppressed. Assuming wobble does not occur and assuming a single base change in the tRNA anticodon, what are all the possible amino acids that might be found in this mutant at the amino acid position in question?

- 22-3 Sleuthing Using Mutants.** You identify three independent missense mutations that all affect the same gene. In fact, all three mutations affect the same codon but do not cause the same amino acid substitution. The first mutation results in substitution of arginine (Arg), the second results in substitution of tyrosine (Tyr), and the third results in substitution of glutamine (Gln). Each mutation affects just a single base within this codon *but not necessarily the same base*. What was the original amino acid?

- 22-4 Initiation of Translation.** Figure 22-8 diagrams the initiation of translation in bacterial cells. Using the text on pages 687–688 as a guide, draw a similar sketch outlining the steps in eukaryotic initiation of translation. What are the main differences between bacterial and eukaryotic initiation?

- 22-5 Bacterial and Eukaryotic Protein Synthesis Compared.** For each of the following statements, indicate whether it applies to protein synthesis in bacteria (Ba), in eukaryotes (E), in both (Bo), or in neither (N).

- (a) The mRNA has a ribosome-binding site within its leader region.
 (b) AUG is a start codon.
 (c) The enzyme that catalyzes peptide bond formation is an RNA molecule.
 (d) The mRNA is translated in the 3' → 5' direction.
 (e) The C-terminus of the polypeptide is synthesized last.
 (f) Translation is terminated by special tRNA molecules that recognize stop codons.
 (g) GTP hydrolysis functions to induce conformational changes in various proteins involved in polypeptide elongation.

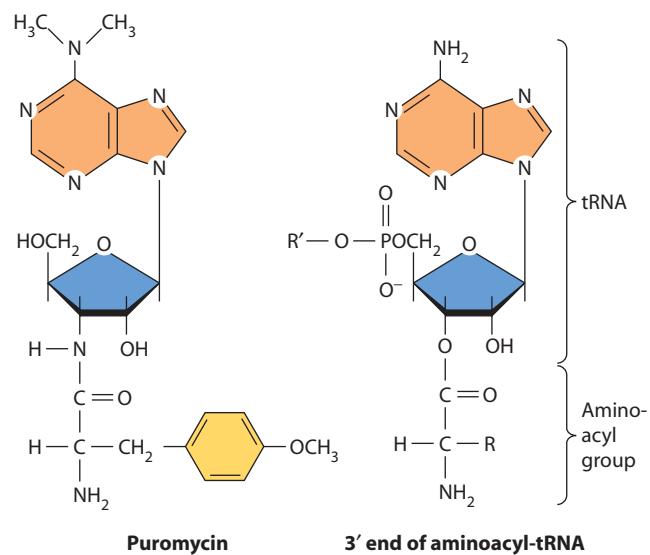

FIGURE 22-21 The Structure of Puromycin. See Problem 22-6.

- (h) ATP hydrolysis is required to attach an amino acid to a tRNA molecule.
 (i) The specificity required to link the right amino acids to the right tRNA molecules is a property of the enzymes called aminoacyl-tRNA synthetases.
- 22-6 An Antibiotic Inhibitor of Translation.** Puromycin is a powerful inhibitor of protein synthesis (see page 697). It is an analog of the 3' end of aminoacyl tRNA, as Figure 22-21 reveals. (R represents the functional group of the amino acid; R' represents the remainder of the tRNA molecule.) When puromycin is added to a cell-free system containing all the necessary machinery for protein synthesis, incomplete polypeptide chains are released from the ribosomes. Each such chain has puromycin covalently attached to one end.
 (a) Explain these results.
 (b) To which end of the polypeptide chains would you expect the puromycin to be attached? Explain.
 (c) Would you expect puromycin to bind to the A or P site on the ribosome or to both? Explain.
 (d) Assuming that it can penetrate into the cell equally well in both cases, would you expect puromycin to be a better inhibitor of protein synthesis in eukaryotes or bacteria? Explain.
- 22-7 A Fictional Antibiotic.** In a study involving a cell-free protein synthesizing system from *E. coli*, the polyribonucleotide AUGUUUUUUUUUUU directs the synthesis of the oligopeptide fMet-Phe-Phe-Phe-Phe. In the presence of Rambomycin, a new antibiotic just developed by Macho Pharmaceuticals, only the dipeptide fMet-Phe is made.
 (a) What step in polypeptide synthesis does Rambomycin inhibit? Explain your answer.
 (b) Will the oligopeptide product be found attached to tRNA at the end of the uninhibited reaction? Will the dipeptide product be found attached to tRNA at the end of the Rambomycin-inhibited reaction? Explain.

22-8 Frameshift Suppression. As discussed in the chapter, a nonsense mutation can be suppressed by a mutant tRNA in which one of the three anticodon nucleotides has been changed. Describe a mutant tRNA that could suppress a *frameshift* mutation. (Hint: Such a mutant tRNA was used to investigate the role played by peptidyl tRNA in the translocation of mRNA during protein synthesis.)

• 22-9 Protein Folding. The role of BiP in protein folding was briefly described in this chapter. Answer the following questions about observations and situations involving BiP.

(a) BiP is found in high concentration in the lumen of the ER but is not present in significant concentrations elsewhere in the cell. How do you think this condition is established and maintained?

(b) If the gene coding for BiP acquires a mutation that disrupts the protein's binding site for hydrophobic amino acids, what kind of impact might this have on the cell?

• 22-10 Cotranslational Import. You perform a series of experiments on the synthesis of the pituitary hormone prolactin, which is a single polypeptide chain 199 amino acids long. The mRNA coding for prolactin is translated in a cell-free protein synthesizing system containing ribosomes, amino acids, tRNAs, aminoacyl-tRNA synthetases, ATP, GTP, and the appropriate initiation, elongation, and termination factors. Under these conditions, a polypeptide chain 227 amino acids long is produced.

(a) How might you explain the discrepancy between the normal length of prolactin (199 amino acids) and the length of the polypeptide synthesized in your experiment (227 amino acids)?

(b) You perform a second experiment, in which you add SRP to your cell-free protein-synthesizing system, and find that translation stops after a polypeptide about 70 amino acids long has been produced. How can you explain this result? Can you think of any purpose this phenomenon might serve for the cell?

(c) You perform a third experiment, in which you add both SRP and ER membrane vesicles to your protein-synthesizing system, and find that translation of the prolactin mRNA now produces a polypeptide 199 amino acids long. How can you explain this result? Where would you expect to find this polypeptide?

22-11 Two Types of Posttranslational Import. The mechanism by which proteins synthesized in the cytosol are imported into the mitochondrial matrix is different from the mechanism by which proteins enter the nucleus, yet the two mechanisms do share some features. Indicate whether each of the following statements applies to nuclear import (Nu), mitochondrial import (M), both (B), or neither (N). You may want to review the discussion of nuclear import in Chapter 18 before answering this question (see especially Figure 18-31).

- (a) The polypeptide to be transported into the organelle has a specific short stretch of amino acids that targets the polypeptide to the organelle.
- (b) The signal sequence is always at the polypeptide's N-terminus and is cut off by a peptidase within the organelle.
- (c) The signal sequence is recognized and bound by a receptor protein in the organelle's outer membrane.
- (d) ATP hydrolysis is known to be required for the translocation process.
- (e) GTP hydrolysis is known to be required for the translocation process.
- (f) There is strong evidence for the involvement of chaperone proteins during translocation of the protein.
- (g) The imported protein enters the organelle through some sort of protein pore.
- (h) The pore complex consists of more than two dozen proteins and is large enough to be readily seen with the electron microscope.

The Regulation of Gene Expression

In our coverage of biological information flow thus far, we have identified DNA as the main repository of genetic information, we have seen how DNA is replicated and repaired, and we have examined the steps involved in expressing DNA's genetic information via transcription and translation. In concluding our consideration of information flow, we will now explore how the various steps in gene expression are regulated so that each gene product is made at the proper time and in proper amounts for each cell's needs.

Regulation is an important aspect of almost every process in nature. This is especially true of gene expression. Most genes are not expressed all the time. In some cases, selective gene expression enables cells to be metabolically thrifty, synthesizing only those gene products that are of immediate use under the prevailing environmental conditions; this is often the situation with bacteria. In multicellular organisms, selective gene expression allows cells to fulfill specialized roles. For example, cells in the skin, nails, and hair produce huge amounts of keratin, whereas red blood cells produce large quantities of hemoglobin. Understanding the sequence of events that leads to such dramatic differences in gene expression between cells requires us to understand in detail how different cell types can begin or cease expressing particular genes as their changing circumstances (and identities) demand.

As you might expect, our first knowledge about the regulation of gene expression came from studying bacteria. But subsequent advances in DNA technology have permitted major progress with eukaryotes as well. We will look first at bacteria and highlight some of the gene control mechanisms discovered in these organisms, and we will then turn to a consideration of eukaryotes.

Bacterial Gene Regulation

Of the several thousand genes present in a typical bacterial cell, some are so important that they are always active in growing cells. Examples of such *constitutive*

genes include ribosomal genes and genes encoding the enzymes of glycolysis. For most other genes, however, expression is regulated so that the amount of the final gene product—protein or RNA—is carefully tuned to the cell's need for that product. A number of these *regulated genes* encode enzymes for metabolic processes that, unlike glycolysis, are not constantly required. One way of regulating the intracellular concentrations of such enzymes is by starting and stopping gene transcription in response to cellular needs. Because this control of enzyme-coding genes helps bacterial cells adapt to their environment, it is commonly referred to as *adaptive enzyme synthesis*.

Catabolic and Anabolic Pathways Are Regulated Through Induction and Repression, Respectively

Bacteria use somewhat different approaches for regulating enzyme synthesis, depending on whether a given enzyme is involved in a *catabolic* (degradative) or *anabolic* (synthetic) pathway. The enzymes that catalyze such pathways are often regulated coordinately; that is, the synthesis of all the enzymes involved in a particular pathway is turned on and off together. Here we briefly describe two well-understood pathways, one catabolic and one anabolic.

Catabolic Pathways and Substrate Induction.

Catabolic enzymes exist for the primary purpose of degrading specific substrates, often as a means of obtaining energy. **Figure 23-1** depicts the steps in the catabolic pathway that degrades the disaccharide lactose into simple sugars that can then be metabolized by glycolysis. The central step in this pathway is the hydrolysis of lactose into the monosaccharides glucose and galactose, a reaction catalyzed by the enzyme β -galactosidase. However, before lactose can be hydrolyzed, it must first be transported into the cell. A protein called *galactoside*

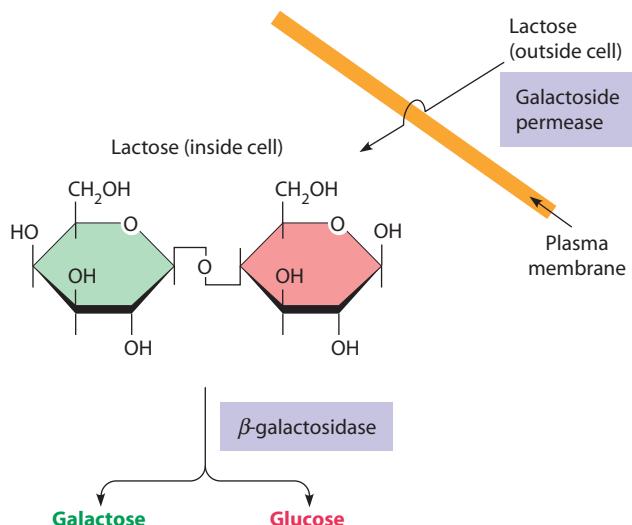

FIGURE 23-1 Lactose Breakdown: A Typical Catabolic Pathway. Breakdown of the disaccharide lactose involves enzymes (purple boxes) whose synthesis is regulated coordinately. See Figures 23-3 and 23-4 for the organization and regulation of the genes that code for these enzymes. (The enzymes responsible for the subsequent catabolism of the monosaccharides glucose and galactose are not part of the same regulatory unit.)

permease is responsible for this transport, and its synthesis is regulated coordinately with β -galactosidase.

Since the function of a catabolic enzyme is to degrade a specific substrate, such enzymes are needed only when the cell is confronted by the relevant substrate. The enzyme β -galactosidase, for example, is useful only when cells have access to lactose; in the absence of lactose, the enzyme is superfluous. Accordingly, it makes sense in terms of cellular economy for the synthesis of β -galactosidase to be turned on, or *induced*, in the presence of lactose but to be turned off in its absence. This turning on of enzyme synthesis is called **substrate induction**, and enzymes whose synthesis is regulated in this way are referred to as **inducible enzymes**. Most catabolic pathways in bacterial cells are subject to substrate induction of their enzymes.

Anabolic Pathways and End-Product Repression. The regulation of anabolic pathways is in a sense just the opposite of that for catabolic pathways. For anabolic pathways, the amount of enzyme produced by a cell usually correlates inversely with the intracellular concentration of the end-product of the pathway. Such a relationship makes sense. For example, as the concentration of tryptophan rises, it is advantageous for the cell to economize on its metabolic resources by reducing its production of the enzymes involved in synthesizing tryptophan. But it is equally important that the cell be able to turn the production of these enzymes back on when the level of tryptophan decreases again. This kind of control is made possible by the ability of the end-product of an anabolic pathway—in our example, tryptophan—to somehow

repress (reduce or stop) the further production of the enzymes involved in its formation. Such reduction in the expression of the enzyme-coding genes is called **end-product repression**. Most biosynthetic pathways in bacterial cells are regulated in this way.

Repression is a general term in molecular genetics, referring to the reduction in expression of any regulated gene. True genetic repression always has an effect on protein *synthesis*, not just on protein *activity*. Recall from Chapter 6 that the end-products of biosynthetic pathways often have an inhibitory effect on enzyme activity as well. This *feedback inhibition* differs from repression in both mechanism and result. In feedback inhibition, molecules of enzyme are still present, but their catalytic activity is inhibited. In end-product repression, the enzyme molecules are not even made.

Effector Molecules. One feature common to both induction and repression of enzyme synthesis is that control is triggered by small organic molecules present within the cell or in the cell's surroundings. Geneticists call small organic molecules that function in this way **effectors**. For catabolic pathways, effectors are almost always substrates (lactose in our example), and they function as inducers of gene expression and, thus, of enzyme synthesis. For anabolic pathways, effectors are usually end-products (tryptophan in our example), and they usually lead to the repression of gene expression and thus repression of enzyme synthesis.

The Genes Involved in Lactose Catabolism Are Organized into an Inducible Operon

The classic example of an inducible enzyme system occurs in the bacterium *Escherichia coli* and involves a group of enzymes involved in lactose catabolism—the enzymes that catalyze the steps shown in Figure 23-1. Much of what we know about the control of gene expression in bacteria, including the vocabulary used to express that knowledge, is based on the pioneering studies of this system carried out by French molecular geneticists François Jacob and Jacques Monod, who received the Nobel Prize in Physiology or Medicine in 1965 for their work. In 1961, Jacob and Monod published a classic paper that has probably influenced our understanding of gene regulation more than any other work.

In their paper, Jacob and Monod proposed a general model of gene regulation with far-reaching implications. The cornerstone of this model rested on their discovery that the control of lactose catabolism involves two types of genes: the first are genes coding for enzymes involved in lactose uptake and metabolism, and the second is a regulatory gene whose product controls the activity of the first set of genes. The genes involved in lactose metabolism are (1) the *lacZ* gene, which codes for β -galactosidase, the enzyme that hydrolyzes lactose and other β -galactosides; (2) the *lacY* gene, which codes for galactoside permease,

the plasma membrane protein that transports lactose into the cell; and (3) the *lacA* gene, which codes for a transacetylase that adds an acetyl group to lactose as it is taken up by the cell. The *lacZ*, *lacY*, and *lacA* genes lie next to each other in the bacterial chromosome and are expressed only when an inducer such as lactose is present. Taken together, these observations led Jacob and Monod to suggest that the three genes belong to a single regulatory unit, or, as they called it, an **operon**—a group of genes with related functions that are clustered together with DNA sequences that allow the genes to be turned on and off simultaneously.

The organization of functionally related genes into operons is commonly observed in prokaryotes but is less common in eukaryotes. In the nematode *Caenorhabditis elegans*, for example, about 15% of genes are found in operons; however, unlike in bacteria, genes in the operons in *C. elegans* are not always functionally related. Nonetheless, the operon model established several basic principles that have shaped our understanding of transcriptional regulation in both prokaryotic and eukaryotic systems.

The *lac* Operon is Negatively Regulated by the *lac* Repressor

A key feature of the operon model is the idea that genes with metabolically related functions are clustered together so their transcription can be regulated as a single unit. But how is this regulation accomplished? Jacob and Monod addressed this question by studying the ability of inducers such as lactose to turn on the production of the enzymes involved in lactose metabolism. They found that for induction to occur, an additional gene must be present—a regulatory gene that they named *lacI* (for inducibility). Whereas normal bacteria will produce β -galactosidase, galactoside permease, and transacetylase only when an

inducer is present, deletion of the *lacI* gene yielded cells that *always* produce these proteins, even when an inducer is absent. Jacob and Monod therefore concluded that the *lacI* gene codes for a product that normally inhibits, and thereby regulates, expression of the *lacZ*, *lacY*, and *lacA* genes. A regulatory gene product that inhibits the expression of other genes is called a **repressor protein**.

To understand how a repressor can regulate gene expression, we need to take a closer look at the organization of the genes involved in lactose metabolism. As **Figure 23-2** shows, the ***lac* operon** consists of the *lacZ*, *lacY*, and *lacA* genes preceded by a **promoter (*P_{lac}*)** and a special nucleotide sequence called the **operator (*O*)**, which actually overlaps the promoter. Transcription of the *lac* operon begins at the promoter, which is the site of RNA polymerase attachment, and then proceeds through the operator and the *lacZ*, *lacY*, and *lacA* genes until finally ending at a terminator sequence. The net result is a single molecule of mRNA coding for the polypeptide products of all three genes. Such mRNA molecules, which code for more than one polypeptide, are called **polycistronic mRNAs**.

The advantage of clustering related genes into an operon for transcription into a single polycistronic mRNA is that it allows the synthesis of several polypeptides to be controlled in a single step. The crucial step in this control is the interaction between an operator site in the DNA and a repressor protein. The interaction between these elements of the *lac* operon is depicted in **Figure 23-3**. The repressor protein, called the *lac* **repressor**, is encoded by the *lacI* regulatory gene, which is located outside the operon (although it happens to be located adjacent to the *lac* operon it regulates). The *lac* repressor is a DNA-binding protein that specifically recognizes and binds to the operator site of the *lac* operon. When the repressor is bound to the operator (Figure 23-3a), RNA polymerase is blocked

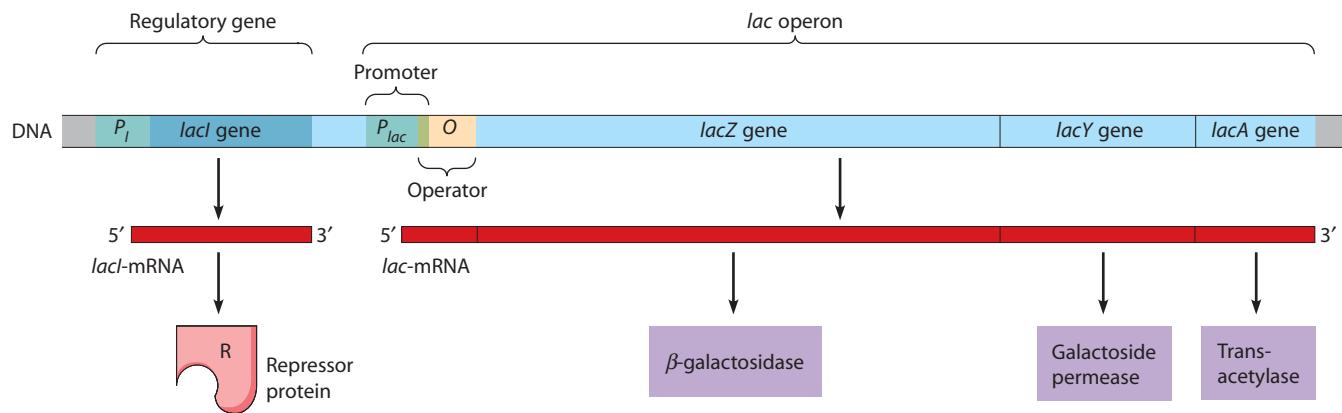

FIGURE 23-2 The Lactose (*lac*) Operon of *E. coli*. The *lac* operon consists of a segment of DNA that includes three contiguous genes (*lacZ*, *lacY*, and *lacA*), which are transcribed and regulated coordinately. The nearby regulatory gene *lacI* codes for the *lac* repressor protein R. Both the regulatory gene and the *lac* operon itself contain promoters (P_I and P_{lac} , respectively) at which RNA polymerase binds and terminators at which transcription halts. P_{lac} overlaps with the operator site (O) to which the active form of the repressor protein binds. The operon is transcribed into a single long molecule of mRNA that codes for all three polypeptides. For details of regulation, see Figure 23-3.

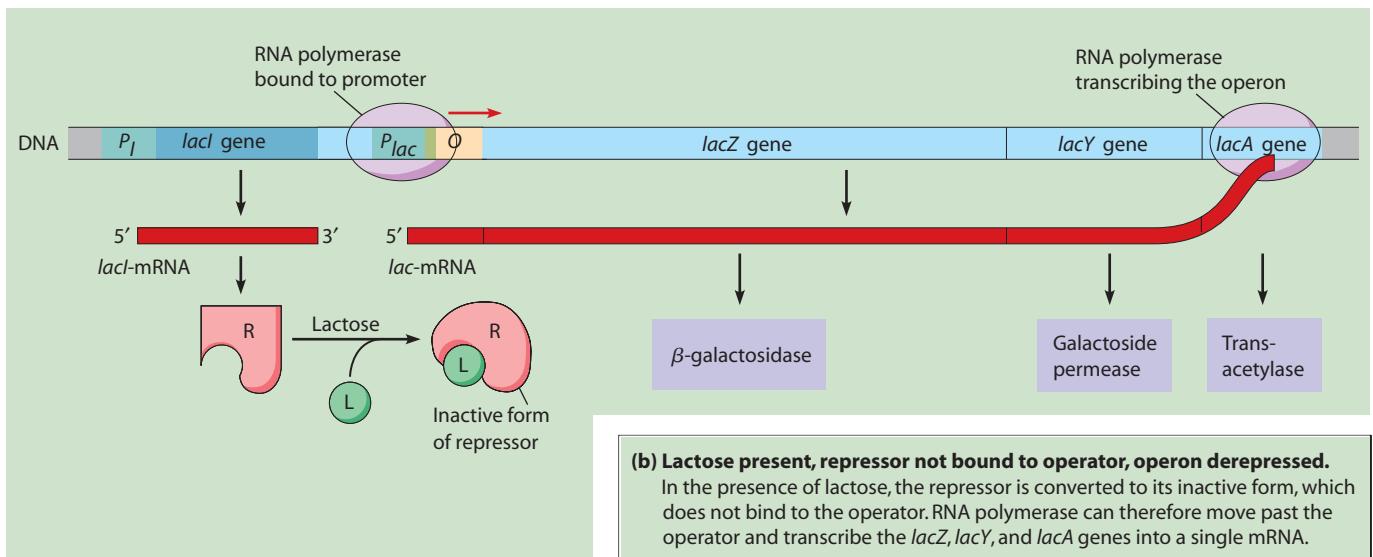

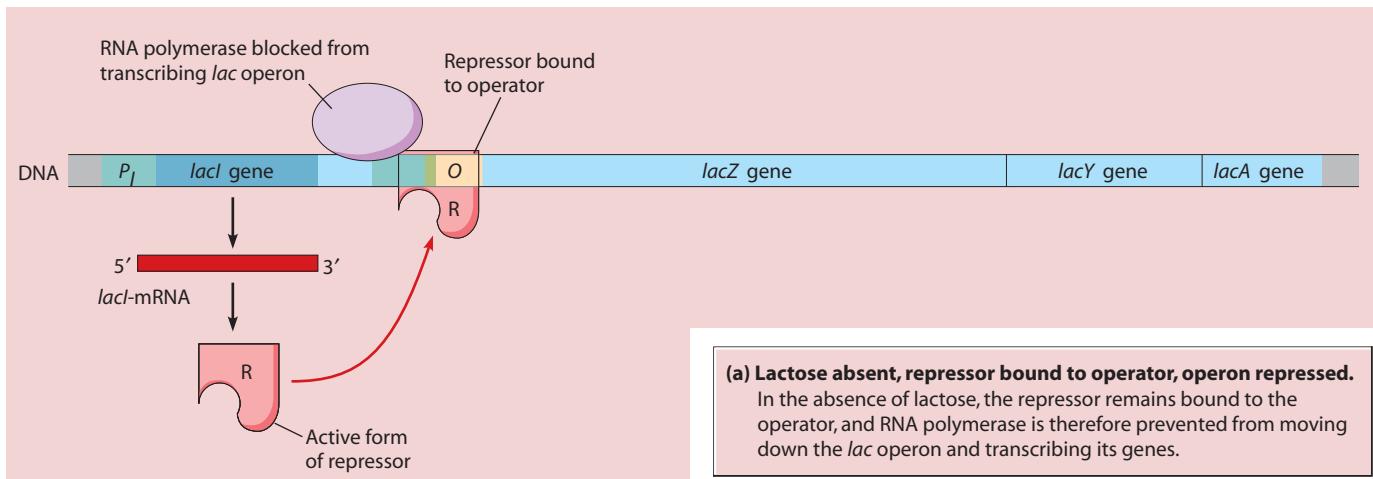

FIGURE 23-3 Regulation of the lac Operon. (a) Transcription of the lac operon is regulated by binding of the lac repressor (R) to the operator. (b) The activity of the lac repressor is in turn regulated by its interaction with a form of lactose called allolactose (L).

from moving down the lac operon and transcribing the lacZ, lacY, and lacA genes. In other words, to use common molecular biology shorthand, binding of the repressor to the operator keeps the operon's genes "turned off."

If binding of the repressor to the operator normally blocks transcription, how do cells "turn on" transcription of the lac operon? The answer is that inducer molecules bind to the lac repressor, thereby altering its conformation so that the repressor loses the ability to bind to the operator site in DNA. Once the operator site is no longer blocked by the repressor, RNA polymerase can bind to the promoter and proceed down the operon, transcribing the lacZ, lacY, and lacA genes into a single polycistronic mRNA molecule (Figure 23-3b).

A crucial feature of a repressor protein, therefore, is its ability to exist in two forms, only one of which binds to the operator. In other words, a repressor is an *allosteric protein*. As we learned in Chapter 6, an allosteric protein can exist in either of two conformational states, depending

on whether or not the appropriate effector molecule is present. In one state the protein is active; in the other state it is inactive, or nearly so. When the effector molecule binds the protein, it induces a change in the conformational state of the protein and therefore in its activity. The binding is readily reversible, however, and departure of the effector results in the protein's rapid return to the alternative form.

Figure 23-3 shows the reversible interaction of the lac repressor with its effector, which is actually not lactose itself but *allolactose*, an isomer of lactose produced after lactose enters the cell. In the absence of allolactose, the repressor binds to the lac operator and inhibits transcription of the lac operon. But the binding of allolactose to the repressor converts the repressor to a conformational form that can no longer bind to the lac operator and inhibit transcription. In this way, lactose triggers the *induction* of the enzymes encoded by the lac operon. Experiments involving the lac operon are usually carried out using the

synthetic β -galactoside *isopropylthiogalactoside* (*IPTG*) rather than lactose or allolactose as the inducing molecule. *IPTG* is a good inducer of the system but cannot be metabolized by cells, so its use avoids possible complications from varying levels of effector caused by its catabolism. Following common usage, we can now formally define the term **inducer** as referring to any effector molecule that turns on the transcription of an inducible operon. Because the *lac* operon is turned off unless induced, it is said to be an **inducible operon**. To borrow a computer term, the “default state” of an inducible operon is *off*. Although we have focused thus far on the control of single operons, it is common for an individual regulatory protein to act on multiple operons, allowing many genes to be coordinately regulated.

Studies of Mutant Bacteria Revealed How the *lac* Operon Is Organized

Much of the early evidence leading to the operon model involved genetic analyses of mutant bacteria that either produced abnormal amounts of the enzymes of the *lac* operon or showed abnormal responses to the addition or removal of lactose. These mutations were found to be located either in the operon genes (*lacZ*, *lacY*, or *lacA*) or in the regulatory elements of the system (*O*, *P_{lac}*, or *lacI*). These two classes of mutations can be readily distinguished because mutations in an operon gene affect only a single protein, whereas mutations in regulatory regions typically affect expression of all the operon genes coordinately.

Table 23-1 summarizes these mutations and their phenotypes, starting in line 1 with the inducible phenotype of the wild-type (nonmutant) cell. The plus signs in the phenotype columns of the table indicate high enzyme levels. The minus signs indicate very low enzyme levels, although not the complete cessation of enzyme production. Even in the absence of lactose, wild-type cells make small amounts of the *lac* enzymes because the binding of repressor to operator is reversible—the active repressor occasionally “falls off” the operator. The resulting low,

background level of transcription is important because it allows cells to produce enough galactoside permease to facilitate the initial transport of lactose molecules into the cell prior to induction of the *lac* operon.

Examining Table 23-1 should help clarify how the analysis of genetic phenotypes led Jacob and Monod to formulate the operon model of gene regulation. We will consider each of the six kinds of mutations shown in lines 2–7 of this table in turn. As we do so, you should be able to see how each type of mutation contributed to formulation of the operon model.

Operon Gene Mutations. Mutations in the *lacY* or *lacZ* genes can lead to production of altered enzymes with little or no biological activity, even in the presence of inducer (Table 23-1, lines 2 and 3). Such mutants are therefore unable to utilize lactose as a carbon source, either because they cannot transport lactose efficiently into the cell (*Y*[−] mutants) or because they cannot cleave the glycosidic bond between galactose and glucose in the lactose molecule (*Z*[−] mutants). Note that mutations in a bacterial gene or regulatory sequence that render it defective are indicated with a superscript minus sign. For example, the genotype of a bacterium carrying a defective *Y* gene is written as *Y*[−]. The wild-type allele is indicated with a superscript plus sign.

Operator Mutations. Mutations in the operator can lead to a constitutive phenotype; that is, the mutant cells will continually produce the *lac* enzymes, whether inducer is present or not (Table 23-1, line 4). These mutations change the base sequence of the operator DNA so that it is no longer recognized by the repressor. The genotype of such *operator-constitutive mutants* is represented as *O*^c. As is expected for mutations in a regulatory site, *O*^c mutations simultaneously affect the synthesis of all three *lac* enzymes in the same way.

Promoter Mutations. Promoter mutations can decrease the affinity of RNA polymerase for the promoter. As a result, fewer RNA polymerase molecules bind per unit

Table 23-1 Genetic Analysis of Mutations Affecting the *lac* Operon

Line Number	Genotype of Bacterium*	Phenotype with Inducer Absent		Phenotype with Inducer Present	
		β -galactosidase	Permease	β -galactosidase	Permease
1	<i>I</i> ⁺ <i>P</i> ⁺ <i>O</i> ⁺ <i>Z</i> ⁺ <i>Y</i> ⁺	—	—	+	+
2	<i>I</i> ⁺ <i>P</i> ⁺ <i>O</i> ⁺ <i>Z</i> [−] <i>Y</i> [−]	—	—	+	—**
3	<i>I</i> ⁺ <i>P</i> ⁺ <i>O</i> ⁺ <i>Z</i> [−] <i>Y</i> ⁺	—	—	—	+
4	<i>I</i> ⁺ <i>P</i> ⁺ <i>O</i> ^c <i>Z</i> ⁺ <i>Y</i> ⁺	+	+	+	+
5	<i>I</i> ⁺ <i>P</i> [−] <i>O</i> ⁺ <i>Z</i> ⁺ <i>Y</i> ⁺	—	—	—	—
6	<i>I</i> ^s <i>P</i> ⁺ <i>O</i> ⁺ <i>Z</i> ⁺ <i>Y</i> ⁺	—	—	—	—
7	<i>I</i> [−] <i>P</i> ⁺ <i>O</i> ⁺ <i>Z</i> ⁺ <i>Y</i> ⁺	+	+	+	+

**P* = *P_{lac}*

**The defective permease exhibits sufficient biological activity to transport minimal amounts of lactose into the cell, thereby permitting induction of the *lac* operon.

Table 23-2 Diploid Analysis of Mutations Affecting the *lac* Operon

Line Number	Genotype of Diploid Bacterium*	Phenotype with Inducer Absent		Phenotype with Inducer Present	
		β -galactosidase	Permease	β -galactosidase	Permease
1	$I^+P^+O^+Z^+Y^+/I^+P^+O^+Z^+Y^+$	—	—	+	+
2	$I^+P^+O^+Z^-Y^+/I^+P^+O^+Z^+Y^-$	—	—	+	+
3	$I^+P^+O^+Z^-Y^+/I^+P^+O^+Z^+Y^-$	—	—	+	+
4	$I^+P^+O^+Z^-Y^+/I^+P^+O^cZ^+Y^-$	+	—	+	+
5	$I^+P^+O^+Z^-Y^+/I^cP^+O^+Z^+Y^-$	—	—	—	—

* $P = P_{lac}$

time to the promoter, and the rate of mRNA production decreases. (However, once an RNA polymerase molecule attaches to the DNA and begins transcription, it elongates the mRNA molecule at a normal rate.) Usually, promoter mutations (P^-) in the *lac* operon decrease both the elevated level of enzyme produced in the presence of inducer and the already low, basal level of *lac* enzyme production the cell manages to achieve in the absence of inducer (Table 23-1, line 5).

Regulatory Gene Mutations. Mutations in the *lacI* gene are of two types. Some mutants fail to produce any of the *lac* enzymes, regardless of whether inducer is present, and are therefore called *superrepressor mutants* (I^s in Table 23-1, line 6). Either the repressor molecule in such mutants has lost its ability to recognize and bind the inducer but can still recognize the operator or else it has a high affinity for the operator regardless of whether inducer is bound to it. In either case, the repressor binds tightly to the operator and represses transcription, and hence enzyme synthesis, under all conditions.

The other class of *lacI* mutations involves synthesis of a mutant repressor protein that does not recognize the operator (or, in some cases, is not synthesized at all). The *lac* operon in such I^- mutants cannot be turned off, and the enzymes are therefore synthesized constitutively (Table 23-1, line 7).

I^- mutants, along with the O^c and P^- mutants, illustrate the importance of specific recognition of DNA base sequences by regulatory proteins during the control of gene transcription. A small change—either in the DNA sequence of promoter or operator, or in the regulatory protein that binds to the operator—can dramatically affect expression of all the genes in the operon.

The Cis-Trans Test Using Partially Diploid Bacteria.

The existence of two different kinds of constitutive mutants, O^c and I^- , raises the question of how one type might be distinguished from the other. A *cis-trans* test is often used to differentiate between *cis*-acting mutations, which affect DNA sites (for example, O^c), and *trans*-acting mutations, which affect proteins (for example, I^-). The basis of the *cis-trans* test is a cell (or organism) that has two different copies of the DNA segment of interest. As

you know, *E. coli* is usually haploid, but Jacob and Monod constructed partially diploid bacteria by inserting a second copy of the *lac* portion of the bacterial genome into the F-factor plasmid of F^+ cells (page 622). This second copy could be transferred by conjugation into a host bacterium of any desired *lac* genotype to create partial diploids such as the types listed in Table 23-2.

If only one copy of the operon contains an I^- or O^c regulatory mutation, it is possible to determine whether the mutation has an effect on both copies of the operon or only on the copy of the operon where it is located. The mutation is said to act in *cis* if the only genes affected are those physically linked to the mutant locus (*cis* means “on this side,” in this case referring to a mutation whose influence is restricted to genes located in the same physical copy of the *lac* operon). In contrast, the mutation is said to act in *trans* if the genes in both copies of the operon are affected (*trans* means “on the other side,” in this case referring to the ability of the mutation to somehow affect the other copy of the *lac* operon).

To determine which copy of the *lac* operon is being expressed in any given cell population, Jacob and Monod used partial diploid cells containing one copy of the *lac* operon with a defective *Z* gene and the other copy with a defective *Y* gene. Table 23-2 shows what happens if one of these *lac* operon copies has a defective I^- allele and the other possesses a normal I^+ allele. In such cells, both β -galactosidase and permease are inducible, even though the functional gene for one of these enzymes (Z^+ allele for β -galactosidase) is physically linked to the defective *I* gene (Table 23-2, line 3). We now know that this occurs because the one functional *I* gene present in the cell produces active repressor molecules that diffuse through the cytosol and bind to both operator sites in the absence of lactose. The repressor is therefore said to be a *trans-acting factor* (the term *factor* refers to a protein in this context).

Quite different results are obtained with partial diploids containing both the O^+ and O^c alleles (Table 23-2, line 4). In this case, genes linked to the O^c allele are constitutively transcribed (Z^+Y^-), whereas those linked to the wild-type allele are inducible (Z^-Y^+). The *O* locus, in other words, acts in *cis*; it affects the behavior of genes only in the operon it is physically a part of. Such *cis* specificity is characteristic of mutations that affect binding sites on DNA rather than

protein products of genes. Like other noncoding DNA sequences involved in the control of gene expression, the *O* site is said to be a **cis-acting element** (the term *element* refers to a nucleic acid sequence in this context).

Catabolite Activator Protein (CAP) Positively Regulates the *lac* Operon

Under normal circumstances, we have seen that the *lac* operon is under *negative* regulation: It is normally turned off and is only turned on when lactose is present. But what if *both* lactose and glucose are present? Glucose is the preferred energy source for almost all cells because the enzymes of the glycolytic and tricarboxylic acid (TCA) pathways are usually produced continuously. Indeed, *E. coli* cells grown in the presence of both glucose and lactose use the glucose preferentially and have very low levels of the enzymes encoded by the *lac* operon, despite the presence of the inducer for that operon. Bacterial cells must therefore have a way to guarantee that other carbon sources are used only when glucose is not available. This phenomenon, known as *catabolite repression*, refers to the ability of glucose to inhibit the synthesis of catabolic enzymes produced by inducible bacterial operons. Catabolite repression is an important example of *positive* transcriptional control.

Like the other regulatory mechanisms we have encountered, this preferential use of glucose is made possible by a genetic control mechanism that involves an allosteric regulatory protein and a small effector molecule. The actual effector molecule that controls gene expression is not glucose but a secondary signal that reflects the level of glucose in the cell. This secondary signal is a form of AMP called *cyclic AMP* or *cAMP* (see Figure 14-6). Glucose acts by indirectly inhibiting adenylyl cyclase, the enzyme that catalyzes the synthesis of cAMP from ATP. So the more glucose present, the less cAMP is made.

How does cAMP influence gene expression? Like other effectors, it acts by binding to an allosteric regulatory protein. As shown in Figure 23-4, this particular regulatory protein, called **catabolite activator protein (CAP)**, or cAMP receptor protein, is an activator protein that turns on transcription. By itself, CAP is nonfunctional. But when complexed with cAMP, CAP can bind to a particular base sequence within operons that produce catabolic enzymes. This base sequence, the *CAP-binding site*, is located upstream of the promoter. Figure 23-4 shows the location of the CAP-binding site (*C*) in the *lac* operon. Similar sites occur in inducible operons involved in the metabolism of many other sugars, such as the sucrose, galactose, and arabinose operons. When CAP, in its active form (that is, the CAP-cAMP complex), attaches to one of its recognition sites in DNA, the binding of RNA polymerase to the promoter is greatly enhanced, thereby stimulating the initiation of transcription. Thus, when glucose is not present, CAP has a *positive* effect on gene expression from the *lac* operon. The CAP-cAMP complex greatly enhances transcription of inducible

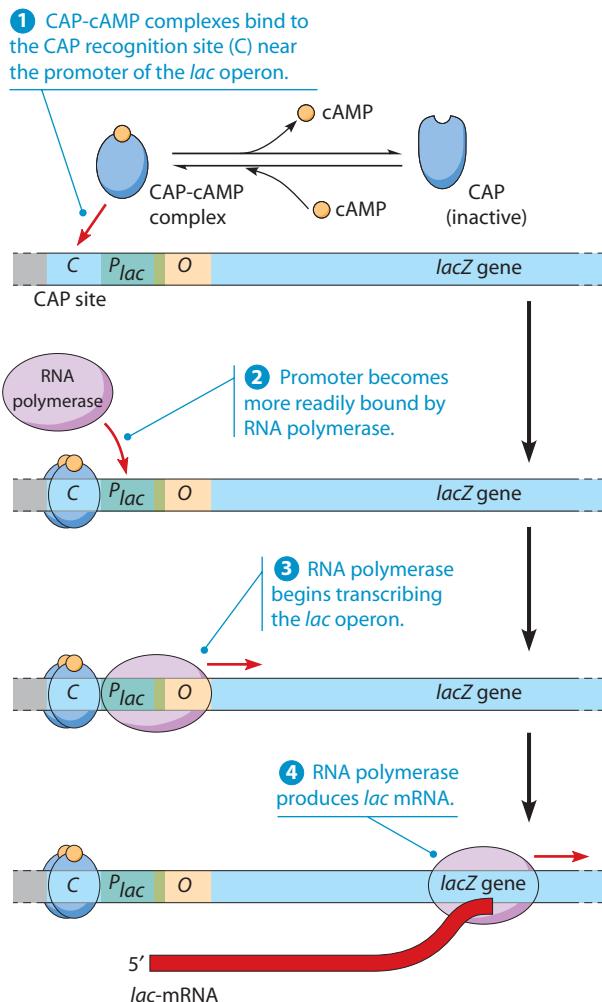

FIGURE 23-4 The Catabolite Activator Protein (CAP) and Its Function. CAP is an allosteric protein that is converted to its active form by binding to cyclic AMP (cAMP), whose concentration is in turn influenced by glucose levels. Two CAP-cAMP complexes mediate catabolite repression by binding to DNA and activating the transcription of various inducible operons, including the *lac* operon shown here.

operons. For example, transcription of the *lac* operon can be increased fiftyfold in this way—provided, of course, that the repressor for that operon has been inactivated by the presence of its effector (that is, allolactose).

This situation changes when the glucose concentration inside the cell is high. In this case, the cAMP concentration falls and CAP is largely in its inactive form. Therefore CAP cannot stimulate the transcription of *lac* operon. In this way, cells turn off the synthesis of catabolic enzymes that are not needed when glucose is abundantly available as an energy source.

The *lac* Operon Is an Example of the Dual Control of Gene Expression

As we have just seen, the *lac* operon is subject to both positive and negative control. Indeed, most tightly regulated genes in prokaryotes and eukaryotes are under such dual

control. To keep negative and positive types of transcriptional control clear in your mind, ask about the primary effect of the regulatory protein that binds to the operon DNA. If, in binding to the DNA, the regulatory protein prevents or turns off transcription, then it is part of a negative control mechanism. If, on the other hand, its binding to DNA results in the activation or enhancement of transcription, then the regulatory protein is part of a positive control mechanism.

The Structure of the *lac* Repressor/Operator Complex Confirms the Operon Model

In 1996, Mitchell Lewis, Ponzy Lu, and colleagues reported the structure of the *lac* repressor protein bound to DNA (Figure 23-5). This structure confirmed previous genetic and biochemical studies and provided insights into how transcription is regulated in detail. The repressor protein encoded by the *lacI* gene (Figure 23-5a) actually interacts with the operator DNA as a tetramer (i.e., four copies of the protein act together; Figure 23-5b). The repressor binds the primary operator, termed O_1 , which is 21 base pairs in length. In addition, there are two other operator DNA sequences, termed O_2 and O_3 . When the repressor is bound to the O_1 and O_3 sites, the repressor is thought to cause the DNA to form a loop, which inhibits the movement of RNA polymerase. The loop is thought to be large enough that CAP can bind to DNA even when the DNA is looped (Figure 23-5c). When allolactose binds at the inducer site, the conformation of the protein changes so that it can no longer interact with DNA, the loop relaxes, and RNA polymerase can move along the DNA to transcribe the *lac* operon.

The Genes Involved in Tryptophan Synthesis Are Organized into a Repressible Operon

Although much of the work leading to the initial formulation of the operon concept involved the *lac* operon of *E. coli*, many other bacterial regulatory systems are now known to follow the same general pattern. Operons coding for enzymes involved in catabolic pathways generally resemble the *lac* operon in being inducible; that is, they are turned *on* by a specific allosteric effector, usually the substrate for the pathway involved. In contrast, operons that regulate enzymes involved in anabolic (biosynthetic) pathways are **repressible operons**; they are turned *off* allosterically, usually by an effector that is the end-product of the pathway. The tryptophan (*trp*) operon is a good example of a repressible operon. The *trp* operon contains genes coding for enzymes involved in tryptophan biosynthesis, along with DNA sequences that regulate the production of these enzymes. The effector molecule in this case is the end-product of the biosynthetic pathway, the amino acid tryptophan.

Production of the enzymes encoded by the *trp* operon is repressed in the presence of tryptophan and derepressed

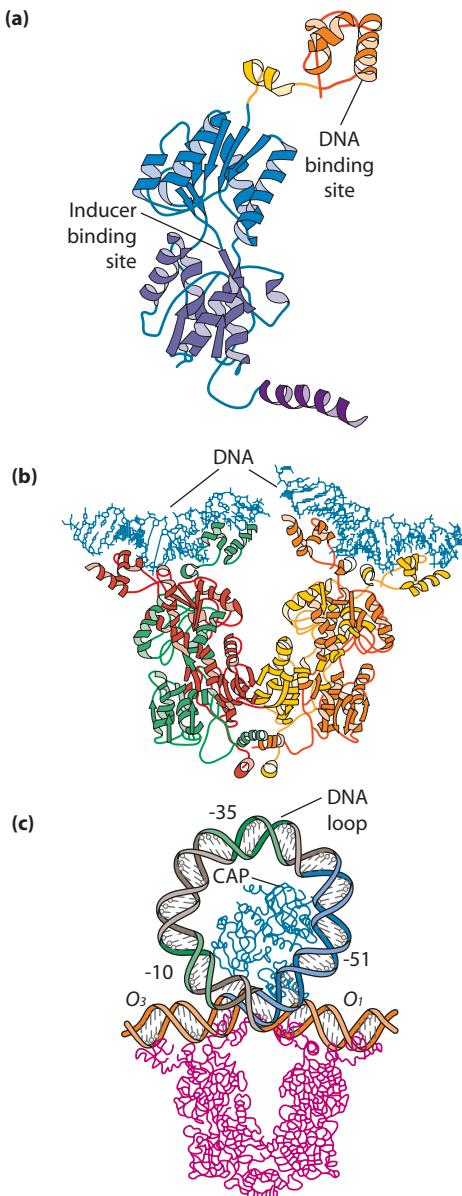

FIGURE 23-5 Structure of the *lac* Repressor/Operator Complex. Models of the *lac* repressor operon bound to operator DNA, based on X-ray crystal structures. (a) The repressor monomer, showing the inducer binding site, and the DNA binding site in red. (b) The repressor dimer bound to two 21-base-pair segments of operator DNA (light blue). (c) The repressor (pink) and CAP (light blue) bound to the *lac* DNA. Binding to operator regions O_1 and O_3 causes a loop to form in the promoter DNA that represses transcription. From M. Lewis, et al., “Crystal Structure of the Lactose Operon Repressor and Its Complexes with DNA and Inducer,” *Science* 271 (1 March 1996): 1247–1254. Reprinted with permission from AAAS.

in its absence (Figure 23-6a). The regulatory gene for this operon, called *trpR*, codes for a *trp* repressor protein that—in contrast to the *lac* repressor—is active (binds to operator DNA) when the effector is attached to it and is inactive in its free form. The effector in such systems (in this case, tryptophan) is sometimes referred to as a **corepressor** because it is required, along with the repressor protein, to shut off transcription of the operon.

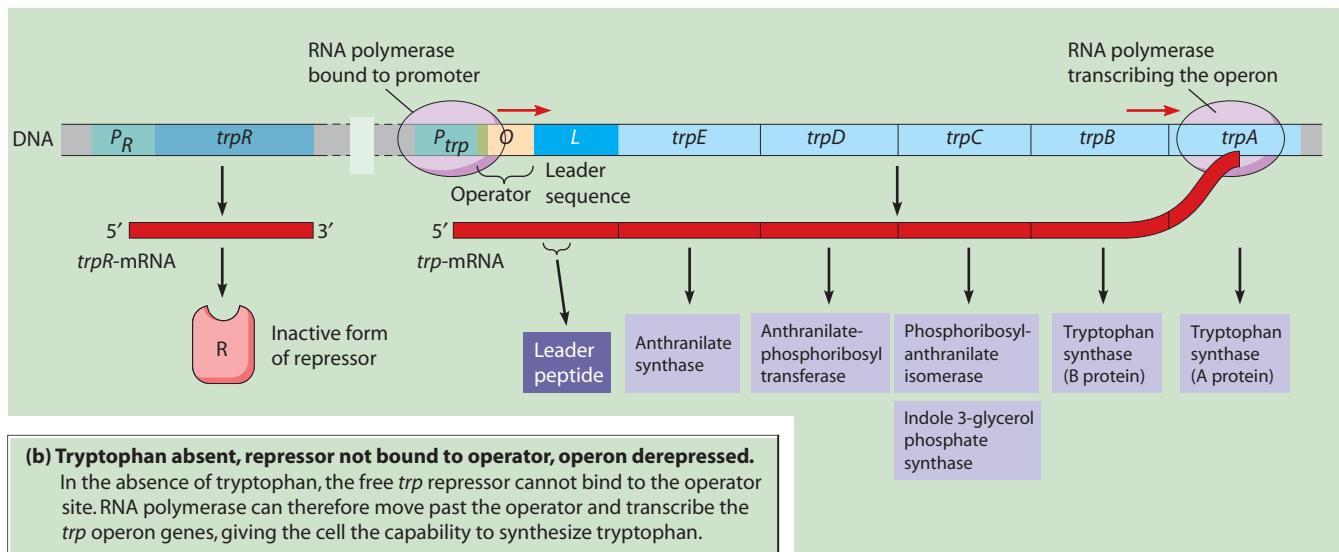

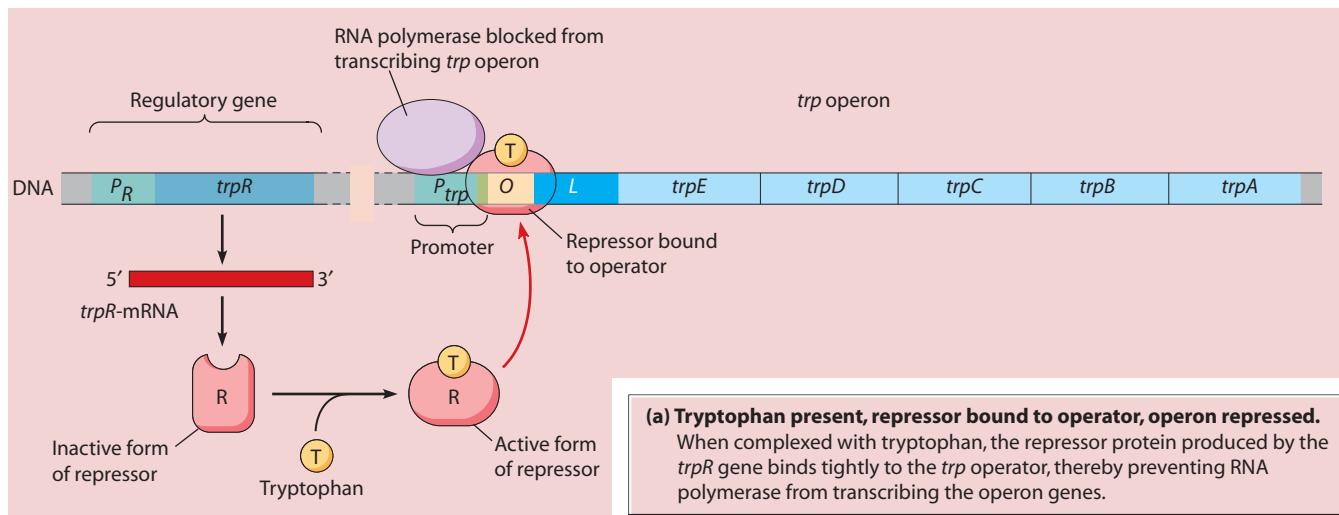

FIGURE 23–6 Regulation of the Tryptophan (*trp*) Operon by the *trp* Repressor. The *trp* operon of *E. coli* consists of a DNA segment that includes five contiguous genes (*trpE*, *trpD*, *trpC*, *trpB*, and *trpA*) as well as promoter (*P_{trp}*), operator (*O*), and leader (*L*) sequences. The genes are regulated and transcribed as a unit, producing a polycistronic message that codes for the enzymes involved in synthesizing tryptophan. An additional regulatory role played by the leader segment of the mRNA will be explained in Figures 23–7 and 23–8.

Sigma Factors Determine Which Sets of Genes Can Be Expressed

In addition to using regulatory proteins that activate or repress specific operons, bacterial cells also employ different sigma (σ) factors to control which genes will be transcribed. Recall from Chapter 21 that the proper initiation of transcription in bacteria requires the RNA polymerase core enzyme to be combined with a sigma factor, a type of protein that recognizes gene promoter sequences. In *E. coli* the most prevalent sigma factor is σ^{70} , which initiates transcription of genes whose products are required for routine growth and metabolism. However, changes in a cell's environment, such as increases in temperature, UV radiation, or acidity, can trigger the use of alternative sigma factors, such as σ^S and σ^{32} . When one of these alternative sigma factors is bound to the RNA

polymerase core enzyme, promoter recognition is altered, thereby initiating the transcription of genes encoding proteins that help the cell adapt to the altered environment. Yet another sigma factor, σ^{54} , enables RNA polymerase to preferentially transcribe genes whose products minimize the slowing of growth under nitrogen-limiting conditions.

Significant differences are observed in the numbers and types of sigma factors found in different kinds of bacteria. For example, *E. coli* has about half a dozen sigma factors, whereas the soil bacteria *Bacillus subtilis* and *Streptomyces coelicolor* use closer to 20 and 60 different sigma factors, respectively. In some cases, the sigma factors that regulate bacterial transcription are produced by bacteriophages. Such an arrangement allows a bacteriophage to infect a bacterial cell and take over its transcriptional machinery by producing a specific sigma

factor that binds to the bacterial RNA polymerase and causes it to recognize only viral promoters.

Attenuation Allows Transcription to Be Regulated After the Initiation Step

The regulatory mechanisms discussed so far control the initiation of transcription. Bacteria also employ regulatory mechanisms that operate after the initiation step. A classic example was first uncovered when Charles Yanofsky and his colleagues found that the *trp* operon of *E. coli* has a novel type of regulatory site located between the promoter/operator and the operon's first gene, *trpE*. This stretch of DNA, called the *leader sequence* (or *L*), is transcribed to produce a leader mRNA segment, 162 nucleotides long, located at the 5' end of the polycistronic *trp* mRNA (see Figure 23-6b).

Analysis of *trp* operon transcripts made under various conditions revealed that, as expected, the full-length, polycistronic *trp* mRNA is produced when tryptophan is scarce. This allows the enzymes of the tryptophan biosynthetic pathway to be synthesized, and hence the pathway produces more tryptophan. On the other hand, when tryptophan is present, transcription of the genes coding for the enzymes of the tryptophan pathway is inhibited—also as expected. An unexpected result, however, was that the DNA corresponding to most of the leader sequence may still be transcribed under such conditions, even though the full-length, polycistronic *trp* mRNA is not produced. Based on these findings, Yanofsky suggested that the leader sequence contains a control element that is more sensitive than the *trp* repressor mechanism in determining whether enough tryptophan is present to support protein synthesis. This control sequence somehow determines not whether *trp* operon transcription can begin, but whether it will continue to completion. Such control was called **attenuation** because

of its role in attenuating, or reducing, the synthesis of mRNA.

To see how attenuation works, let's take a closer look at the leader segment of the *trp* operon mRNA (Figure 23-7). This leader has two unusual features that enable it to play a regulatory role. First, in contrast to the untranslated leader sequences typically encountered at the 5' end of mRNA molecules (see Figure 22-6), a portion of the *trp* leader sequence *is* translated, forming a *leader peptide* 14 amino acids long. Within the mRNA sequence coding for this peptide are two adjacent codons for the amino acid tryptophan; these will prove important. Second, the *trp* leader mRNA also contains four segments (labeled regions 1, 2, 3, and 4) whose nucleotides can base-pair with each other to form several distinctive hairpin loop structures. The region comprising regions 3 and 4 plus an adjacent string of eight U nucleotides is called the *terminator*. When base pairing between regions 3 and 4 creates a hairpin loop, it acts as a transcription termination signal (Figure 23-8a). Recall that the typical bacterial termination signal shown in Figure 21-11 is also a hairpin followed by a string of U's. The formation of such a structure causes RNA polymerase and the growing RNA chain to detach from the DNA.

As Yanofsky's experiments suggested, translation of the leader RNA plays a crucial role in the attenuation mechanism. A ribosome attaches to its first binding site on the *trp* mRNA as soon as the site appears, and from there it follows close behind the RNA polymerase. When tryptophan levels are low (Figure 23-8b), the concentration of tryptophanyl-tRNA (tRNA molecules carrying tryptophan) is also low. Thus, when the ribosome arrives at the tryptophan codons of the leader RNA, it stalls briefly, awaiting the arrival of tryptophanyl-tRNA. The stalled ribosome blocks region 1, allowing an alternative hairpin structure to form by pairing regions 2 and 3, called an *antiterminator hairpin*. When region 3 is tied up in this

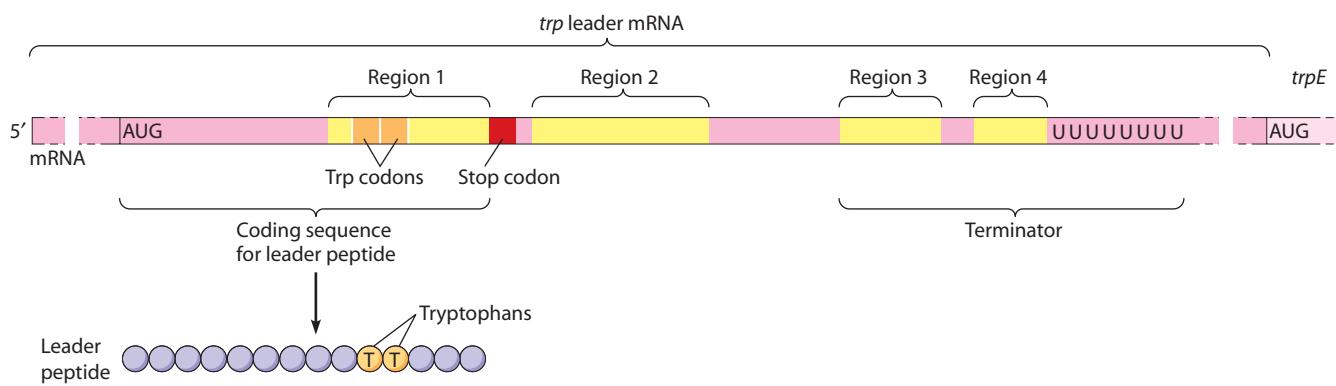

FIGURE 23-7 The *trp* mRNA Leader Sequence. The transcript of the *trp* operon includes a leader sequence of 162 nucleotides situated directly upstream of the start codon for *trpE*, the first operon gene. This leader sequence includes a section encoding a leader peptide of 14 amino acids. Two adjacent tryptophan (Trp) codons within the leader mRNA sequence play an important role in the operon's regulation by attenuation. The leader mRNA also contains four regions capable of base pairing in various combinations to form hairpin structures, as Figure 23-8 shows. A part of the leader mRNA containing regions 3 and 4 and a string of eight U's is called the terminator.

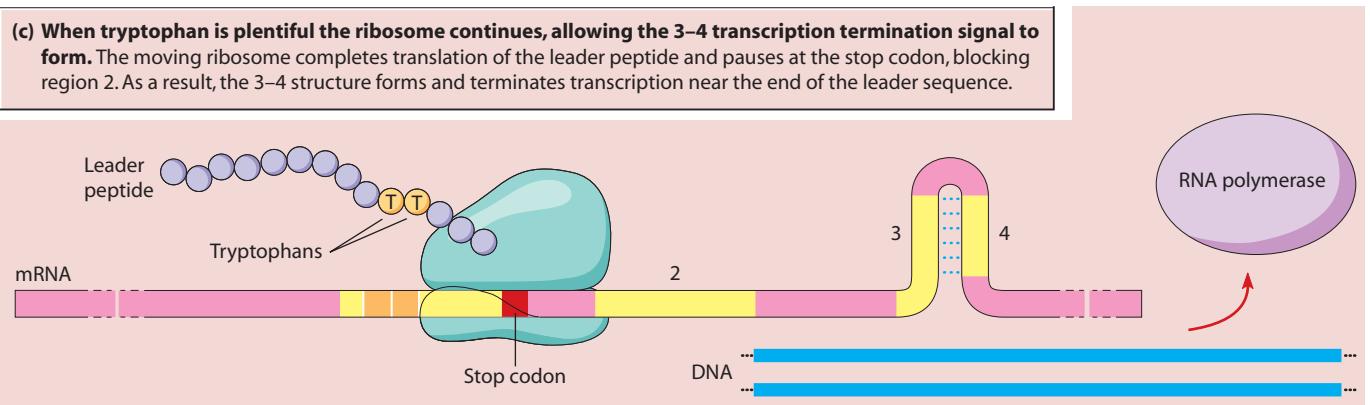

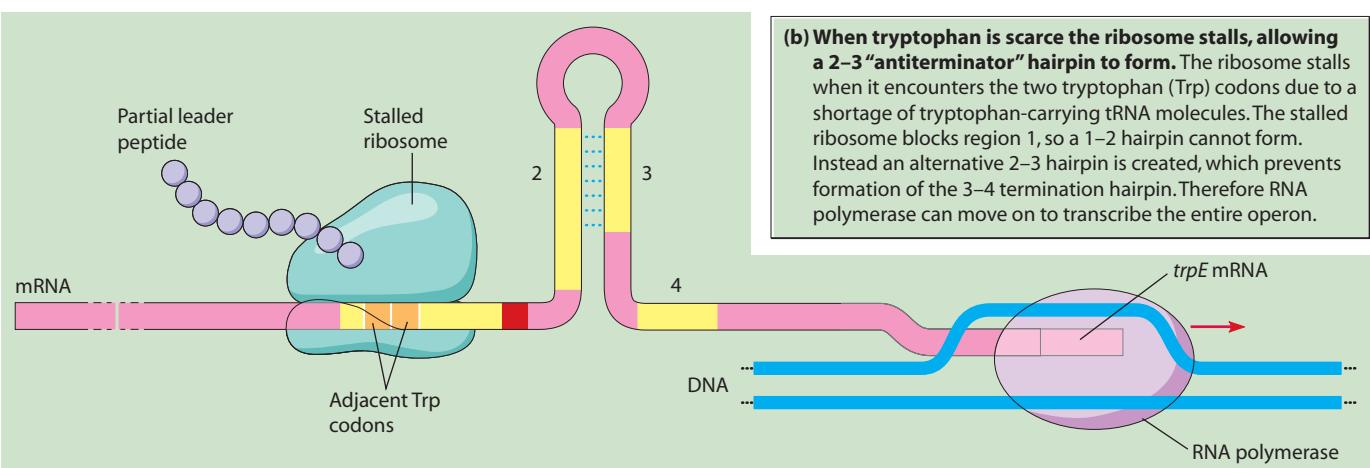

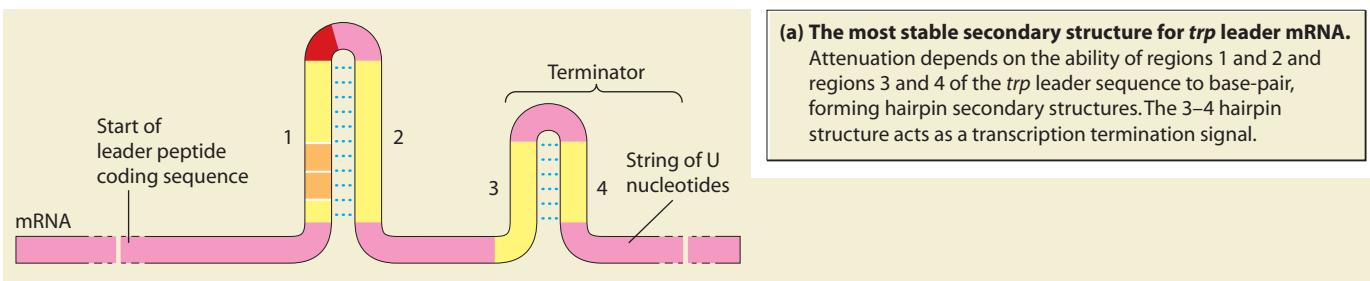

FIGURE 23-8 Attenuation in the *trp* Operon. Attenuation depends on the ability of regions 1 and 2 and regions 3 and 4 of the *trp* mRNA leader sequence to base-pair, forming hairpin secondary structures. The 3–4 hairpin acts as a transcription termination signal; as soon as it forms, RNA polymerase is released from the DNA.

way, it cannot pair with region 4 to create a termination structure, and so *transcription by RNA polymerase continues*, eventually producing a complete mRNA transcript of the *trp* operon. Ribosomes use this mRNA to synthesize the tryptophan pathway enzymes, and production of tryptophan therefore increases.

If, however, tryptophan is plentiful and tryptophanyl-tRNA levels are high, the ribosome does not stall at the tryptophan codons (Figure 23-8c). Instead, the ribosome continues to the stop codon at the end of the coding sequence for the leader peptide and pauses there, blocking region 2. This pause permits the formation of the 3–4 hairpin, which is the transcription termination signal. *Transcription by RNA polymerase is therefore terminated*

near the end of the leader sequence (after 141 nucleotides), and mRNAs coding for the enzymes involved in tryptophan synthesis are no longer produced. The probability of terminating versus continuing transcription is highly sensitive to small changes in the concentration of tryptophanyl-tRNA, providing a more responsive control system than can be achieved by the interaction of free tryptophan with the *trp* repressor as the only means of regulation.

The preceding mechanism, discovered in *E. coli*, requires that ribosomes begin translating the mRNA before transcription is completed. However, attenuation does not always require this coupling of transcription and translation. In the bacterium *B. subtilis*, the leader RNA

transcribed from the *trp* operon is not translated by ribosomes and yet still functions as an attenuator. In this case, formation of the terminator loop is controlled by a tryptophan-binding protein. When tryptophan is present, the protein-tryptophan complex binds to the leader RNA and exposes the terminator loop, thereby terminating transcription and shutting down the *trp* operon.

Although attenuation was once considered to be an unusual type of regulation, it turns out to be relatively common, especially in operons that code for enzymes involved in amino acid biosynthesis. Several mechanisms for achieving attenuation are now known to exist, and in some operons, this may be the only means of regulation. In others, attenuation complements the operator in regulating gene expression, as in the *trp* operon.

Riboswitches Allow Transcription and Translation to Be Controlled by Small Molecule Interactions with RNA

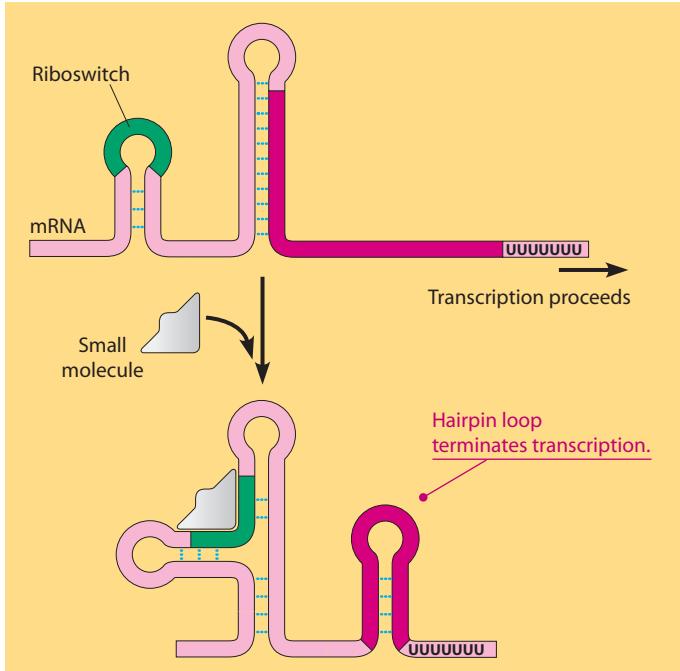

The ability of small molecules to induce shape changes in allosteric proteins plays a central role in regulating gene expression. We have already seen, for example, how gene transcription is controlled by the binding of allolactose to the *lac* repressor protein or tryptophan to the *trp* repressor protein, or of cAMP to a cAMP receptor protein. In each

case, mRNA production is altered by the binding of a small molecule to a regulatory protein.

Small molecules can also regulate gene expression by binding to special sites in mRNA called **riboswitches**. Binding of an appropriate small molecule to its corresponding riboswitch triggers changes in mRNA shape that can affect either transcription or translation. Riboswitches are typically found in the untranslated leader region of mRNAs transcribed from bacterial operons, although they have been detected in mRNAs from archaea and eukaryotes as well. One of the first riboswitches to be discovered is in the RNA transcribed from the *riboflavin* (*rib*) operon of the bacterium *B. subtilis*. The *rib* operon contains five genes coding for enzymes involved in synthesizing the essential coenzymes FMN and FAD. RNA transcribed from the *rib* operon possesses a leader sequence that, like the *trp* leader discussed earlier, can fold into a hairpin loop that terminates transcription. As shown in **Figure 23-9a**, binding of FMN to the leader sequence promotes formation of this hairpin loop. Transcription of the *rib* operon is therefore terminated when FMN is present, halting the production of enzymes that are not necessary because they are involved in synthesizing FMN itself.

Besides regulating transcription, the binding of small molecules to riboswitches can also control mRNA translation. One example occurs in mRNAs coding for enzymes

(a) Transcription termination. Binding of a small molecule to a riboswitch in the leader sequence of some mRNAs triggers the formation of a hairpin loop that terminates transcription. FMN binding to the leader sequence of the mRNA transcribed from the *rib* operon of *B. subtilis* works in this way.

(b) Translation initiation. In other mRNAs, a small molecule binding to a riboswitch triggers formation of a hairpin loop containing the site where ribosomes normally bind, thereby interfering with translation initiation. In *E. coli*, this type of control is used by FMN to inhibit translation of mRNAs coding for enzymes involved in FMN synthesis.

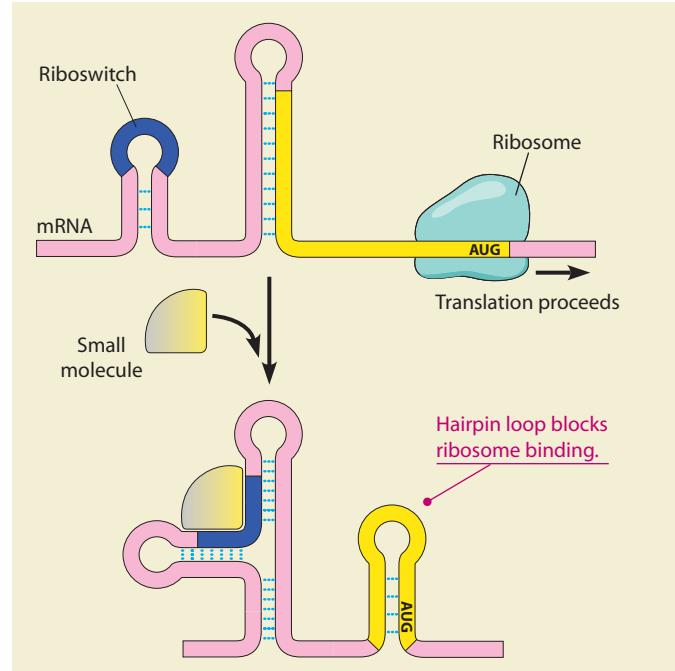

FIGURE 23-9 Riboswitch Control of Gene Expression. These models show two ways in which the binding of small molecules to riboswitches in mRNA can exert control over (a) transcription and (b) translation.

involved in the pathway for synthesizing FMN and FAD in *E. coli*. Unlike the situation in *B. subtilis*, the *E. coli* genes coding for these enzymes are not clustered in a single operon, but some of them are still controlled by riboswitches. In this case, binding of FMN to its mRNA riboswitch promotes the formation of a hairpin loop that includes the sequences required for binding the mRNA to ribosomes. By sequestering away these sequences, the bound FMN prevents the mRNA from interacting with ribosomes and initiating translation (see Figure 23-9b).

Eukaryotic Gene Regulation: Genomic Control

In the early days of molecular biology, there was a popular saying that “what is true of *E. coli* is also true of elephants.” This maxim expressed the initial conviction that almost everything learned about bacterial cell function at the molecular level would also apply to eukaryotes. Such predictions have turned out to be only partly true, however. In terms of central metabolic pathways, mechanisms for transporting solutes across membranes, and such fundamental features as DNA structure, protein synthesis, and enzyme function, there are numerous similarities between the bacterial and eukaryotic worlds, and findings from studies with bacteria can often be extrapolated to eukaryotes.

When it comes to the regulation of gene expression, the comparison needs to be scrutinized more carefully. The DNA of eukaryotic cells is packaged into chromatin fibers and located in a nucleus that is separated from the protein synthetic machinery by a nuclear envelope. Eukaryotic genomes are usually much larger than those of bacteria, and multicellular eukaryotes must create a variety of different cell types from the same genome. Such differences require a diversity of genetic control mechanisms that in some cases differ significantly from those routinely observed in bacteria.

Multicellular Eukaryotes Are Composed of Numerous Specialized Cell Types

To set the stage for our discussion of eukaryotic gene control, let's briefly consider the enormous regulatory challenges faced by multicellular eukaryotes, which are often composed of hundreds of different cell types. In such cases, a single organism consists of a complex mixture of specialized or *differentiated* cell types—for example, nerve, muscle, bone, blood, cartilage, and fat—brought together in various combinations to form tissues and organs. Differentiated cells are distinguished from each other based on differences in their microscopic appearances and in the products they manufacture. For example, red blood cells synthesize hemoglobin, nerve cells produce neurotransmitters, and lymphocytes make antibodies. Such differences indicate that selectively controlling the expression of a wide variety of different genes must play a central role in the mechanism responsible for creating differentiated cells.

Differentiated cells are produced from populations of immature, nonspecialized cells by a process known as **cell differentiation**. The classic example occurs in embryos, in which cells of the early embryo produce all the cell types that make up the organism.

Eukaryotic Gene Expression Is Regulated at Five Main Levels

The fact that a multicellular plant or animal may need to produce hundreds of different cell types using a single genome underscores the difficulty of explaining eukaryotic gene regulation entirely in terms of known bacterial mechanisms—elephants are not just large *E. coli* after all! If we are to thoroughly understand gene regulation in eukaryotic cells, we must approach the topic from a eukaryotic perspective.

The pattern of genes being expressed in any given eukaryotic cell is ultimately reflected in the spectrum of functional gene products—usually protein molecules but in some cases RNA—produced by that cell. The overall pattern is the culmination of controls exerted at several different levels. These potential control points are highlighted in **Figure 23-10**, which traces the flow of genetic information from genomic DNA in the nucleus to functional proteins in the cytoplasm (many, but not all, of these control points also apply to prokaryotes). As you can see, control is exerted at five main levels: ① the genome, ② transcription, ③ RNA processing and export from nucleus to cytoplasm, ④ translation, and ⑤ posttranslational events. Regulatory mechanisms in the last three categories are all examples of *posttranscriptional control*, a term that encompasses a wide variety of events. In the rest of the chapter, we will examine some of the mechanisms eukaryotes use to exert control over gene expression at each of the five levels.

As a General Rule, the Cells of a Multicellular Organism All Contain the Same Set of Genes

The first level of control is exerted at the level of the overall genome. In multicellular plants and animals, each specialized cell type uses only a small fraction of the total number of genes contained within the organism's genome. Yet almost all cells in such organisms (other than the haploid sperm and eggs) retain the same complete set of genes. Dramatic evidence that specialized cells still carry a full complement of genes was provided in 1958 by Frederick Steward, who grew complete new carrot plants from single carrot root cells. Because the cells of each new carrot plant contained the same nuclear DNA that was present in the original carrot root cells, each new plant was a **clone** (genetically identical copy) of the plant from which the original root cells were obtained.

The first successful cloning of animal cells was reported in 1964 by John Gurdon and his colleagues. In studies with *Xenopus laevis*, the African clawed frog, they transplanted nuclei from differentiated tadpole cells into

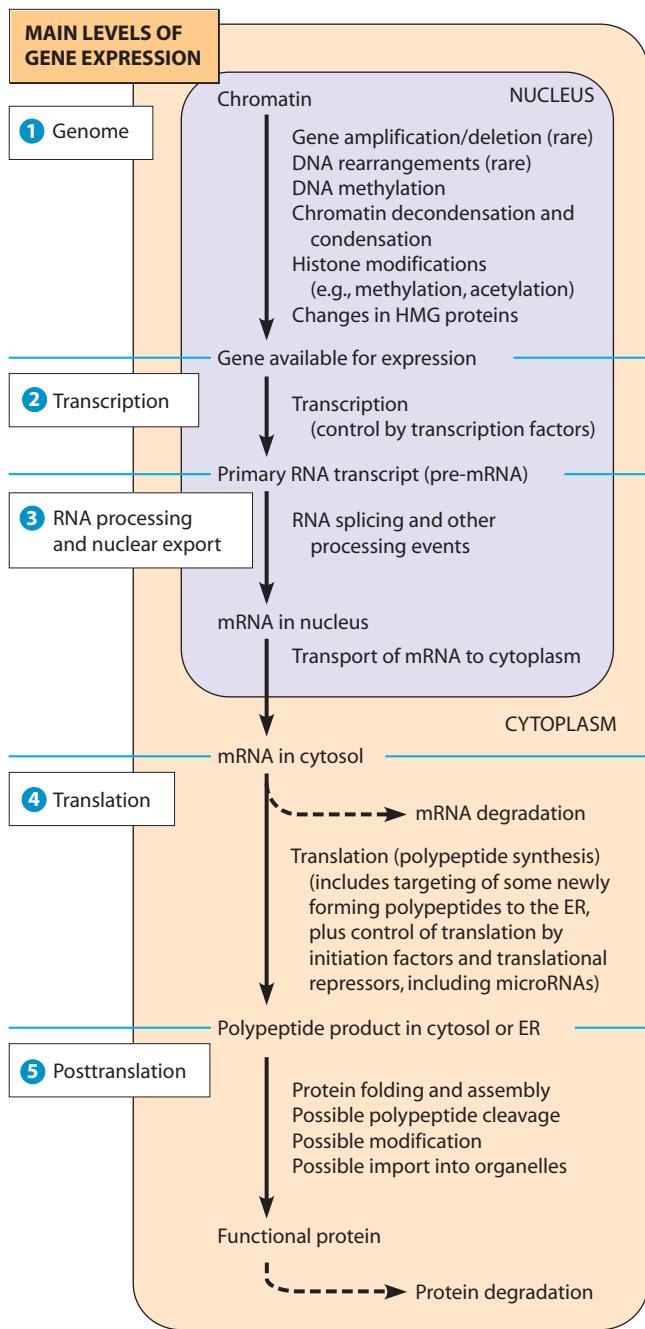

FIGURE 23–10 The Multiple Levels of Eukaryotic Gene Expression and Regulation.

Expression and Regulation. Gene expression in eukaryotic cells is regulated through a diverse array of mechanisms operating at five distinct levels: **1** the genome, **2** transcription, **3** RNA processing and nuclear export, **4** translation, and **5** posttranslational events. Controls operating at the last three levels are all considered to be *posttranscriptional control* mechanisms.

unfertilized eggs that had been deprived of their own nuclei. Although the frequency of success was low, some eggs containing transplanted nuclei gave rise to viable, swimming tadpoles. A new organism created by this process of *nuclear transplantation* is a clone of the organism from which the original nucleus was taken. The results of both the carrot and frog studies indicated that the nucleus of a

differentiated cell can direct the development of an entire new organism. Such a nucleus is therefore said to be *totipotent*: it contains the complete set of genes needed to create a new organism of the same type as the organism from which the nucleus was taken.

An especially dramatic example of animal cloning was reported in 1997, when Ian Wilmut and his colleagues in Scotland made newspaper headlines by announcing the birth of a cloned lamb, Dolly—the first mammal ever cloned from a cell derived from an adult. Dolly was born from a sheep egg whose original nucleus had been replaced by a nucleus taken from a single cell of an adult sheep. Similar techniques have subsequently been used to clone many other mammals. As we discuss in **Box 23A**, cloning is a remarkable feat that raises numerous scientific and ethical questions about the future applications of such technology.

One major proposed use of cloning has relevance to medicine. Modern regenerative medicine seeks to replace defective cells in human patients with genetically engineered substitutes. So-called therapeutic cloning seeks to produce embryonic stem cells that are genetically matched to a human patient but flexible in their ability to differentiate. An alternative that avoids many of the ethical obstacles of therapeutic cloning is the production of induced pluripotent stem cells (see Box 23A).

Gene Amplification and Deletion Can Alter the Genome

Although the preceding evidence indicates that the genome tends to be identical in all cells of an adult eukaryotic organism, a few types of gene regulation create exceptions to this rule. One example is the use of **gene amplification** to create multiple copies of the same gene. Amplification is accomplished by replicating the DNA in a specific chromosomal region many times in succession, thereby creating dozens, hundreds, or even thousands of copies of the same stretch of DNA. Gene amplification can be regarded as an example of **genomic control**—that is, a regulatory change in the makeup or structural organization of the genome.

One of the best-studied examples of gene amplification involves the ribosomal RNA genes in *Xenopus laevis*, the organism used by Gurdon in his nuclear transplantation experiments. The haploid genome of *Xenopus* normally contains about 500 copies of the genes that code for 5.8S, 18S, and 28S rRNA. However, the DNA of these genes is selectively replicated about 4000-fold during oogenesis (development of the egg prior to fertilization). As a result, the mature oocyte contains about 2 million copies of the genes for rRNA. This level of amplification is apparently needed to sustain the enormous production of ribosomes that occurs during oogenesis, which in turn is required to sustain the high rate of protein synthesis needed for early embryonic development.

This particular example of gene amplification involves genes whose products are RNA rather than

Cloning by Nuclear Transfer and Pluripotent Stem Cells

Dolly—the Sheep Without a Father

In February of 1997, Ian Wilmut made newspaper headlines around the world by introducing us to Dolly, the first mammal ever cloned from an adult cell. Dolly was created by removing the nucleus from the cell of an adult sheep and transferring it into a different sheep's egg whose own nucleus had been removed. Although this **nuclear transfer** technique had been used before to clone mammals, it had never been successful with cells taken from an adult.

Wilmut suspected that these previous failures were caused by the state of the chromatin in the donor cells. The secret to his

team's success was that they took mammary gland cells from the udder of a 6-year-old female sheep and starved them in culture to force them into the dormant, G₀ phase of the cell cycle. When such a cell was fused with an egg cell lacking a nucleus, it delivered the diploid amount of DNA in a condition that allowed the egg cytoplasm to reprogram the DNA to support normal embryonic development. Implanting such an egg into the uterus of another female sheep led to the birth of a lamb with no father—that is, a lamb whose cells had the same nuclear DNA as the cells of the 6-year-old female sheep that provided the donor nucleus (**Figure 23A-1**). Within a few years of these pioneering experiments, similar techniques had been used to clone other mammals, including livestock, mice, cats, dogs, and, very recently, monkeys.

Why did Wilmut's team pursue such technology? One reason is to clone valuable transgenic animals. This approach had been used to generate sheep that produce milk containing medically important proteins, such as blood-clotting factors, that are difficult to produce in sufficient quantities by other means. Commercial applications include cloning the beefiest cattle or the fastest racehorses. An even more dramatic application of cloning involves attempts to clone animals that are on the verge of extinction or have recently become extinct.

But the most controversial possibility concerns whether it would ever be ethical to attempt cloning with human cells. For the moment, it appears that producing healthy human clones—or *reproductive cloning*—would be exceedingly difficult. It took 277 attempts to produce Dolly, and many cloned animals that seem normal at birth develop health problems later and die prematurely. These common defects result from a failure of the DNA in the donated nucleus to undergo proper *epigenetic reprogramming*, including methylation of important genes related to growth. In the face of such problems and nearly universal unease about the prospect of human cloning, many individuals have called for laws banning the use of such technology for duplicating human beings. Others have suggested that society might eventually find cloning acceptable under certain restricted circumstances.

Stem Cells—Full of Potential

The most frequent proposed application of the nuclear transfer technique is for producing stem cells genetically matched to a human patient. Some hope that such *therapeutic cloning* could be used to replace damaged cells in human patients. To see why this

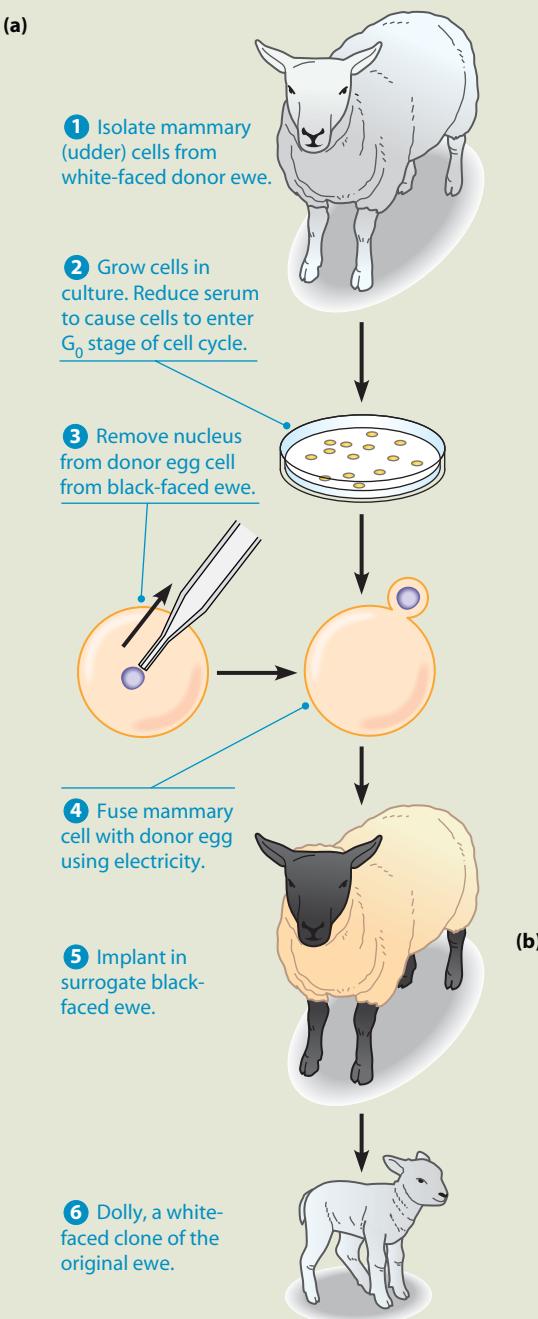

FIGURE 23A-1 Dolly, the First Mammal Cloned from an Adult Cell. (a) Dolly was cloned from a serum-starved mammary (udder) cell that was fused with an egg cell from which the nucleus had been removed. (b) Dolly as an adult.

approach has been proposed, we need to consider why stem cells have such useful properties.

Stem cells are defined by their capacity to replenish themselves through continued division, as well as by their ability, in the presence of appropriate signals, to produce daughter cells that differentiate into a variety of specialized cell types, usually accompanied by the cessation of cell division. Stem cells can be isolated from mature organisms, such as umbilical cord blood of newborns, as well as from adults. Such cells, especially in the case of blood and bone marrow, have been used successfully for years to treat human patients. Such stem cells are considered to be *multipotent*: They can form several cell types, but their repertoire is fairly limited. **Embryonic stem (ES) cells** on the other hand, do not suffer this limitation. They are *pluripotent*; that is, they can form all types of cells that give rise to a human organism except those that form structures such as the placenta and other support membrane needed during gestation.

ES cells are derived from the inner cell mass cells of the early embryo, known as a *blastocyst* (Figure 23A-2a). Inner cell mass cells, once isolated, behave as true stem cells. When treated with various growth factors or in other ways, they can be pushed to become various types of cells.

The ability to isolate and grow stem cells in the laboratory raises the possibility that scientists will be able to produce healthy new cells to replace damaged tissues in patients with various diseases. For example, stem cells that can differentiate into nerve cells might eventually be used to repair the brain damage that occurs in patients suffering from stroke, Parkinson disease, or Alzheimer disease. Or stem cells might be utilized to replace the defective pancreatic cells of patients with diabetes or the defective skeletal muscle cells present in individuals with muscular dystrophy. If the stem cells were produced using therapeutic cloning, they would have the further benefit of being a genetic match to the patient's own cells, avoiding issues of immune rejection.

Despite their developmental potential and their promise in therapies, there is a major ethical objection raised by many people regarding harvesting of ES cells. Isolating ES cells necessarily involves the destruction of a human organism—the embryo. Many view each human organism as an inviolable end in itself, worthy of profound moral respect, making procurement of ES cells ethically impermissible. Others' intuition is that the blastocyst has a different moral status from more advanced human organisms, and view ES cell production as an important potential medical therapy. Clearly, it would be highly desirable to find cells that seem to have developmental potential similar to ES cells, without the associated ethical issues.

In 2006, Shinya Yamanaka announced just such a method: He and his research team had succeeded in coaxing differentiated cells from mice into reverting to a pluripotent state. Such **induced pluripotent stem (iPS) cells** seem to have many of the same properties as ES cells. To produce iPS cells, Yamanaka's team forced cells to express four transcription factor proteins that are expressed by pluripotent cells: Oct4, Sox2, Klf4, and c-Myc (Figure 23A-2b). Further work by Yamanaka's group and by James Thomson and colleagues at the University of Wisconsin extended these studies to human cells. Technical progress has been rapid ever since.

iPS cells seem quite similar to ES cells, and so they seem to be an ideal source of genetically matched, pluripotent cells for medical

treatments. There are some issues to be overcome before they can be used in therapies, however. First, in the original experiments the genes were introduced using a retrovirus, which incorporated its DNA into the host cell's genome. It has since been shown that similar effects can be achieved without integration of viral DNA. Second, c-Myc is a proto-oncogene, which can promote tumor formation (see Chapter 24). However, some cell types can be induced to pluripotency without c-Myc. Finally, many iPS cells do not seem to have the methylation status of their DNA fully reset, unlike ES cells. For this reason, many stem cell biologists who are not opposed to ES cell harvesting favor continuing ES and iPS cell research in parallel since the two types of cells may exhibit somewhat different properties.

Given the widely varying viewpoints about ES cells, cloning, and similar procedures, debate continues about the ethics of these technologies. The rapid pace of scientific developments in this field makes it essential for society not to shy away from the debate.

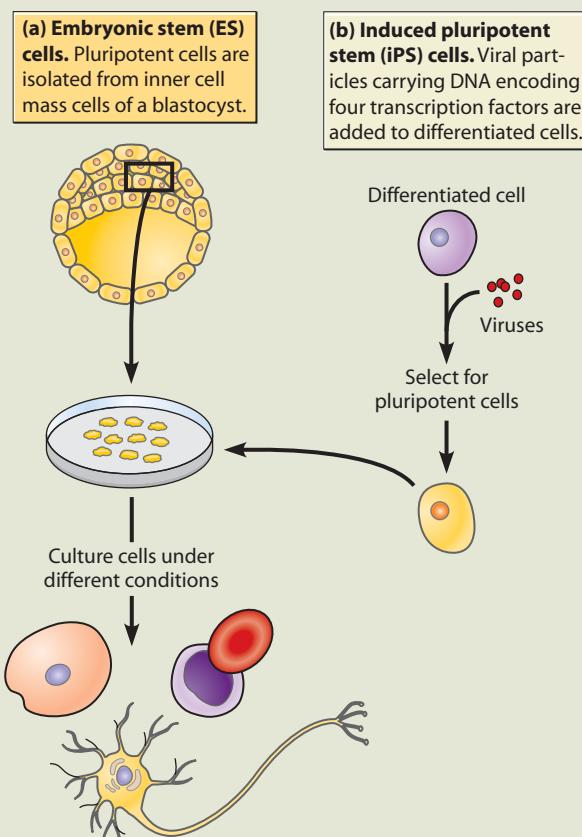

FIGURE 23A-2 Two Different Ways to Produce Pluripotent Stem Cells. (a) Embryonic stem (ES) cells are produced from inner cell mass cells of a blastocyst. The embryo is destroyed to harvest the ES cells. (b) Induced pluripotent stem (iPS) cells result when cells are forced to express four transcription factor proteins. Pluripotent cells are selected using drugs that only allow pluripotent cells to survive. Once ES or iPS cells are isolated, they are cultured under a variety of conditions, causing them to differentiate into various cell types.

protein molecules. The expression of genes that encode proteins—even proteins needed in large amounts, such as ribosomal proteins—can usually be increased sufficiently by increasing the rate of mRNA translation without a need for gene amplification. Nonetheless, enhanced production of certain proteins can occasionally be traced to gene amplification. One example in normal cells is the synthesis of chorion proteins in insect eggs. Abnormal amplification of genes coding for proteins involved in cell cycle signaling is a frequently observed abnormality in cancer cells (Chapter 24).

In addition to amplifying gene sequences whose products are in great demand, some cells delete genes whose products are not required. An extreme example of **gene deletion** (also called *DNA diminution*) occurs in mammalian red blood cells, which discard their nuclei entirely after adequate amounts of hemoglobin mRNA have been made. A less-extreme example occurs in nematode worms and in a group of tiny crustaceans known as copepods. During the embryonic development of copepods, the heterochromatic (transcriptionally inactive) regions of their chromosomes are excised and discarded from all cells except those destined to become gametes. In this way, up to half of the organism's total DNA content is removed from its body cells.

DNA Rearrangements Can Alter the Genome

A few cases are known in which gene regulation is based on the movement of DNA segments from one location to another within the genome, a process known as **DNA rearrangement**. Two particularly interesting examples involve the mechanism used by yeast cells to control mating and the mechanism used by vertebrates to produce millions of different antibodies.

Yeast Mating-Type Rearrangements. In the yeast *Saccharomyces cerevisiae*, mating occurs when haploid cells of two different mating types, called *α* and *a*, fuse together to form a diploid cell (see Figure 14-18). All haploid cells carry both alleles for mating type; however, a cell's actual mating phenotype depends on which of the two alleles, *α* or *a*, is present at a special site in the genome called the ***MAT* locus**. Cells frequently switch mating type, presumably to maximize opportunities for mating. They do so by moving the alternative allele into the *MAT* locus. This process of DNA rearrangement is called the **cassette mechanism** because the mating-type locus is like a tape deck into which either the *α* or the *a* “cassette” (allele) can be inserted and “played” (transcribed).

Figure 23-11 describes the yeast cassette mechanism in more detail. The *MAT* locus, containing either the *α* or *a* allele, is located on yeast chromosome 3, approximately midway between extra copies of the two alleles. The locus that stores the extra copy of the *α* allele is called *HMLα*, and the locus with the extra copy of the *a* allele is called *HMRa*. To switch mating type, an endonuclease, called *HO endonuclease*, creates a break in the chromo-

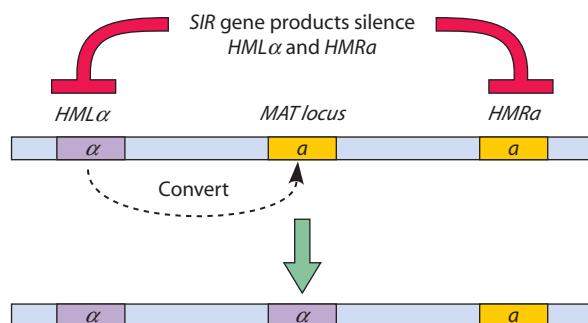

FIGURE 23-11 Cassette Mechanism of the Yeast Mating-Type Switch. Chromosome 3 of *Saccharomyces cerevisiae* contains three copies of the mating-type information. The *HMLα* and *HMRa* loci contain complete copies of the *α* and *a* forms of the gene, respectively, but the transcription of these loci is inhibited by the products of the *SIR* gene. The cell's actual mating type is determined by the allele present at the *MAT* locus. When a cell switches mating types, the *α* or *a* DNA at the *MAT* locus is removed and replaced by a DNA copy of the alternative mating-type DNA. As an example, this figure illustrates a switch in mating type from *a* to *α*.

some at the *MAT* locus. Exonucleases then act on the cut DNA to degrade it. The *HMLα* or *HMRa* DNA is used as the template to repair the resulting gap in the DNA, which results in a gene conversion event at the *MAT* locus that switches the mating type allele found there (we discussed gene conversion in Chapter 20).

The DNAs of the two mating-type alleles code for transcription factors that control the expression of genes whose protein products give the cell either an “*α*” or an “*a*” mating phenotype. But the presence of extra copies of the alleles at *HMLα* and *HMRa* raises an important question: If the cell contains complete copies of *both* the *α* and the *a* alleles at these locations, why aren't proteins specifying both the *α* and the *a* mating phenotypes made? The answer is that a group of regulatory genes, known as the *silent information regulator (SIR) genes*, act together to prevent expression of the genetic information at *HMLα* and *HMRa*. The proteins encoded by the *SIR* genes block transcription of *HMLα* and *HMRa* by binding to specific DNA sequences that surround the *α* and *a* DNA cassettes at *HMLα* and *HMRa*.

Antibody Gene Rearrangements. A somewhat different type of DNA rearrangement is used by lymphocytes of the vertebrate immune system for producing antibody molecules. Antibodies are proteins composed of two kinds of polypeptide subunits, called *heavy chains* and *light chains*. Vertebrates make millions of different kinds of antibodies, each produced by a different lymphocyte (and its descendants) and each capable of specifically recognizing and binding to a different foreign molecule. But this enormous diversity of antibody molecules creates a potential problem: If every antibody molecule were to be encoded by a different gene, virtually all of a person's DNA would be occupied by the millions of required antibody genes.

Lymphocytes get around this problem by starting with a relatively small number of different DNA segments

and rearranging them in various combinations to produce millions of unique antibody genes, each one formed in a different, developing lymphocyte. The rearrangement process involves four kinds of DNA sequences, called *V*, *J*, *D*, and *C* segments. The *C* segment codes for a heavy or light chain *constant region* whose amino acid sequence is the same among different antibodies. The *V*, *J*, and *D* segments together code for *variable regions* that differ among antibodies and give each one the ability to recognize and bind to a specific type of foreign molecule.

To see how this works, let's consider human antibody heavy chains, which are constructed from roughly 200 kinds of *V* segments, more than 20 kinds of *D* segments, and at least 6 kinds of *J* segments. As shown in **Figure 23–12**, the DNA regions containing the various *V*, *D*, and *J* segments are rearranged during lymphocyte development to randomly bring together one *V*, one *D*, and one *J* segment in each lymphocyte. This random rearrangement allows the immune system to create at least $200 \times 20 \times 6 = 24,000$ different kinds of heavy chain variable regions. In a similar fashion, thousands of different kinds of light chain variable regions can also be created (light chains are constructed from their own types of *V*, *J*, and *C* segments; they do not use *D* segments). Finally, any one of the thousands of different kinds of heavy chains can be assembled with any one of the thousands of different kinds of light chains, creating the possibility of millions of different types of antibodies. The net result is that millions of different antibodies are produced from the human genome by rearranging a few hundred different kinds of *V*, *D*, *J*, and *C* segments.

The DNA rearrangement process that creates antibody genes also activates transcription of these genes via a mechanism involving special DNA sequences called *enhancers*. As we will discuss shortly, enhancers increase the rate of transcription initiation. Enhancers are located near DNA sequences coding for *C* segments, but a promoter sequence is not present in this area so transcription does not normally occur. The promoter for gene transcription is located upstream from the DNA coding for *V* segments, but it is not efficient enough to promote transcription in the absence of an enhancer sequence. Hence, prior to DNA rearrangement, the promoter and enhancer sequences of an antibody gene are so far apart that transcription does not occur. Only after rearrangement are they close enough for transcription to be activated.

Chromosome Puffs Provide Visual Evidence That Chromatin Decondensation Is Involved in Genomic Control

We encounter another aspect of genome-level control when we consider what is involved in making the eukaryotic genome—that is, chromosomal DNA—accessible to the cell's transcription machinery. Recall from Chapter 21 that, to initiate transcription, a eukaryotic RNA polymerase must interact with both DNA and a number of specific proteins (general transcription factors) in the promoter region of a

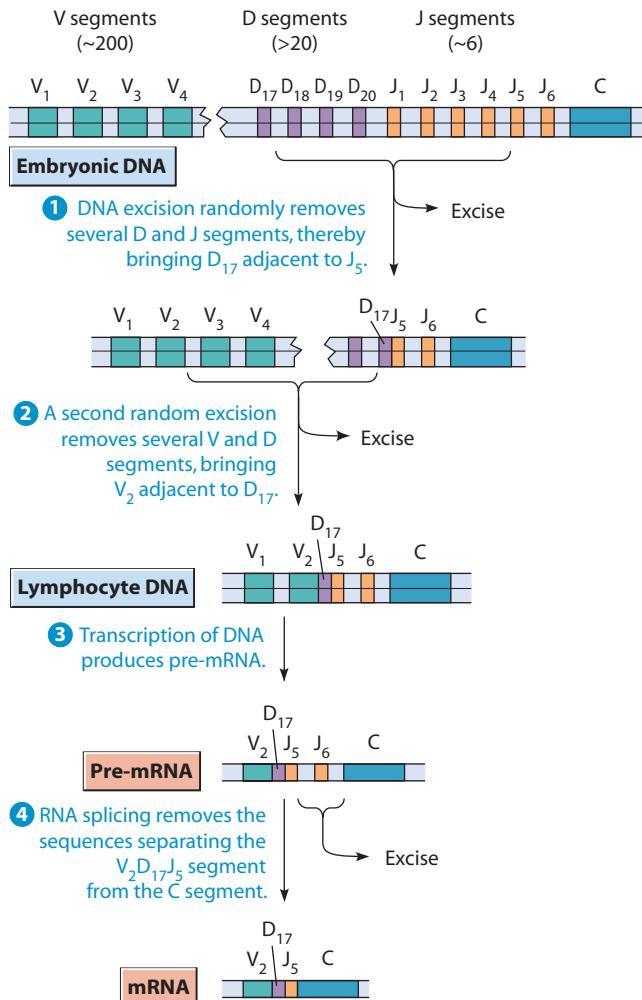

FIGURE 23–12 DNA Rearrangement During the Formation of Antibody Heavy Chains. Genes coding for human antibody heavy chains are created by DNA rearrangements that involve multiple types of *V*, *D*, and *J* segments. In this example, random DNA excisions bring together a unique combination of *V*, *D*, and *J* segments. After transcription, RNA splicing removes the RNA sequences that separate this *VDJ* segment from the *C* segment.

gene. Except when a gene is being transcribed, its promoter region is embedded within a highly folded and ordered chromatin superstructure. Thus, some degree of chromatin decondensation (unfolding) appears to be necessary for the expression of eukaryotic genes.

The earliest evidence that chromatin decondensation is required for gene transcription came from microscopic visualization of certain types of insect chromosomes caught in the act of transcription. Because the DNA of most eukaryotic cells is dispersed throughout the nucleus as a mass of intertwined chromatin fibers, it is usually difficult to observe the transcription of individual genes with a microscope. But a way around this obstacle is provided by an unusual type of insect cell. In the fruit fly *Drosophila melanogaster* and related insects, some metabolically active tissues (such as the salivary glands and intestines) grow by an enormous increase in the size of,

rather than the number of, their constituent cells. The development of giant cells is accompanied by successive rounds of DNA replication, but, because this replication occurs in cells that are not dividing, the newly synthesized chromatids accumulate in each nucleus and line up in parallel to form multistranded structures called **polytene chromosomes**. Each polytene chromosome contains the multiple chromatids generated during replication of both members of each homologous chromosome pair. The four giant polytene chromosomes found in the salivary glands of *Drosophila* larvae, for example, are generated by ten rounds of chromosome replication.

Polytene chromosomes are enormous structures measuring hundreds of micrometers in length and several micrometers in width—roughly ten times longer and a hundred times wider than the metaphase chromosomes of typical eukaryotic cells. The micrograph in **Figure 23-13** shows a polytene chromosome. Visible in each polytene chromosome is a characteristic pattern of dark bands. Each band represents a chromatin domain that is highly condensed compared with the chromatin in the “inter-band” regions between the bands. Activation of the genes of a given chromosome band causes the compacted chromatin strands to uncoil and expand outward, resulting in a **chromosome puff**. Such puffs consist of DNA loops that are less condensed than the DNA of bands elsewhere in the chromosome. Though puffs are not the only sites of gene transcription along the polytene chromosome, the extent of chromosome decondensation at puffs correlates well with the enhancement of transcriptional activity at these sites. That puffs are indeed sites of active transcription is confirmed by the fact that puffs are sites where RNA polymerase II, the key enzyme that carries out polymerization of protein-coding RNAs, accumulates.

As the *Drosophila* larva proceeds through development, each of the polytene chromosomes in salivary gland

nuclei undergoes reproducible changes in puffing patterns under the control of an insect steroid hormone called *ecdysone*. Ecdysone functions by binding to, and thus activating, a regulatory protein that stimulates the transcription of certain genes. (This is similar to the action of vertebrate steroid hormones, which we cover later in the chapter.) It appears, in other words, that the characteristic puffing patterns seen during the development of *Drosophila* larvae are direct visual manifestations of the selective decondensation and transcription of specific DNA segments according to a genetically determined developmental program.

DNase I Sensitivity Provides Further Evidence for the Role of Chromatin Decondensation in Genomic Control

The absence of polytene chromosomes in most eukaryotic cells makes it difficult to visualize chromatin decondensation in regions of active genes. Nonetheless, other kinds of evidence support the idea that chromatin decondensation is generally associated with gene transcription. One particularly useful research tool is *DNase I*, an endonuclease isolated from the pancreas. In test tube experiments, low concentrations of DNase I preferentially degrade transcriptionally active DNA in chromatin. The increased sensitivity of these DNA regions to degradation by DNase I provides evidence that the DNA is uncoiled.

Figure 23-14 illustrates a classic DNase I sensitivity experiment focusing on the chicken gene for a globin polypeptide, one of the polypeptide subunits of hemoglobin. The globin gene is actively expressed in the nuclei of chicken *erythrocytes* (red blood cells). In contrast to the erythrocytes of many other vertebrates, avian erythrocytes retain their nucleus at maturity. If these nuclei are isolated and the chromatin is digested with DNase I, the globin gene is completely digested at low DNase I concentrations that do not affect the globin gene in other tissues, such as oviduct tissue. As you might predict, a gene that is not active in erythrocytes (for example, the gene for ovalbumin, an egg white protein) is not digested by DNase I. The opposite result is obtained when the same procedure is carried out using chromatin isolated from the oviduct, where the ovalbumin gene is expressed and the globin gene is inactive. In this case, the ovalbumin gene is more sensitive than the globin gene to DNase I digestion. Such data demonstrate that transcription of eukaryotic DNA is correlated with an increased sensitivity to DNase I digestion.

The results of these experiments are compatible with two alternative explanations: Either chromatin uncoiling is necessary to give transcription factors and RNA polymerase access to DNA, or the binding of these proteins to DNA causes the uncoiling. This issue has been resolved by studies showing that sensitivity to DNase I is detected in genes that are being actively transcribed, in genes that have recently been transcribed but are no longer active, and in DNA sequences located adjacent to genes of the preceding two types. Such observations suggest that

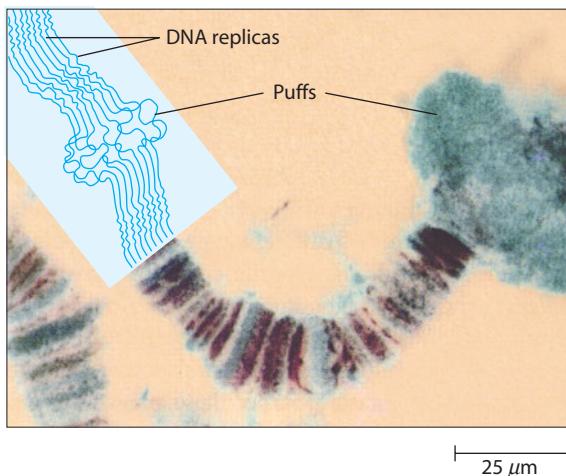

FIGURE 23-13 Puffs in Polytenic Chromosomes. Puffs are regions in which transcriptionally active chromatin has become less condensed, as indicated diagrammatically. The light micrograph shows part of a polytenic chromosome.

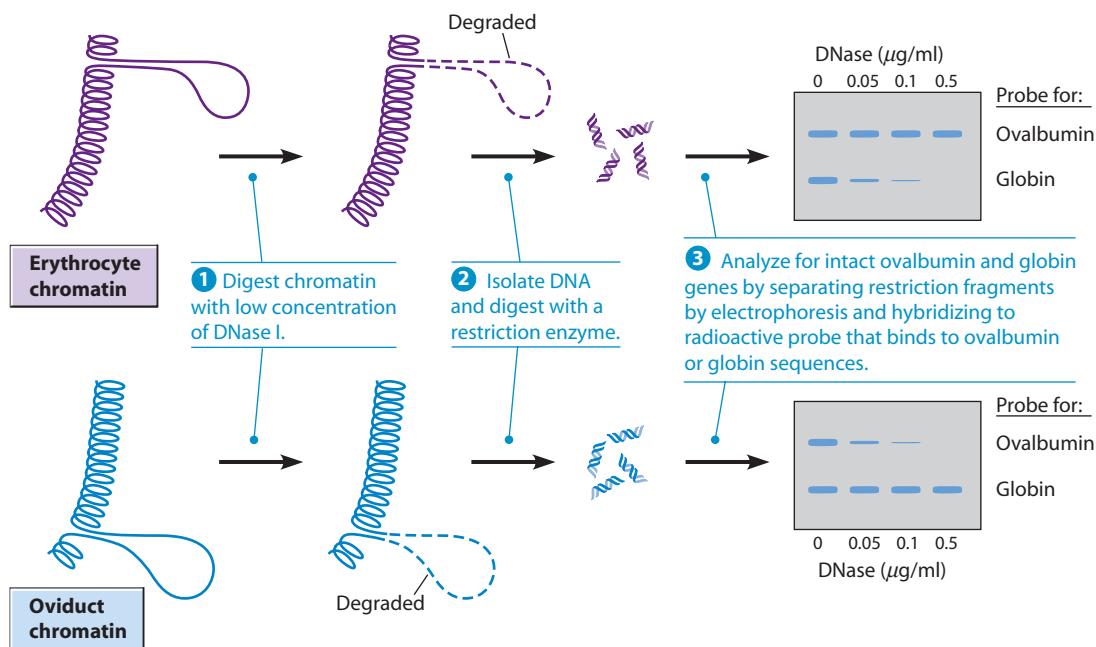

FIGURE 23-14 Sensitivity of Active Genes in Chromatin to Digestion with DNase I. The chromatin configuration of active genes can be studied by exposing cell nuclei to DNase I, which digests DNA by cutting internal phosphodiester bonds. DNA in condensed chromatin is protected from DNase I attack because it is highly coiled and condensed. The experiment shown here uses chromatin from two different cell types, chicken erythrocytes and oviduct cells, and focuses on genes for globin and ovalbumin, which are expressed in erythrocytes and oviduct cells, respectively. Digesting chromatin with a low concentration of DNase I preferentially digests the DNA in uncoiled regions (1). The DNA is then purified and digested with a restriction enzyme (2) that releases DNA fragments containing an intact globin or ovalbumin gene (if it has not been nicked by DNase I). The presence of such restriction fragments is detected in step 3 by separating the DNA using electrophoresis, transferring the separated fragments to filter paper (a Southern blot), and hybridizing with radioactive DNA probes for the globin and ovalbumin genes. Note that DNA isolated from erythrocyte chromatin treated with increasing amounts of DNase I contains progressively smaller amounts of intact globin gene, and comparable results are obtained for the ovalbumin gene in oviduct chromatin. In contrast, even high concentrations of DNase I have no effect on the globin gene in oviduct chromatin or on the ovalbumin gene in erythrocyte chromatin. In other words, genes are more susceptible to DNase I attack in tissues where they are actively transcribed.

DNase I sensitivity is not caused by the process of gene transcription itself, but instead reflects an altered chromatin structure in regions associated with active or potentially active genes. Presumably this means that chromatin uncoiling is a prerequisite for—rather than a consequence of—transcriptional activation.

DNase I has also been employed in other kinds of experiments. When nuclei are treated with very low concentrations of DNase I, it is possible to detect specific locations in the chromatin that are exceedingly susceptible to digestion. These **DNase I hypersensitive sites** tend to occur up to a few hundred bases upstream from the transcriptional start sites of active genes. Compared to the bulk of the DNA found in active genes, the DNase I hypersensitive sites are about ten times more sensitive to DNase I digestion. These regions appear to correspond to regions in which the DNA is not part of a nucleosome. The idea that DNase I hypersensitive sites may represent regions that are free of nucleosomes first emerged from studies involving the eukaryotic virus SV40. When the SV40 virus infects a host cell, its circular DNA molecule becomes associated with histones and forms typical nucleosomes

that can be observed with an electron microscope. However, a small region of the viral DNA remains completely uncoiled and free of nucleosomes (Figure 23-15). This region, which includes several DNase I hypersensitive sites, contains DNA sequences that bind regulatory proteins involved in activating transcription.

DNA Methylation Is Associated with Inactive Regions of the Genome

Another way of regulating the availability of specific regions of the genome is through **DNA methylation**, the addition of methyl groups to selected cytosine bases in DNA. The DNA of most vertebrates contains small amounts of methylated cytosine, which tend to cluster near the 5' ends of genes where promoter sequences are located. Methylation of promoter regions can either block access of proteins required for transcriptional activation or serve as a binding site for proteins that condense chromatin into inactive configurations. The net effect is either a localized or regional silencing of gene expression.

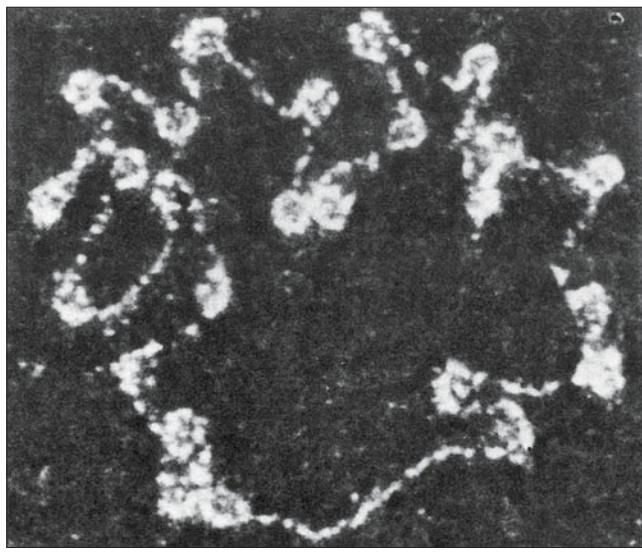

FIGURE 23-15 Circular DNA Molecule of an SV40 Virus from an Infected Host Cell. In this high-power electron micrograph of an SV40 DNA molecule, the bracketed region of the DNA lacks nucleosomes. This region corresponds to the location of several DNase I hypersensitive sites (TEM).

The enzyme responsible for DNA methylation acts preferentially on cytosines situated in 5'-CG-3' sequences that are base-paired to complementary 3'-GC-5' sequences that are themselves already methylated. In other words, if the old DNA strand in a newly replicated DNA double helix has a methylated 5'-CG-3' sequence, then the complementary 3'-GC-5' sequence in the new strand will become a target for methylation. This phenomenon allows DNA methylation patterns to be inherited during successive rounds of DNA replication. The net result is that DNA methylation provides a means for creating **epigenetic changes**—that is, stable alterations in gene expression that are transmitted from one cellular generation to the next without requiring changes in a gene's underlying base sequence.

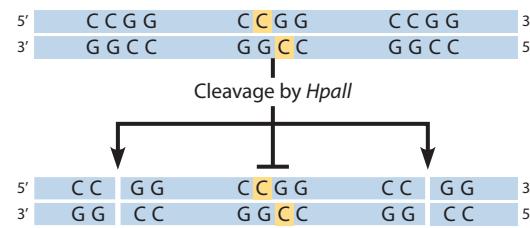

A striking example involves the X chromosomes of female mammals, which inherit an X chromosome from each of their two parents. Because males have only one X chromosome, a potential imbalance exists in the expression of X-linked genes between males and females. Nature's solution to the problem is to randomly inactivate one of the two X chromosomes in females during early embryonic development. During this process of *X-inactivation*, the DNA of one X chromosome becomes extensively methylated, the chromatin fibers condense into a tight mass of heterochromatin whose DNA is less accessible to transcription factors and RNA polymerase, and gene transcription ceases. When interphase cells are examined under a microscope, the inactivated X chromosome is visible as a dark spot called a *Barr body*. Once a given X chromosome has been inactivated in a particular cell, the same X chromosome remains inactivated in all of the cells produced by

succeeding cell divisions. As a result females, like males, contain only one active X chromosome per adult cell.

Additional evidence suggesting that DNA methylation can inhibit gene activity has come from studies using the restriction enzymes *MspI* and *HpaII*. Both of these enzymes cleave the recognition site –CCGG–. However, *HpaII* works only if the central C is unmethylated, whereas *MspI* cuts whether the C is methylated or not (**Figure 23-16**). Comparing the DNA fragments generated by these two enzymes has revealed that certain DNA sites are methylated in a tissue-specific fashion—that is, the sites are methylated in some tissues but not in others. In general such sites are methylated in tissues where the gene is inactive, but they are unmethylated in tissues where the gene is active or potentially active. For example, CG sequences located near the promoter region of the globin gene are methylated in tissues that do not produce hemoglobin but are unmethylated in red blood cells.

The pervasive importance of DNA methylation is made clear by the discovery that a growing number of human diseases, including cancer, are associated with abnormalities in DNA methylation. DNA methylation also plays a role in genomic **imprinting**—a process that causes certain genes to be expressed differently depending on whether they are inherited from a person's mother or father. For example, some imprinted genes are expressed in the copy inherited from the mother and silenced in the copy inherited from the

(a) *HpaII* cuts DNA at CCGG sequences but is blocked when the second C is methylated, producing one long fragment of DNA.

(b) *MspI* cuts DNA at all CCGG sequences, producing two fragments of DNA.

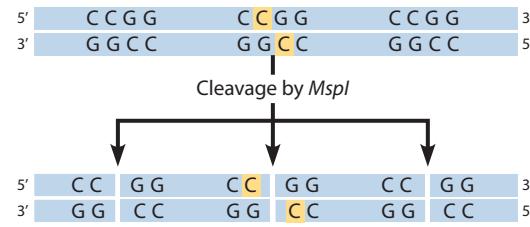

FIGURE 23-16 Differences in DNA Methylation Detected Using Enzymatic Digestion.

Both *HpaII* and *MspI* cut DNA at CCGG sequences, but *HpaII* will not cut if the second C is methylated (yellow). (a) When the DNA shown is cut with *HpaII*, a long fragment is generated that can be detected using a Southern blot (see Box 18C). (b) When the same DNA is cut with *MspI*, two shorter fragments from the same region are produced.

father. This differing behavior stems from differing methylation patterns: The promoter region of the inherited paternal copy is extensively methylated, whereas the same region in the inherited maternal copy is not. (Imprinting also works in the opposite way—the maternal copy rather than the paternal copy of some genes is inactivated by methylation.) Some diseases result from deletions in specific imprinted genes. One well understood example involves deletions in the same region of human chromosome 15, which contains imprinted genes. *Prader-Willi syndrome* is characterized by deletion of paternal genes in this region and is characterized by mild mental retardation, compulsive eating and obesity, and defects in gonad development. Conversely, *Angelman syndrome* results when a gene in this region on the maternal chromosome is deleted. Angelman syndrome patients exhibit frequent laughter and smiling, as well as hand flapping movements.

Inheritance is not the only factor that influences DNA methylation patterns: Studies involving identical twins have revealed that environment plays a role as well. Identical twins exhibit DNA methylation patterns that are virtually indistinguishable when the twins are young, but significant differences emerge as twins grow older. The greatest differences in DNA methylation, and in the pattern of genes being expressed, are seen in twins who spend large amounts of time apart, suggesting that environmental factors influence DNA methylation and, in turn, gene expression.

Changes in Histones and Chromatin Remodeling Proteins Can Alter Genome Activity

DNA methylation is not the only type of genomic alteration involved in epigenetic control. Another mechanism involves changes in histones, the proteins whose role in the packaging of chromosomal DNA was described in Chapter 18. Each histone molecule has a protruding tail that can be tagged at various locations by the addition of methyl, acetyl, or phosphate groups. Various combinations of these tags create a **histone code** that is read by other proteins as a set of signals for modifying chromatin structure and gene activity.

One type of tagging reaction involves *methylation* of the amino acid lysine, which can serve as a signal for either the activation or repression of gene expression, depending on the particular lysine and class of histone involved. For example, methylation at lysine 4 in histone H3 is a hallmark of most active genes, whereas methylation of lysines 9 and 27 is associated with gene silencing. In certain cases, methylation of lysine 27 leads to the recruitment and activation of enzymes that methylate the adjoining DNA, thereby coupling two epigenetic alterations involved in gene silencing.

Another mechanism for altering histone structure is through *acetylation*—the addition of acetyl groups to amino acid side chains. In particular, the enzyme **histone acetyltransferase (HAT)** adds acetyl groups to histone molecules and thereby promotes chromatin decondensa-

tion. Another enzyme, **histone deacetylase (HDAC)**, performs the opposite function, removing acetyl groups from histones. Regulatory proteins that bind DNA can recruit complexes that contain these enzymes, thereby changing the availability of a region of DNA for transcription. **Repressor** proteins, which cause transcription to occur less frequently at a particular site, recruit HDAC complexes, and **activator** proteins recruit HAT complexes (**Figure 23-17a**; we will discuss transcriptional activators and repressors in more detail later in this chapter). Evidence that acetylated histones are preferentially associated with active genes has been provided by studies in which chromatin was incubated with DNase I to selectively degrade

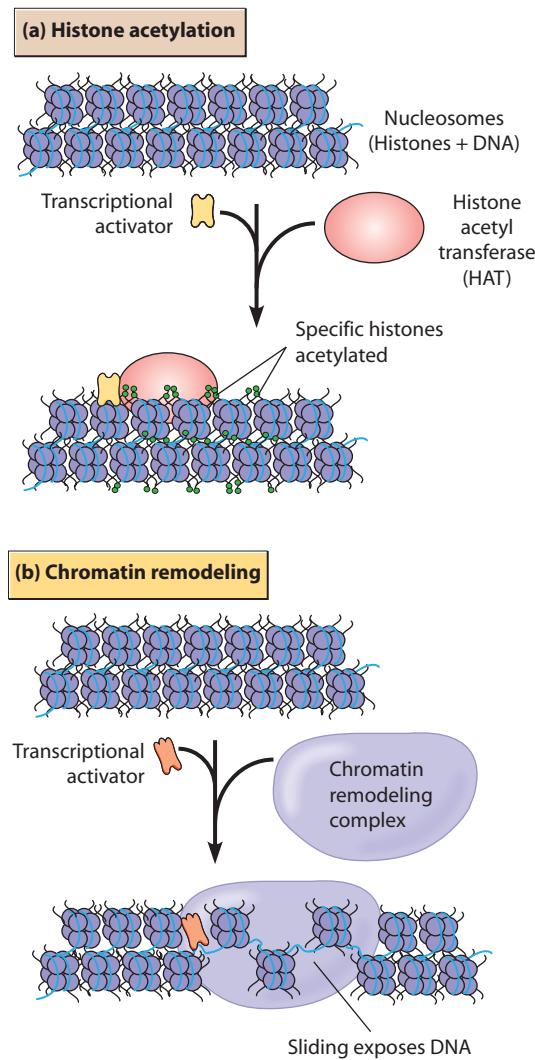

FIGURE 23-17 Roles of Histone Acetylation and Chromatin Remodeling Proteins during Transcriptional Activation.

(a) Transcriptional activator proteins recruit histone acetyltransferase (HAT) complexes to the region near a gene. These enzymes then add acetyl groups, which leads to the opening or closing of the chromatin structure in the region. **(b)** Chromatin remodeling proteins can have several effects on nucleosomes. In the case shown here, a chromatin remodeling protein causes sliding of nucleosomes, exposing a region of DNA that could then be transcribed.

genes that are transcriptionally active. Such treatment causes the release of the acetylated form of histones H3 and H4, suggesting that acetylation of these histones is associated with gene activation. Such acetylation-induced changes in nucleosome structure are thought to loosen chromatin packing and thereby facilitate the access of transcription factors to gene promoters.

Yet another way in which histones affect chromatin structure and gene activity is suggested by studies showing that transcriptionally active chromatin often lacks histone H1. Since histone H1 is required for folding chromatin into 30-nm chromatin fibers (Figure 18-22b), the absence of histone H1 may help to maintain active chromatin in the form of uncoiled 10-nm fibers. A related feature of transcriptionally active chromatin is its large content of *high-mobility group (HMG) proteins*, a group of nonhistone proteins whose name reflects their rapid mobility during electrophoresis. When HMG proteins are removed from a preparation of isolated chromatin, the active genes lose their sensitivity to DNase I. If certain HMG proteins are then isolated from another tissue and added to the HMG-depleted chromatin, the pattern of DNase I sensitive genes is found to resemble the tissue from which the chromatin, not the HMG proteins, was obtained. This means that chromatin exhibits tissue-specific properties that are recognized by HMG proteins, allowing them to bind selectively to genes that are capable of being activated in any given tissue. Binding of HMG is thought to impart DNase I sensitivity by helping uncoil chromatin fibers into a more open configuration, perhaps by displacing histone H1 from the 30-nm fiber.

In addition to modifications of the histones within nucleosomes, other proteins alter the position of nucleosomes along DNA. These **chromatin remodeling proteins** couple ATP hydrolysis to changes in the organization and position of nucleosomes along DNA (Figure 23-17b). One important class of remodelers are the **SWI/SNF** family. These proteins are thought to slide nucleosomes or cause them to be ejected from a region of chromatin, making regions of DNA more accessible to the transcriptional machinery. Recall that histone acetylation is positively correlated with gene activity. SWI/SNF remodelers have domains that bind the acetylated tails of histone proteins, coupling changes in histones and chromatin remodeling.

Eukaryotic Gene Regulation: Transcriptional Control

We have now described some common regulatory changes in the composition and structure of the genome. However, the existence of structural changes associated with active regions of the genome does not address the underlying question of how the DNA sequences contained in these regions are actually selected for activation. The answer is to be found in the phenomenon of **transcriptional control**, the second main level for controlling eukaryotic gene expression (see Figure 23-10).

Different Sets of Genes Are Transcribed in Different Cell Types

When we consider transcriptional control, we come to a level of gene regulation where knowledge has blossomed in recent years. The first direct evidence for the importance of transcriptional regulation in eukaryotes came from experiments comparing newly synthesized RNA in the nuclei of different mammalian tissues. Liver and brain cells, for example, produce different sets of proteins, although there is considerable overlap between the two sets. How can we determine the source of this difference? If the different proteins produced by the two cell types are a reflection of *differential gene transcription*—that is, transcription of different genes to produce different sets of RNAs—we should see corresponding differences between the populations of nuclear RNAs derived from brain and liver cells. On the other hand, if all genes are equally transcribed in liver and brain, we would find few, if any, differences between the populations of nuclear RNAs from the two tissues, and we would conclude that the tissue-specific differences in protein synthesis were due to posttranscriptional mechanisms that control the ability of various RNAs to be translated.

One way of distinguishing between these alternatives is to use the technique of *nuclear run-on transcription*, which provides a snapshot of the transcriptional activity occurring in a nucleus at a given moment in time (Figure 23-18). Transcriptionally active nuclei are gently isolated from cells and allowed to complete synthesis of RNA molecules in the presence of radioactively labeled nucleoside triphosphates. When such an experiment is performed using liver and brain cells, the newly transcribed (radioactively labeled) RNAs in the liver nuclei contain sequences from liver-specific genes, but these liver-specific sequences are not detected in the labeled RNAs synthesized by isolated brain nuclei. Likewise, the newly transcribed (radioactively labeled) RNAs in the brain nuclei contain sequences from brain-specific genes, but these brain-specific sequences are not detected in the labeled RNAs synthesized by isolated liver nuclei.

By failing to detect the synthesis of RNA from liver-specific genes in brain cell nuclei and vice versa, these experiments indicate that gene expression is being regulated at the transcriptional level. In other words, different cell types transcribe different sets of genes, thereby allowing each cell type to produce those proteins needed for carrying out that cell's specialized functions.

DNA Microarrays Allow the Expression of Thousands of Genes to Be Monitored Simultaneously

Although the preceding kinds of observations reveal that different sets of genes are transcribed in different cell types, they cannot easily identify which individual genes are turned on or off. One method for determining

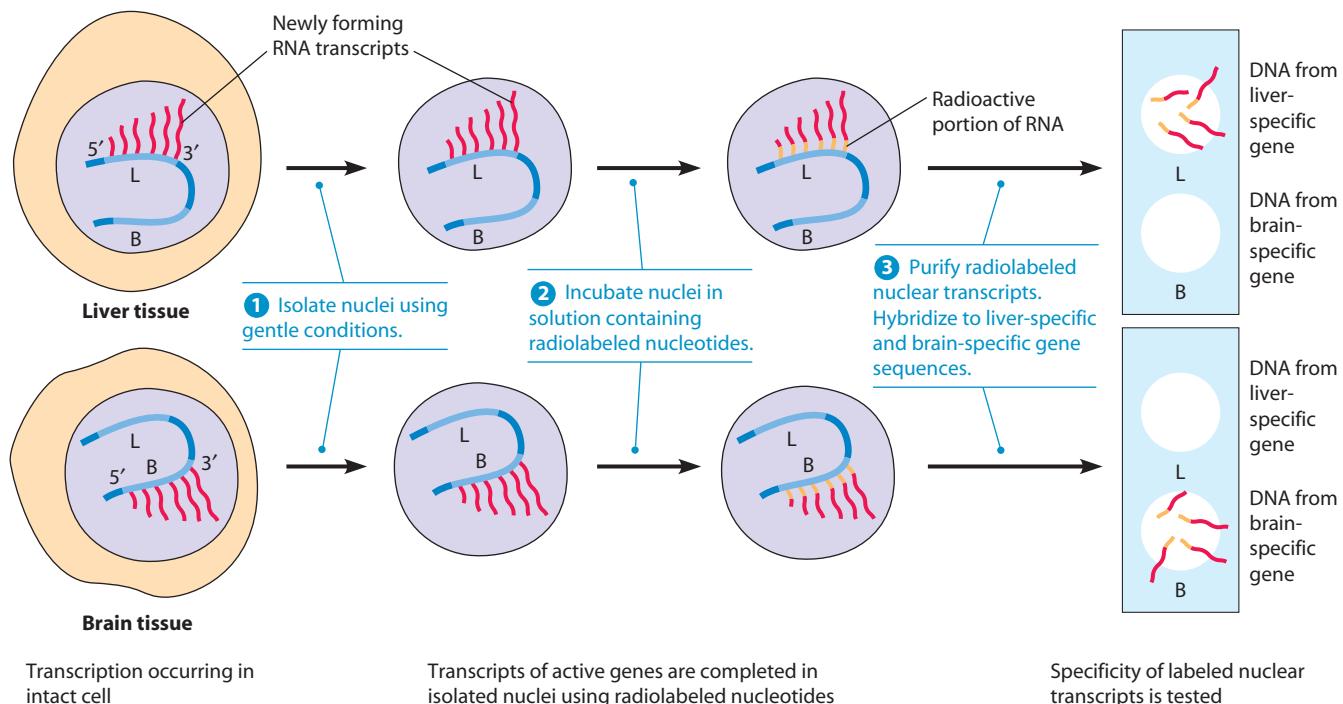

FIGURE 23-18 Demonstration of Differential Transcription by Nuclear Run-on Transcription

Assays. In these studies, B represents a hypothetical gene that is expressed only in brain tissue, and L is a gene expressed only in liver tissue. Isolated nuclei are incubated in a solution containing radioactively labeled ribonucleotides, which become incorporated into the mRNA being synthesized by active genes. If different genes are active in liver and brain tissue, some labeled sequences in the liver nuclear transcripts will not be present in brain transcripts and vice versa. The composition of the labeled RNA population is assayed by allowing the labeled RNA to hybridize with DNA sequences representing different genes that have been attached to a filter-paper support (3). Labeled liver transcripts hybridize with a different set of genes than do labeled brain transcripts, indicating that the identities of the active genes in the two tissues differ.

whether a particular gene is active is to assay for its corresponding mRNA using an RNA detection technique that is somewhat fancifully called **Northern blotting** to contrast it with Southern blotting (a DNA detection technique described in Box 18C). In Northern blotting, an RNA sample is size-fractionated by gel electrophoresis and transferred to a special blotting paper. The paper is then exposed to a radioactive (or otherwise labeled) DNA probe containing the gene sequence of interest, and the amount of mRNA is quantified by measuring the bound radioactivity.

Alternatively, to monitor the expression of hundreds or even thousands of genes simultaneously, a tool known as a **DNA microarray** can be used. A DNA microarray is a thin, fingernail-sized chip made of plastic or glass that has been spotted at fixed locations with thousands of DNA fragments corresponding to various genes of interest. A single microarray may contain 10,000 or more spots, each representing a different gene. To determine which genes are being expressed in any given cell population, RNA molecules (the products of gene transcription) are isolated from the cells and copied with the enzyme reverse transcriptase into single-stranded cDNA molecules, which are then attached to a fluorescent dye. When the DNA microarray is bathed with the fluorescent cDNA, each cDNA molecule

will bind by complementary base pairing to the spot containing the specific gene it was transcribed from.

Figure 23-19 illustrates how this approach can be used to compare the patterns of gene expression in brain and liver cells. In this particular example, two fluorescent dyes are used: a green dye to label cDNAs derived from brain cells and a red dye to label cDNAs derived from liver cells. When the green and red cDNAs are mixed together and placed on a DNA microarray, the green cDNAs will bind to genes expressed in brain cells, and the red cDNAs will bind to genes expressed in liver cells. Green spots therefore represent higher expression of a gene in brain cells, red spots represent higher expression of a gene in liver cells, yellow spots (caused by a mixture of green and red fluorescence) represent genes whose expression is roughly the same, and black spots (absence of fluorescence) represent genes expressed in neither cell type. Consequently, measuring the color and intensity of each fluorescent spot allows the expression of thousands of genes to be monitored simultaneously. Such data have revealed that many genes are selectively expressed in particular cell types, such as brain cells, liver cells, or other differentiated cells.

DNA microarrays also have practical applications. For example, human cancers that appear to be the same disease based on microscopic examination sometimes

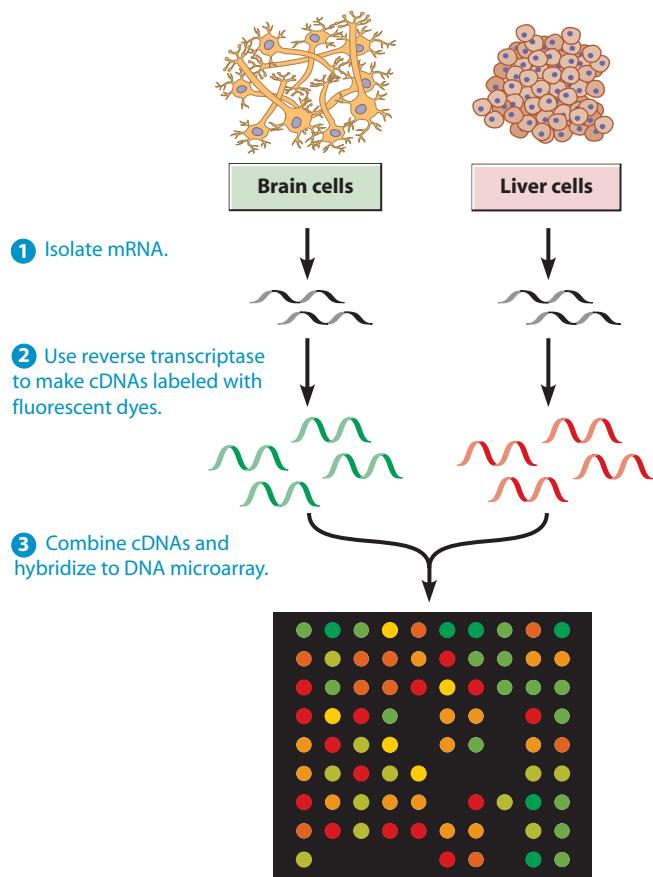

FIGURE 23-19 Using a DNA Microarray for Studying Gene Expression Profiles. In this example, gene expression in brain cells and liver cells is compared by isolating mRNA from the two populations of cells, using reverse transcriptase to make cDNA copies of the mRNAs, and attaching a green fluorescent dye to the brain cell cDNAs and a red fluorescent dye to the liver cell cDNAs. A DNA microarray containing DNA fragments representing thousands of different genes is then bathed with a mixture of the two cDNA populations (only a small section of the DNA microarray is illustrated). Each cDNA hybridizes to the spot containing the specific gene it corresponds to. Green spots therefore represent genes expressed preferentially in brain cells, red spots represent genes expressed preferentially in liver cells, yellow spots (a mixture of green and red fluorescence) represent genes whose expression is similar in the two cell populations, and dark regions (missing spots) represent genes that are not expressed in either cell type.

exhibit different gene expression profiles when tested using DNA microarray technology. Such information allows cancers from different patients to be more accurately characterized, thereby improving the prospects for custom-tailored treatments that are most appropriate for each individual person.

Proximal Control Elements Lie Close to the Promoter

In discussing how gene transcription is regulated in different cell types, we will now focus our attention on protein-coding genes, which are transcribed by RNA polymerase II. As we saw in Chapter 21, the specificity of transcription—that is,

where on the DNA it is initiated—is determined not by RNA polymerase itself, but by proteins called *transcription factors*. (Unlike bacterial sigma factors, which also determine initiation specificity, none of the eukaryotic transcription factors are considered to be an integral part of an RNA polymerase molecule.) The transcription factors discussed in Chapter 21 were *general transcription factors*, which are essential for the transcription of *all* the genes transcribed by a given type of RNA polymerase.

For genes transcribed by RNA polymerase II, the general transcription factors assemble with RNA polymerase at the *core promoter*, a DNA region located in the immediate vicinity of the transcriptional startpoint (see Figure 21-11b). The interaction of general transcription factors and RNA polymerase with the core promoter often initiates transcription at only a low, “basal” rate, so that few transcripts are produced. However, in addition to a core promoter, most protein-coding genes have short DNA sequences farther upstream (and, in some cases, downstream) to which other transcription factors bind, thereby improving the efficiency of the core promoter. If these additional DNA elements are deleted experimentally, the frequency and accuracy of transcription is reduced.

In discussing such regulatory DNA sequences, we will use the term **proximal control elements** to refer to sequences located upstream of the core promoter but within about 100–200 base pairs of it. The number, exact location, and identities of these proximal control elements vary with each gene, but three types are especially common: the *CAAT box*, the *GC box*, and the *octamer* (the first two were discussed in Chapter 21 and are illustrated in Figure 23-20). Transcription factors that selectively bind to one of these, or to other control sequences located outside the core promoter, are called **regulatory transcription factors**. They increase (or sometimes decrease) transcription initiation by interacting with components of the transcription apparatus.

Enhancers and Silencers Are Located at Variable Distances from the Promoter

Proximal control elements, like most bacterial control elements, lie close to the core promoter on its upstream side. A second class of DNA control sequences are located either upstream or downstream from the genes they regulate and often lie far away from the promoter. This second type of control region is called an **enhancer** if it stimulates gene transcription or a **silencer** if it inhibits transcription. Originally, such control sequences were called *distal control elements* because they can function at distances up to several hundred thousand base pairs upstream or downstream from the promoter they regulate (the word *distal* means “away from”). However, the distinctive feature of such sequences is not how far away from the promoter they are located, but the fact that their position relative to the promoter can vary significantly. Their orientation can even be reversed without interfering with their ability to regulate transcription. Thus, enhancers and silencers need

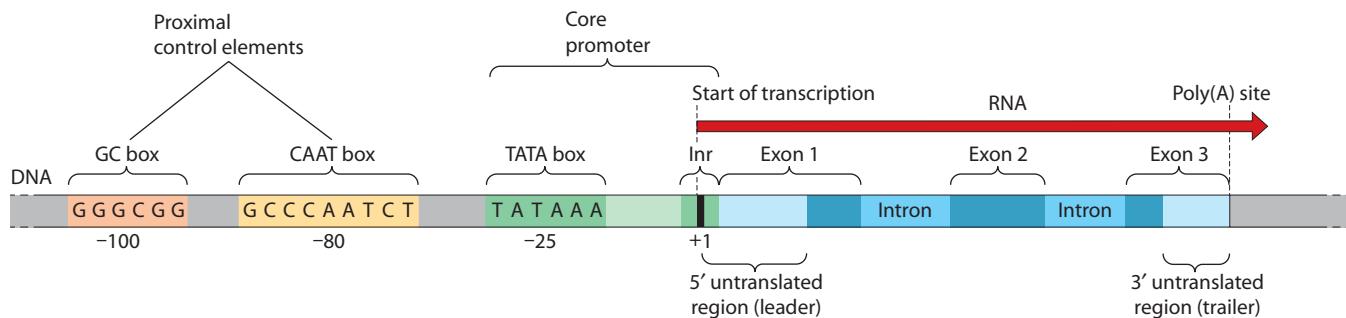

FIGURE 23-20 Anatomy of a Typical Eukaryotic Gene, with Its Core Promoter and Proximal Control Region.

Region. This diagram (not to scale) features a typical protein-coding eukaryotic gene, which is transcribed by RNA polymerase II. The promoter—called the core promoter to distinguish it from the proximal control region—is characterized by an initiator (Inr) sequence surrounding the transcriptional startpoint and a TATA box located about 25 bp upstream (to the 5' side) of the startpoint. The core promoter is where the general transcription factors and RNA polymerase assemble for the initiation of transcription. Within about 100 nucleotides upstream from the core promoter lie several proximal control elements, which stimulate transcription of the gene by interacting with regulatory transcription factors. The number, identity, and exact location of the proximal elements vary from gene to gene. Here we show a simple case involving one copy of each of two common elements, the GC box and the CAAT box. The transcription unit includes a 5' untranslated region (leader) and a 3' untranslated region (trailer), which are transcribed and included in the mRNA but do not contribute sequence information for the protein product. At the end of the last exon is a site where, in the primary transcript, the RNA will be cleaved and given a poly(A) tail.

not be located at great distances from the promoter. They can be located quite close to the promoter and are even found occasionally *within* genes; one example is an enhancer found within an intron of certain antibody genes.

Since enhancers are better understood than silencers, we will consider them first. Enhancers, varying in specific sequence but sharing common properties, are associated with many eukaryotic genes. A typical enhancer contains several different control elements within it, each consisting of a short DNA sequence that serves as a binding site for a different regulatory transcription factor. Some of these DNA

sequences may be identical to proximal control elements; the octamer and the GC box, for instance, can act both as proximal control elements and as components of enhancers. For an enhancer to function, the regulatory transcription factors that bind to its various control elements must be present. Because enhancers are involved in activating transcription, these regulatory transcription factors are called **activators**.

To investigate the properties of enhancers, researchers have used recombinant DNA techniques to alter enhancer location and orientation with respect to the regulated gene. As shown in **Figure 23-21**, such studies reveal that enhancers can function properly when relocated at variable distances from the transcription startpoint, as long as the promoter is present (Figure 23-21a, d–g). When either the promoter or enhancer is removed, no expression occurs (Figure 23-21b, c). Activity is retained when the position of the enhancer is moved further upstream (Figure 23-21e),

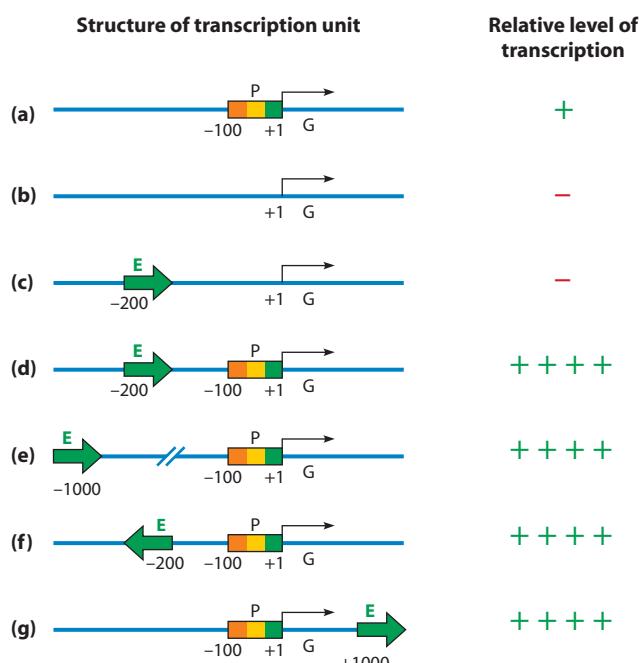

FIGURE 23-21 Effects of Enhancer Orientation and Location. Recombinant DNA techniques have been used to alter the orientation and location of DNA control elements and study the effect of such changes on gene transcription. The black arrows indicate the direction of transcription of gene G, with the startpoint (first transcribed nucleotide) labeled +1. The other numbers give the positions of nucleotides relative to the startpoint. (a) The core promoter (P) alone, in its typical location just upstream of gene G, allows a basal level of transcription to occur. (b) When the core promoter is removed from the gene, no transcription occurs. (c) An enhancer (E) alone cannot substitute for the promoter region, but (d) combining an enhancer with a core promoter results in a significantly higher level of transcription than occurs with the promoter alone. (e) This increase in transcription is observed when the enhancer is moved farther upstream, (f) when it is inverted in orientation, and (g) even when it is moved to the 3' side of the gene.

when its orientation relative to the beginning of the gene is reversed (Figure 23-21f), or when the enhancer is relocated *downstream* of the 3' end of the gene (Figure 23-21g). These properties are often used to distinguish enhancers from proximal control elements, whose precise locations within the DNA tend to be more critical for their function. Nonetheless, as more and more enhancers and proximal control elements have been discovered and investigated, distinctions between these two categories have become less clear-cut, and it now appears that a broad spectrum of transcription control elements exist with overlapping properties. At one extreme are certain proximal control elements that must be precisely located at specific positions near the promoter—in such cases, moving them even 15–20 nucleotides farther from the promoter causes them to lose their influence. At the other extreme are enhancers whose positions can be varied widely, up to tens of thousands of nucleotides away from a promoter, without interfering with their ability to activate transcription.

Silencers share many of the features of enhancers, except that they inhibit rather than activate transcription. Because the binding of regulatory transcription factors to silencers reduces rather than increases gene transcription rates, such transcription factors are called eukaryotic **repressors**. (While they resemble bacterial repressors in turning off transcription, the eukaryotic mechanisms are somewhat different and more varied.) We encountered an example of silencers earlier in the chapter when discussing the yeast *SIR* genes, which produce proteins that inhibit transcription of the *HML α* and *HM $R\alpha$* mating-type genes by binding to DNA sequences surrounding these two genes. The proteins produced by the *SIR* genes are examples of repressors, and the DNA sites these repressors bind to, located near *HML α* and *HM $R\alpha$* , are examples of silencers.

One complication encountered with silencers and enhancers stems from their ability to influence the transcription of faraway genes, which could be problematic if genes with opposing functions reside in neighboring regions. For example, a group of genes active in one cell type might lie near another set of genes that should not be active in those same cells. In such situations, DNA sequences called *insulators* are sometimes employed to prevent an enhancer (or silencer) from inadvertently acting on both groups of genes simultaneously. Insulator sequences, along with their associated binding proteins, create physical barriers between neighboring DNA regions that prevent enhancers or silencers from exerting their effects across the barrier.

Coactivators Mediate the Interaction Between Regulatory Transcription Factors and the RNA Polymerase Complex

Since enhancers and silencers can reside far from the genes they control, you might wonder how regulation is achieved over such long distances. In addressing this issue, we will again focus on enhancers (silencers appear

to behave in a related fashion). Two basic principles govern the interaction between enhancers and the genes they regulate. First, looping of the DNA molecule can bring an enhancer into close proximity with a promoter, even though the two lie far apart in terms of linear distance along the DNA double helix. And second, a diverse group of **coactivator** proteins mediate the interaction between activators bound to the enhancer and the RNA polymerase complex associated with the promoter.

Several types of coactivators play roles in these interactions, including chromatin remodeling proteins and enzymes that modify histones, which we have seen are important for altering chromatin structure. In addition, a large multiprotein complex called **Mediator** functions as a coactivator by serving as a “bridge” that binds to activator proteins associated with the enhancer and to RNA polymerase, thereby linking enhancers to the components involved in initiating transcription at RNA polymerase II promoters. Mediator serves as a central coordinating unit for gene regulation, receiving both positive and negative inputs and transmitting the information to the transcription machinery.

Figure 23-22 shows how such interactions can trigger gene activation. In step ①, a group of activator proteins bind to their respective DNA control elements within the enhancer, forming a multiprotein complex called an *enhanceosome*. One or more of these activator proteins causes the DNA to bend, creating a DNA loop that brings the enhancer close to the core promoter. In step ②, the activators interact with coactivators such as chromatin remodeling proteins (SWI/SNF) and histone acetyltransferase (HAT), which alter chromatin structure to make the DNA in the promoter region more accessible. Finally, the activators bind to Mediator (step ③), which facilitates the correct positioning of RNA polymerase and the general transcription factors at the promoter site and thus allows transcription to begin.

The sequence of events and the particular set of components involved in the preceding example represent a general model whose details vary among different genes and regulatory proteins. But these details are less important than the main idea: When activator proteins for a particular gene are present in the cell, their binding to an enhancer can trigger interactions with various coactivators that in turn lead to formation of the transcription complex at the promoter, resulting in more efficient initiation of transcription. Thus, differential gene transcription within a cell is determined mainly by the activators a cell makes (as well as by factors that control the activity of the activators, a topic we will discuss shortly).

Multiple DNA Control Elements and Transcription Factors Act in Combination

The realization that multiple DNA control elements and their regulatory transcription factors are involved in controlling eukaryotic gene transcription has led to a

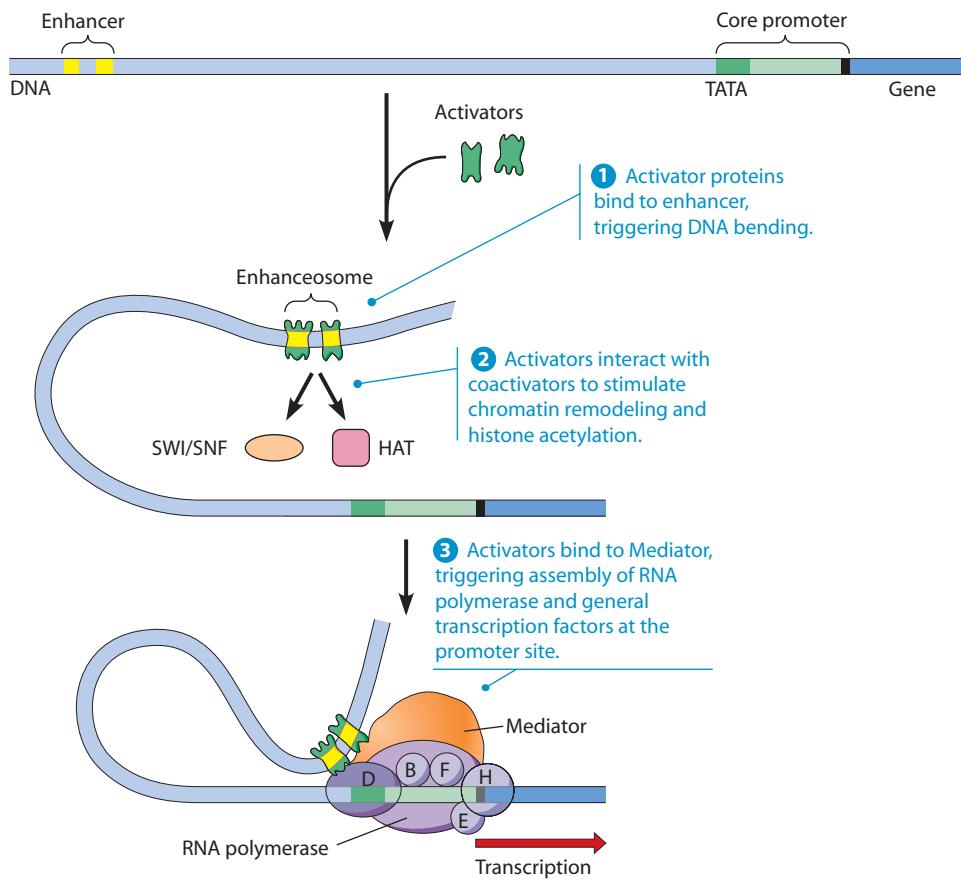

FIGURE 23-22 A Model for Enhancer Action. In this model, an enhancer located at a great distance along the DNA from the protein-coding gene it regulates is brought close to the core promoter by a looping of the DNA. ① Regulatory transcription factors called activators first bind to the enhancer elements, triggering DNA bending that brings the activators closer to the core promoter. ② The activators then interact with coactivator proteins such as SWI/SNF, which causes chromatin remodeling, and HAT (histone acetyltransferase), which catalyzes histone acetylation. The net effect is to decondense the chromatin and make the DNA in the promoter region more accessible. ③ The activators then bind to another coactivator called Mediator, and the activator-Mediator complex facilitates the correct positioning of general transcription factors and RNA polymerase at the promoter site, allowing transcription to be initiated. For simplicity, the figure is drawn with only two activators, but often half a dozen or more are involved.

combinatorial model for gene regulation. This model proposes that a relatively small number of different DNA control elements and transcription factors, acting in different combinations, can establish highly specific and precisely controlled patterns of gene expression in different cell types.

The model begins with the assumption that some transcription factors are present in many cell types. These include the general transcription factors, required for transcription in all cells, plus any regulatory factors needed for transcribing constitutive genes and other genes that are frequently expressed. In addition, transcription of genes that encode tissue-specific proteins requires the presence of transcription factors or *combinations* of transcription factors that are unique to individual cell types. To illustrate this concept, **Figure 23-23** shows how such a model would allow liver cells to produce large amounts of proteins such as albumin but would prevent significant production of these proteins in other tissues, such as

brain. The original version of the combinatorial model was “all or none,” proposing that transcription of a gene could not be initiated unless the entire set of regulatory factors for the gene was present. What now seems clear is that a wide range of efficiencies of transcriptional initiation is possible for most genes: a basal level, occurring when *no* regulatory factors are available, to a maximum level, which occurs only when the full set of activating regulatory factors is present.

Several Common Structural Motifs Allow Regulatory Transcription Factors to Bind to DNA and Activate Transcription

Although not all transcription factors bind directly to DNA, those that do play critical roles in controlling transcription. Proteins in this category include the general transcription factor TFIID and, more importantly, the wide variety of regulatory transcription factors (activators

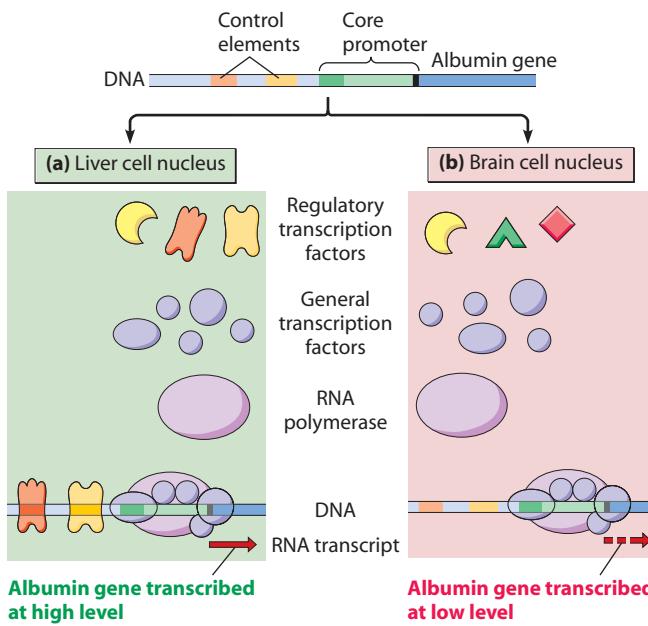

FIGURE 23-23 A Combinatorial Model for Gene Expression.

The gene for the protein albumin, like other genes, is associated with an array of regulatory DNA elements. Here we show only two control elements, as well as the core promoter. Cells of all tissues contain RNA polymerase and the general transcription factors, but the set of regulatory transcription factors available varies with the cell type. As shown here, (a) liver cells contain a set of regulatory transcription factors that includes the factors for recognizing all the albumin gene control elements. When these factors bind to DNA, they facilitate transcription of the albumin gene at a high level. (b) Brain cells, however, have a different set of regulatory transcription factors that does not include all those for the albumin gene. Consequently, in brain cells, the transcriptional complex can assemble at the promoter but not very efficiently. The result is that brain cells transcribe the albumin gene only at a low level.

and repressors) that recognize and bind to specific DNA sequences found in proximal control elements, enhancers, and silencers. What features of these regulatory transcription factors enable them to carry out their functions?

Regulatory transcription factors possess two distinct activities, the ability to bind to a specific DNA sequence and the ability to regulate transcription. The two activities reside in separate protein domains. The domain that recognizes and binds to a specific DNA sequence is called the transcription factor's **DNA-binding domain**, whereas the protein region required for regulating transcription is known as the **transcription regulation domain** (or **activation domain** because many transcription factors activate, rather than inhibit, transcription). The existence of separate DNA-binding and activation domains has been demonstrated by "domain-swap" experiments in which the DNA-binding region of one transcription factor is combined with various regions of a second transcription factor. The resulting hybrid molecule can activate gene transcription only if it contains an activation domain provided by the second transcription factor. The separation of the DNA binding and activation domains of a transcription factor

has been exploited in another way in a technique known as the yeast two-hybrid system (**Box 23B**), which is commonly used to identify interacting proteins.

Studies have revealed that activation domains often possess a high proportion of acidic amino acids, producing a strong negative charge that is clustered on one side of an α helix. Mutations that increase the number of negative charges tend to increase a protein's ability to activate transcription, whereas mutations that decrease the net negative charge or disrupt the clustering on one side of the α helix diminish the ability to activate transcription. Several other kinds of activating domains have been identified in transcription factors as well. Some are enriched in the amino acid glutamine, and others contain large amounts of proline. Hence several types of protein structure are capable of creating an activation domain that can stimulate gene transcription.

Unique types of protein structure have also been detected in the DNA-binding domains of transcription factors. In fact, most regulatory transcription factors can be placed into one of a small number of categories based on the secondary structure pattern, or *motif*, that makes up the DNA-binding domain. In the following paragraphs, we briefly describe several of these DNA-binding motifs.

Helix-Turn-Helix Motif. One of the most common DNA-binding motifs, detected in both eukaryotic and prokaryotic regulatory transcription factors, is the **helix-turn-helix** (**Figure 23-24a**). This motif consists of two α helices separated by a bend in the polypeptide chain. Although the amino acid sequence of the motif differs among various DNA-binding proteins, the overall pattern is always the same: One α helix, called the *recognition helix*, contains amino acid side chains that recognize and bind to specific DNA sequences by forming hydrogen bonds with bases located in the major groove of the DNA double helix, while the second α helix stabilizes the overall configuration through hydrophobic interactions with the recognition helix. The *lac* and *trp* repressors, the CAP protein, and many phage repressor proteins are examples of prokaryotic proteins exhibiting the helix-turn-helix motif, and transcription factors that regulate embryonic development (the class of factors encoded by homeotic genes, described later) are eukaryotic examples. Figure 23-24a includes a model of the phage λ repressor, a helix-turn-helix protein, bound to DNA. Like many DNA-binding regulatory proteins, the phage λ repressor consists of two identical polypeptides, each containing a DNA-binding domain.

Zinc Finger Motif. Initially identified in a transcription factor for the 5S rRNA genes (TFIIIA), the **zinc finger** DNA-binding motif consists of an α helix and a two-segment β sheet, held in place by the interaction of precisely positioned cysteine or histidine residues with a zinc ion. The number of zinc fingers present per protein molecule varies among the transcription factors that

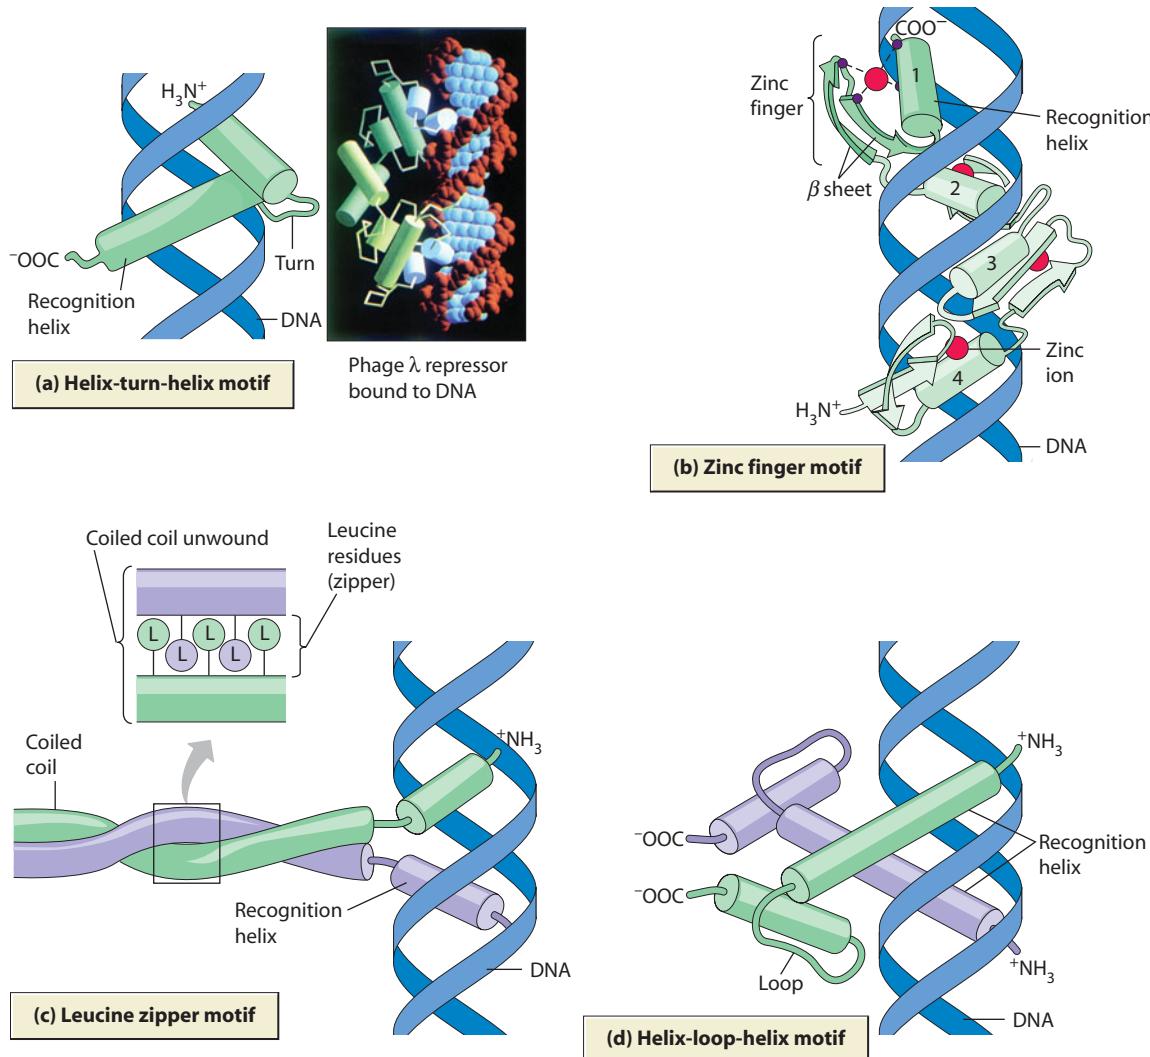

FIGURE 23-24 Common Structural Motifs in DNA-Binding Transcription Factors. Several motifs are commonly found in the DNA-binding domains of regulatory transcription factors. The parts of these domains that directly interact with specific DNA sequences are usually α helices, called recognition helices, that fit into DNA's major groove. In this figure, all α helices are shown as cylinders. (a) The helix-turn-helix motif, in which two α helices are joined by a short, flexible turn. The computer graphic model shows the phage λ repressor, an example of a helix-turn-helix protein, bound to DNA. It is a dimer of two identical subunits. The helices of the two DNA-binding domains are light blue. (b) The zinc finger motif. Each zinc finger consists of an α helix and a two-segment, antiparallel β sheet (shown as ribbons), all held together by the interaction of four cysteine residues, or two cysteine and two histidine residues, with a zinc ion. At the top of the diagram, these key residues are shown as small purple balls; the zinc ions are shown as larger red balls. Zinc finger proteins typically have several zinc fingers in a row; here we see four. (c) The leucine zipper motif, in which an α helix with regularly arranged leucine residues in one polypeptide (green) interacts with a similar region in a second polypeptide (purple). The two helices coil around each other. (d) The helix-loop-helix motif, in which a short α helix connected to a longer α helix by a polypeptide loop interacts with a similar region in another polypeptide to create a dimer.

possess them, ranging from two fingers to several dozen or more. Figure 23-24b shows a protein with four zinc fingers in a row (TFIIIA has nine). Zinc fingers protrude from the protein surface and serve as the points of contact with specific base sequences in the major groove of the DNA.

Leucine Zipper Motif. The **leucine zipper** motif is formed by an interaction between two polypeptide chains, each containing an α helix with regularly spaced leucine

residues. Because leucines are hydrophobic amino acids that attract one another, the stretch of leucines exposed on the outer surface of one α helix can interlock with a comparable stretch of leucines on the other α helix, causing the two helices to wrap around each other into a coil that “zippers” the two α helices together (Figure 23-24c). In some transcription factors, leucine zippers are used to “zip” two identical polypeptides together. In other transcription factors, two kinds of polypeptides are joined

The Yeast Two-Hybrid System

Transcriptional activators have two physically separate, essential domains that lead to their ability to regulate transcription: a DNA-binding domain and an activation domain (see page 738). The ability to separate these two parts of a yeast transcriptional activator known as *Gal4* was exploited by Stanley Fields and colleagues to study protein-protein interactions in a technique called the **yeast two-hybrid system** (Figure 23B-1), or an interaction trap assay. *Gal4* activates transcription of a gene (*Gal1*) that encodes a galactose metabolic enzyme. To do so, it binds to a sequence, the *upstream activating sequence* (or *UAS*), of *Gal1*. The key to the two-hybrid technique is that it is possible to use genetic engineering to separate the DNA that encodes the DNA binding domain of *Gal4* from its activation domain and to place each piece of DNA on a different plasmid. The DNA encoding the DNA binding domain is placed next to DNA encoding a protein of interest. Such a construct is called a “*bait*” construct, because it is used to “catch” interactions with other proteins. A separate plasmid contains a sequence encoding the activation domain of *Gal4*, plus DNA encoding a protein we wish to test for interaction with the bait protein. This construct is called a “*prey*” construct because it is “caught” by the assay.

The two plasmids are introduced into yeast carrying a reporter gene, often the *lacZ* gene. When this gene is transcribed and the mRNA is translated in the yeast, its presence can be detected through a color reaction. Yeast carrying both plasmids are identified by virtue of selectable markers carried by the two plasmids. If the bait protein produced in the yeast binds the prey protein, then the DNA binding and activation domains of *Gal4* attached to each protein fragment are brought sufficiently close together to reconstitute the transcriptional activating activity of *Gal4*. When this happens, the reporter gene is expressed, indicating that the bait and the prey proteins bind one another.

The yeast two-hybrid assay is a powerful way to rapidly assess whether proteins interact. If a library of prey plasmids are used to transform yeast, this method can be used to screen for unknown proteins that bind to a known bait. In addition, genome-wide two-hybrid screens have been carried out in yeast, flies, worms, and humans. The information from these large screens can suggest that two proteins interact, which can be followed up using more traditional biochemical techniques.

together. In either case, DNA binding is made possible by two additional α -helical regions located adjacent to the leucine zipper. These two α -helical segments, one derived from each of the two polypeptides, fit into the DNA's major groove and bind to specific base sequences.

Helix-Loop-Helix Motif. The helix-loop-helix motif is composed of a short α helix connected by a loop to another, longer α helix (Figure 23-24d). Like leucine zippers, helix-loop-helix motifs contain hydrophobic regions that usually connect two polypeptides, which may be either similar or different. Formation of the four-helix bundle results in the juxtaposition of a recognition helix

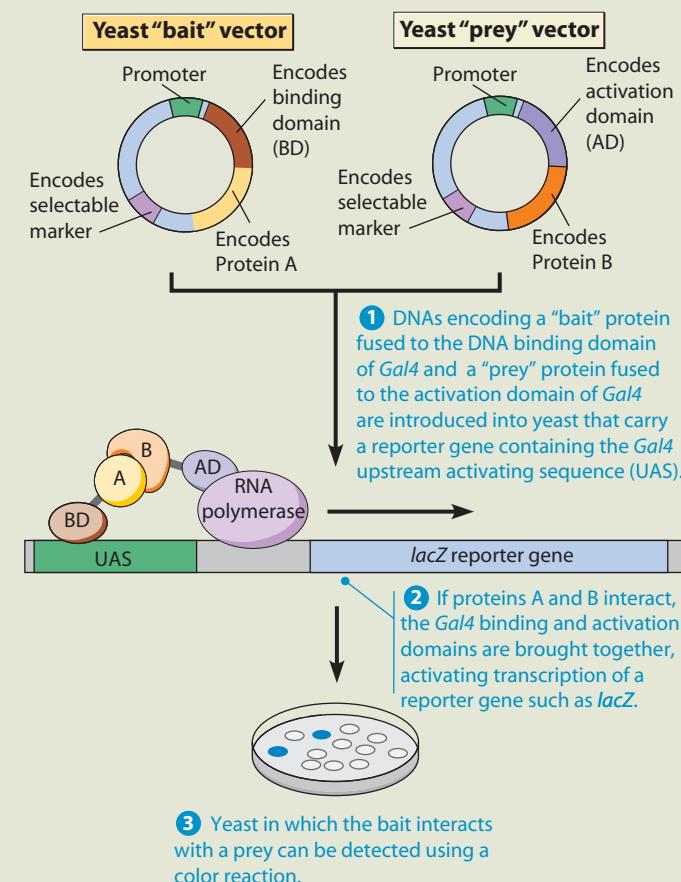

FIGURE 23B-1 The Yeast Two-Hybrid System. The yeast two-hybrid system detects protein-protein interactions by using two different DNA constructs: (1) a “*bait*” vector that fuses DNA encoding the DNA binding domain of *Gal4* to DNA encoding a protein of interest (Protein A), and (2) a “*prey*” vector that fuses DNA encoding the activation domain of *Gal4* to DNA encoding a second protein (Protein B). If the proteins interact, a reporter gene (in this case, *lacZ*) will be expressed.

derived from one polypeptide with a recognition helix derived from the other polypeptide, creating a two-part DNA-binding domain.

DNA Response Elements Coordinate the Expression of Nonadjacent Genes

So far we have focused our attention on how transcription factors bind to DNA and regulate the transcription of individual genes. But eukaryotic cells, like bacteria, often need to activate a group of related genes at the same time. In unicellular eukaryotes, as in bacteria, such coordinate gene regulation may be required to respond to some signal

from the external environment. In multicellular eukaryotes, coordinate gene regulation is critical for the development and functioning of specialized tissues. For example, during embryonic development a single fertilized animal egg may give rise to trillions of new cells of hundreds of differing types, each transcribing a different group of genes—nerve cells expressing genes required for nerve function, muscle cells expressing genes required for muscle function, and so forth. How do eukaryotes coordinate the expression of groups of related genes under such conditions?

Unlike the situation in prokaryotes, where genes with related functions often lie next to each other in operons, eukaryotic genes that must be turned on (or off) at the same time are usually scattered throughout the genome. To coordinate the expression of such physically separated genes, eukaryotes employ DNA control sequences called **response elements** to turn transcription on or off *in response* to a particular environmental or developmental signal. Response elements can function either as proximal control elements or as components of enhancers. In either case, placing the same type of response element next to genes residing at different chromosomal locations allows these genes to be controlled together even though they are not located next to one another.

Because they allow groups of genes to be controlled in a coordinate fashion, response elements play important roles in regulating gene expression during embryonic development and during tissue responses to changing environmental and physiological conditions. In the next several sections, we will describe some examples of such coordinated gene regulation.

Steroid Hormone Receptors Act as Transcription Factors That Bind to Hormone Response Elements

The phenomenon of coordinated gene regulation is nicely illustrated by the behavior of *steroid receptor* proteins, which we introduced in Chapter 14. Steroid receptors, as well as the related *retinoid receptors*, belong to the zinc finger class of transcription factors and typically consist of three domains: One domain recognizes and binds to a specific response element in DNA, a second domain binds to a particular steroid hormone, and the third domain activates transcription. The gene-specific effects of steroid hormones stem from the ability of steroid receptors to act as transcription factors that bind to DNA sequences called **hormone response elements**. All the genes activated by a particular steroid hormone are associated with the same type of response element, allowing them to be regulated together. For example, genes activated by estrogen have a 15-bp *estrogen response element* near the upstream end of their promoters, whereas genes activated by glucocorticoids lie adjacent to a *glucocorticoid response element* exhibiting a slightly different base sequence (Figure 23-25a).

(a) Response element for:

Glucocorticoids

5' AGAACAnnnTGTTCT 3'
3' TCTTGTnnnACAAGA 5'

Estrogen

5' AGTCAnnnTGACCT 3'
3' TCCAGTnnnACTGGA 5'

Thyroid hormone

5' AGTCATGACCT 3'
3' TCCAGTACTGGA 5'

(b)

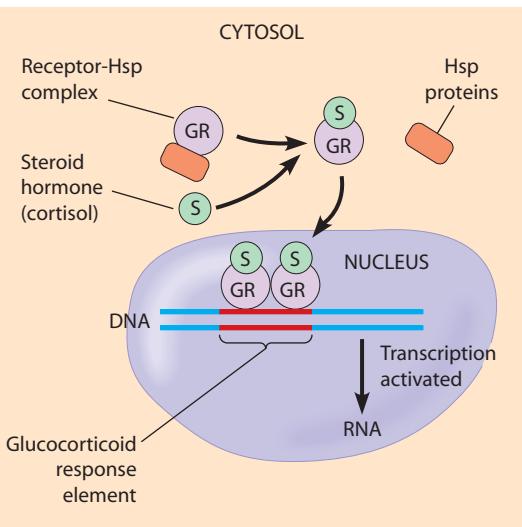

FIGURE 23-25 Steroid Hormone Receptor Interaction with DNA. (a) Different types of hormone response elements. Notice that all three examples contain inverted repeats (two copies of the same sequence oriented in opposite directions). For example, reading the sequence of the glucocorticoid response element in the 5' → 3' direction from either end yields the same DNA sequence: 5'-AGAAC-3'. The highlighted nucleotides are the only bases of the inverted repeat sequences that vary between the three types of elements. The thyroid hormone element contains the same inverted repeat sequences as the estrogen element, but the three bases that separate the two copies of the sequence in the estrogen element are not present. (The "n" signifies that any nucleotide can be located at that position. The dashed lines are included to help you line up the comparable regions of the estrogen and thyroid hormone elements.) (b) Activation of transcription by glucocorticoid receptors. The steroid hormone cortisol (S) diffuses through the plasma membrane and binds to the glucocorticoid receptor (GR), causing the release of Hsp proteins and activating the GR molecule's DNA-binding site. The GR molecule then enters the nucleus and binds to a glucocorticoid response element in DNA, which in turn causes a second GR molecule to bind to the same response element. The resulting GR dimer activates transcription of the adjacent gene.

How are these hormone response elements used by steroid receptors to control gene activity? To illustrate how this arrangement works with a specific steroid hormone, let us consider *cortisol* (hydrocortisone) as an example. Cortisol is a member of a related group of steroid hormones, called *glucocorticoids* because they stimulate glucose production and are made in the adrenal cortex. In response to physical stress, cortisol is released from the

adrenal gland into the bloodstream. Among its many effects, the circulating cortisol enters target cells in the liver and activates transcription of genes coding for enzymes involved in synthesizing glucose from amino acids and lipids.

Figure 23-25b summarizes how cortisol regulates the expression of such genes by binding to the glucocorticoid receptor present in cortisol's target cells. Normally the glucocorticoid receptor (GR) is located mainly in the cytosol, where it is bound to members of the *Hsp* family of chaperone proteins. As long as it remains associated with Hsp proteins, GR is prevented from entering the nucleus and binding to DNA. But the binding of cortisol to GR triggers the release of the Hsp proteins. The GR molecule (with its bound cortisol) is then free to move into the nucleus, where it binds to glucocorticoid response elements wherever they may reside in the DNA. The binding of a GR molecule to a response element in turn facilitates the binding of a second GR molecule to the same response element. The resulting GR *dimer* activates transcription of the adjacent genes by recruiting coactivators that promote assembly of the transcriptional machinery.

This binding of *two* GR molecules to the same DNA site occurs because the DNA sequence of the glucocorticoid response element contains an **inverted repeat**—that is, *two* copies of the same DNA sequence oriented in opposite directions. Therefore the two GR molecules in a GR dimer each bind to one of the two DNA sequence repeats. Such binding of a protein dimer to an inverted repeat sequence within a DNA control element is a common theme among regulatory transcription factors.

Since glucocorticoid response elements are located near all genes that need to be turned on by cortisol, the presence of cortisol activates all these genes simultaneously, regardless of their chromosomal location. Although there are minor differences between various steroid hormones, this model provides a framework for understanding how steroid hormones, transported through the bloodstream to virtually all cells of the body, can turn on a specific set of genes in the appropriate target tissues.

Although steroid hormone receptors usually stimulate gene transcription, in a few cases they inhibit it. For example, the glucocorticoid receptor binds to two types of DNA response elements—one type associated with genes whose transcription is activated, the other with genes whose transcription is inhibited. After binding to the inhibitory type of response element, the glucocorticoid receptor does not form dimers as it does when bound to activating response elements. Instead, the nondimerized glucocorticoid receptor depresses the initiation of gene transcription by recruiting histone deacetylase, which promotes chromatin condensation. The existence of separate activating and inhibiting response elements for the same hormone receptor allows a single hormone to stimulate transcription of genes coding for one group of proteins while it simultaneously depresses transcription of genes coding for other proteins.

CREBs and STATs Are Examples of Transcription Factors Activated by Phosphorylation

The steroid hormone receptors we have been discussing are allosteric proteins that regulate gene expression by changing their DNA-binding affinity in response to steroid hormones in much the same way that bacterial repressors change their DNA-binding properties after binding to the appropriate small molecules. An alternative approach for controlling the activity of transcription factors is based on *protein phosphorylation* (addition of phosphate groups). One common example of this type of control involves *cAMP* (*cyclic AMP*), the widely employed second messenger whose role in mediating the effects of a variety of extracellular signaling molecules was discussed in Chapter 14. As we saw earlier in this chapter, cAMP also plays a role in controlling catabolite-repressible operons in bacteria. In eukaryotes, cAMP functions by stimulating the activity of protein kinase A (Figure 14-8), which in turn catalyzes the phosphorylation of a variety of proteins, including a transcription factor called **CREB** (Figure 23-26). The CREB protein normally binds to DNA sequences called *cAMP response elements* (CRE), which are located adjacent to genes whose transcription is induced by cAMP. Upon being phosphorylated, the CREB protein recruits a transcriptional coactivator called **CBP** (CREB-binding protein). CBP then catalyzes histone acetylation, which loosens the packing of nucleosomes and interacts with RNA polymerase to facilitate assembly of the transcription machinery at nearby gene promoters.

Protein phosphorylation is also involved in activating a family of transcription factors called **STATs** (for signal

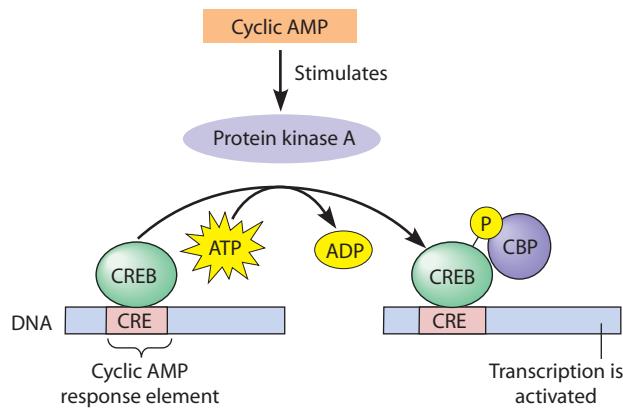

FIGURE 23-26 Activation of Gene Transcription by Cyclic AMP. Genes activated by cyclic AMP possess an upstream cyclic AMP response element (CRE) that binds a transcription factor called CREB. In the presence of cyclic AMP, cytoplasmic protein kinase A is activated, and its activated catalytic subunit then moves into the nucleus, where it catalyzes CREB phosphorylation. Phosphorylated CREB in turn binds to CBP, a transcriptional coactivator that exhibits histone acetyltransferase activity. Besides catalyzing histone acetylation that loosens the packing of nucleosomes, CBP associates with RNA polymerase and facilitates assembly of the transcription machinery at gene promoters.

transducers and activators of transcription). Among the signaling molecules that activate STATs are the *interferons*, a group of glycoproteins produced and secreted by animal cells in response to viral infection. The secreted interferons bind to receptors on the surface of neighboring cells, causing them to produce proteins that make the target cells more resistant to viral infection. The binding of interferon to its cell surface receptor causes the cytosolic domain of the receptor to associate with and activate an intracellular protein kinase called **Janus kinase (Jak)**. The activated Jak protein in turn catalyzes the phosphorylation of STAT molecules, which are normally present in an inactive form in the cytoplasm. Phosphorylation causes the STAT molecules to dimerize and move from the cytoplasm to the nucleus, where they bind to appropriate DNA response elements and activate transcription.

The Jak-STAT signaling pathway exhibits considerable specificity. For example, the different types of interferon trigger the phosphorylation and activation of different STAT proteins. Each STAT associates with its own distinctive DNA response element and activates the transcription of a unique set of genes. In addition to interferons, several other types of signaling molecules bind to cell surface receptors that trigger the phosphorylation of STATs.

STATs and the CREB protein are only two of the many types of transcription factors known to be activated by phosphorylation. You learned in Chapter 14, for example, that the TGF β family of growth factors bind to plasma membrane receptors whose activation leads to the phosphorylation of cytoplasmic proteins called *Smads*, which then travel to the nucleus and function as transcription factors that turn on the transcription of specific genes. And we described in Chapter 19 how other growth factors trigger the activation of protein kinases called *MAP kinases*, which phosphorylate and activate transcription factors involved in controlling cell growth and division.

The Heat-Shock Response Element Coordinates the Expression of Genes Activated by Elevated Temperatures

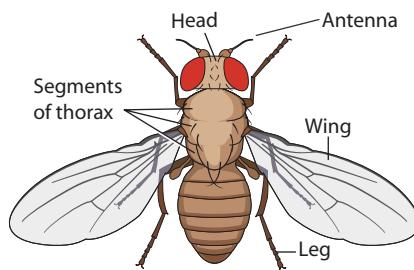

The **heat-shock genes** provide another example of how eukaryotes coordinate the regulation of genes located at different chromosomal sites. Heat-shock genes were initially defined as genes expressed in response to an increase in temperature. But they are now known to respond to other stressful conditions as well, and so they are also called *stress-response genes*. There are a number of different heat-shock genes in both prokaryotic and eukaryotic genomes, and the appropriate environmental trigger activates all of them simultaneously. For example, briefly warming cultured cells by raising the temperature a few degrees activates the transcription of multiple heat-shock genes. Although the functions of these genes are not completely understood, the proteins produced by at least some of them help minimize the damage resulting from thermal denaturation of important cellular proteins.

In cells of *Drosophila*, for example, the most prominent product of the heat-shock genes is Hsp70 (page 691), a molecular chaperone involved in normal protein folding that can also facilitate the refolding of heat-damaged proteins. The region immediately upstream from the start site of the *hsp70* gene contains several sequences commonly encountered in eukaryotic promoters, such as a TATA box, a CAAT box, and a GC box. In addition, a 14-bp sequence called the **heat-shock response element** is located 62 bases upstream from the transcription start site of the *Drosophila hsp70* gene and in a comparable location in other genes whose transcription is activated by high temperatures. Subsequent investigations have revealed that the activation of heat-shock genes is mediated by the binding of a protein called the **heat-shock transcription factor** to the heat-shock response element. The heat-shock transcription factor is present in an inactive form in non-heated cells, but elevated temperatures cause a change in the structure of the protein that allows it to bind to the heat-shock response element in DNA. The protein is then further modified by phosphorylation, which makes it capable of activating gene transcription.

The heat-shock system again illustrates a basic principle of eukaryotic coordinate regulation: Genes located at different chromosomal sites can be activated by the same signal if the same response element is located near each of them.

Homeotic Genes Code for Transcription Factors That Regulate Embryonic Development

Some especially striking examples of coordinate gene regulation in eukaryotes involve an unusual class of genes known as **homeotic genes**. When mutations occur in one of these genes, a strange thing happens during embryonic development—one part of the body is replaced by a structure that normally occurs somewhere else. The discovery of homeotic genes can be traced back to the 1940s, when Edward B. Lewis discovered a cluster of *Drosophila* genes, the *bithorax gene complex*, in which certain mutations cause drastic developmental abnormalities such as the growth of an extra pair of wings (compare **Figure 23-27a** and Figure 23-27b). Later, Thomas C. Kaufman and his colleagues discovered a second group of genes that, when mutated, lead to different but equally bizarre developmental changes—for example, causing legs to grow from the fly's head in place of antennae (Figure 23-27c). This group of genes is the *antennapedia gene complex*. The *bithorax* and *antennapedia* genes are called homeotic genes because *homeo* means “alike” in Greek, and mutations in these genes change one body segment of *Drosophila* to resemble another. A clue to how homeotic genes work first emerged from the discovery that the *bithorax* and *antennapedia* genes each contain a similar, 180-bp sequence near their 3' end that resembles a comparable sequence found in other homeotic genes. Termed the

(a) Wild-type *Drosophila*. Two wings and six legs extend from its three thorax segments.

(b) Bithorax mutant. An additional set of wings is formed.

(c) Antennapedia mutant. Legs develop where the antennae should be.

FIGURE 23-27 Homeotic Mutants of *Drosophila*. Mutations in the *bithorax* gene complex convert the third thoracic segment to a second thoracic segment (the wing-producing segment), and so an additional set of wings is formed. Mutations in the *antennapedia* gene complex cause legs to develop where the antennae should be.

homeobox, this DNA sequence codes for a stretch of 60 amino acids called a **homeodomain** (Figure 23-28).

Although such phenomena might at first appear to be no more than oddities of nature, the growth of an extra pair of wings or legs in the wrong place suggests that homeotic genes play a key role in determining the body plan of developing fly embryos. Homeotic genes exert their influence by coding for a family of regulatory transcription factors that activate (or inhibit) the transcription of developmentally important genes by binding to specific DNA sequences. By binding to all copies of the appropriate DNA element in the genome, each homeotic transcription factor can influence the expression of dozens or even hundreds of genes in the growing embryo.

The result of this coordinated gene regulation is the establishment of fundamental body characteristics such as appendage shape and location.

A remarkable result of modern genomics and molecular developmental biology is the high degree of conservation of homeotic genes in animals. Sequences similar to those in the homeotic genes of flies have been detected in the genes of organisms as diverse as nematode worms, insects, sea squirts, frogs, mice, and humans—an evolutionary distance of more than 500 million years. Remarkably, with a few minor exceptions, the physical organization of these *Hox* genes has been retained across these great distances. In both flies and vertebrates, the 3'- 5' location of these genes within a chromosome corresponds to the anterior to posterior region along the body axis these proteins regulate (Figure 23-29). In vertebrates, there appears to have been a duplication of the original single set of these genes possessed by fruit flies and other simple animals: Whereas fruit flies have one set of homeotic genes, mammals have four sets of *Hox* genes. Based on analysis of the expression pattern of mouse *Hox* genes and the effects of making “knockout” mutants for individual and multiple *Hox* genes, it is clear that, like their fly counterparts, they control the identity of structures along the anterior-posterior axis of vertebrates. Mutations in human *Hox* genes have also been identified. For example, mutations in the *HoxD13* locus result in *syndactyly*, characterized by fusions and duplications of fingers and toes. A major theme of modern efforts to unite evolutionary and developmental biology is to understand how subtle changes in *Hox* genes lead to changes in the body plans of higher animals.

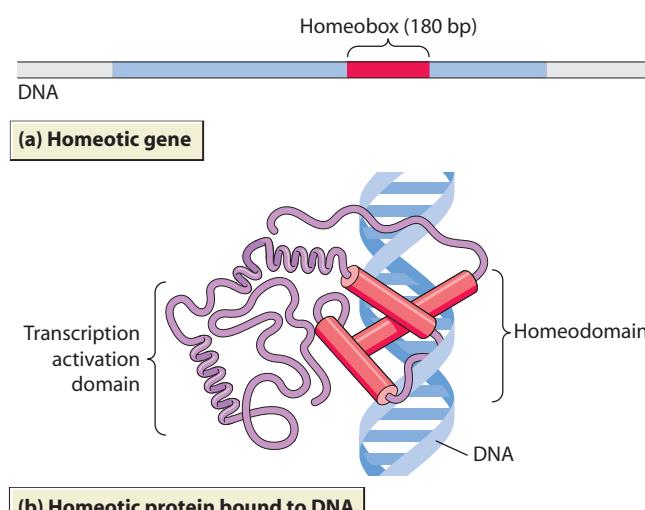

FIGURE 23-28 Homeotic Genes and Proteins. Homeotic mutants like the ones in Figure 23-27 have mutations in homeotic genes. (a) Homeotic genes all contain a 180-bp segment, called a homeobox, that encodes a homeodomain in the homeotic protein. (b) The homeodomain (red) is a helix-turn-helix DNA-binding domain that, in combination with a transcription activation domain, enables the protein to function as a regulatory transcription factor. Notice that the homeodomain has three α helices (shown as cylinders).

Eukaryotic Gene Regulation: Posttranscriptional Control

We have now examined the first two levels of regulation for eukaryotic gene expression, namely genomic controls and transcriptional controls. After transcription has taken place, the flow of genetic information involves a complex series of

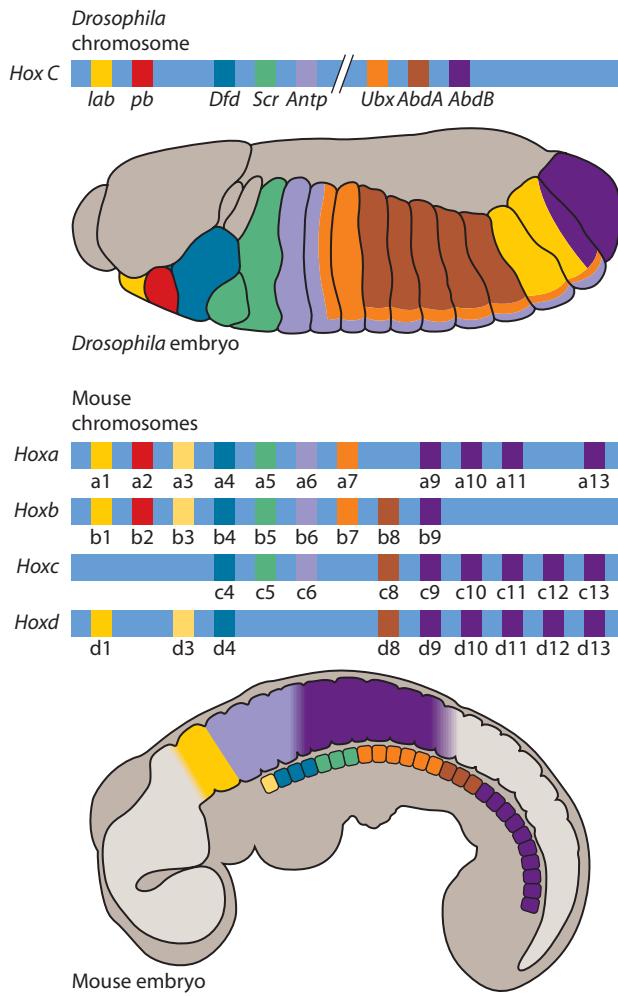

FIGURE 23-29 Organization and Expression of Hox Genes in *Drosophila* and the mouse. In the *Drosophila* embryo, int = intercalary segment, mx = maxillary segment, la = labial segment, T = thoracic, A = abdominal. Note that the mouse has four *Hox* complexes, labeled a-d. Corresponding genes in each of the four *Hox* clusters in the mouse are numbered with the lowest numbers being the most anteriorly expressed. Note that some genes are not found in some clusters. Genes with the same color represent similar genes. Note that the single *AbdB* gene in flies (dark purple) appears to have been duplicated multiple times in the mouse (genes 9-13).

posttranscriptional events, any or all of which can turn out to be regulatory points (see Figure 23-10, steps ③, ④, and ⑤). Posttranscriptional regulation may be especially useful in providing ways to rapidly fine-tune the pattern of gene expression, allowing cells to respond to transient changes in the intracellular or extracellular environment without changing their overall transcription patterns.

Control of RNA Processing and Nuclear Export Follows Transcription

Posttranscriptional control begins with the processing of primary RNA transcripts, which provides many opportunities for the regulation of gene expression. As we learned in Chapter 21, virtually all RNA transcripts in eukaryotic

nuclei undergo substantial processing, including addition of a 5' cap and a 3' poly(A) tail, chemical modifications such as methylation, splicing together of exons accompanied by the removal of introns, and RNA editing. Among these processing events, RNA splicing is an especially important control site because its regulation allows cells to create a variety of different mRNAs from the same pre-mRNA, thereby permitting a gene to generate more than one protein product.

This phenomenon, called **alternative splicing**, is based on a cell's ability to permit some splice sites to be skipped and others to become activated (see Figure 21-23). Roughly half of all human genes produce pre-mRNAs that are alternatively spliced, reinforcing the view that splicing control is an important component of gene regulation. Splicing patterns are determined by various factors, including the presence of regulatory proteins and small nucleolar RNA molecules (snoRNAs) that bind to *splicing enhancer* or *splicing silencer* sequences in pre-mRNA. By increasing the ways in which a given pre-mRNA can be spliced, these regulatory molecules make it possible for a single gene to yield dozens or even hundreds of alternate mRNAs. A remarkable example occurs in the inner ear of birds, where 576 alternatively spliced forms of mRNA are produced from a single potassium channel gene. Expression of varying subsets of these mRNAs in different cells of the inner ear facilitates perception of different sound frequencies.

Figure 23-30 illustrates another well-documented example of alternative splicing, in this case involving the mRNA coding for a type of antibody called *immunoglobulin M* (*IgM*). The IgM protein exists in two forms, a secreted version and a version that becomes incorporated into the plasma membrane of the cell that makes it. Like all antibodies, IgM consists of four polypeptide subunits—two heavy chains and two light chains. It is the sequence of the heavy chain that determines whether IgM is secreted or membrane bound. The gene coding for the heavy chain has two alternative poly(A) sites where RNA transcripts can terminate, yielding two kinds of pre-mRNA molecules that differ at their 3' ends. The exons within these pre-mRNAs are then spliced together in two different ways, producing mRNAs that code for either the secreted version of the heavy chain or the version that is bound to the plasma membrane. Only the splicing pattern for the membrane-bound version includes the exons encoding the hydrophobic amino acid domain that anchors the heavy chain to the plasma membrane.

After RNA splicing, the next posttranscriptional step subject to control is the export of mRNA through nuclear pores to the cytoplasm. We know that this export step can be controlled because RNAs exhibiting defects in capping or splicing are not readily exported from the nucleus. Even with normal mRNAs, certain molecules are retained in the nucleus until their export is triggered by a stimulus signaling that a particular mRNA is needed in the cytoplasm for translation. Export control has also been observed

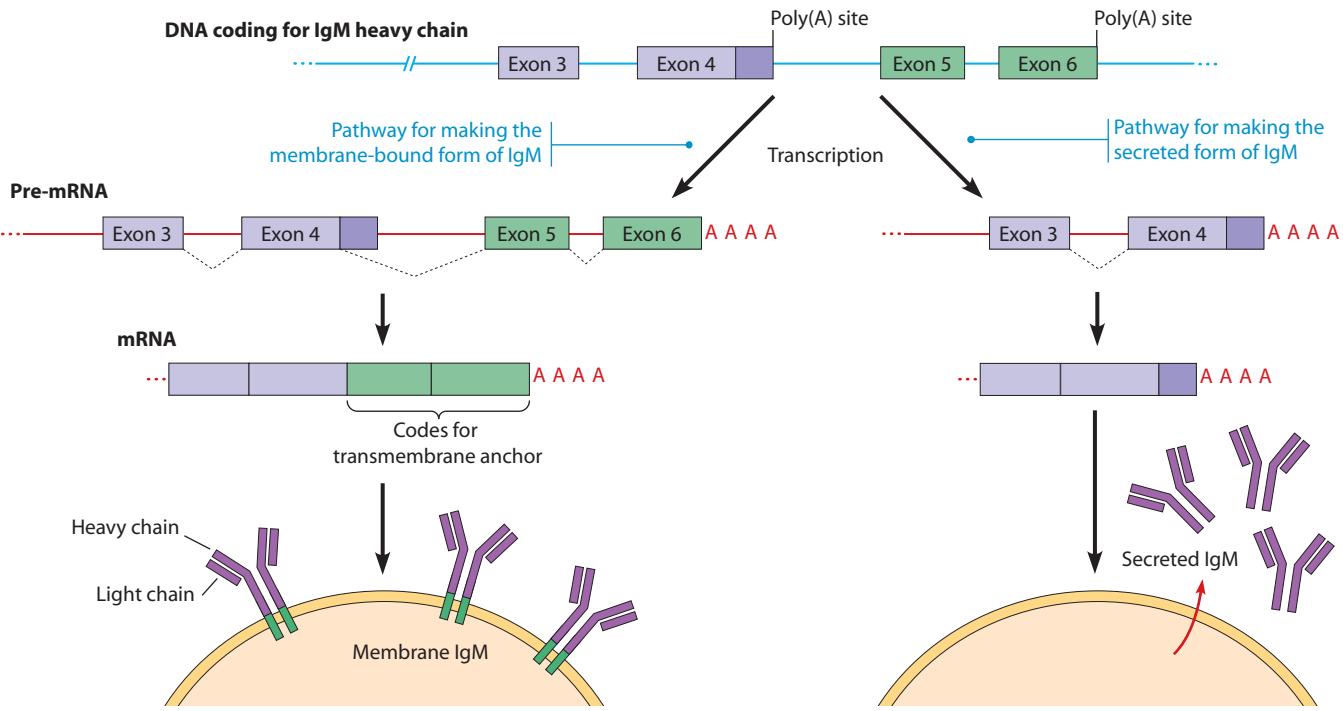

FIGURE 23–30 Alternative Splicing to Produce Variant Gene Products. The antibody protein immunoglobulin M (IgM) exists in two forms, secreted IgM and membrane-bound IgM, which differ in the carboxyl ends of their heavy chains. A single gene carries the genetic information for both types of IgM heavy chain. The end of the gene corresponding to the polypeptide's C-terminus is shown at the top of the figure. This DNA has two possible poly(A) addition sites, where RNA transcripts can terminate, and four exons that can be spliced in two alternative configurations. The splices made in the primary transcripts are indicated by V-shaped, thin dashed lines beneath each pre-mRNA. A splicing pattern that uses a splice junction within exon 4 and retains exons 5 and 6 results in the synthesis of membrane IgM heavy chains that are held in the plasma membrane by a transmembrane anchor encoded by exons 5 and 6. The alternative product is secreted because a splice within exon 4 is not made and the transcript is terminated after exon 4.

with viral RNAs produced in infected cells. For example, HIV—the virus responsible for AIDS—produces an RNA molecule that remains in the nucleus until a viral protein called Rev is synthesized. The amino acid sequence of the Rev protein includes a *nuclear export signal* (page 540) that allows Rev to guide the viral RNA out through the nuclear pores and into the cytoplasm.

Translation Rates Can Be Controlled by Initiation Factors and Translational Repressors

Once mRNA molecules have been exported from the nucleus to the cytoplasm, several **translational control** mechanisms are available to regulate the rate at which each mRNA is translated into its polypeptide product. Some translational control mechanisms work by altering ribosomes or protein synthesis factors; others regulate the activity and/or stability of mRNA itself. Translational control takes place in prokaryotes as well as eukaryotes, but we will restrict our discussion to several eukaryotic examples.

One well-studied example of translational control occurs in developing erythrocytes, where *globin* polypeptide chains are the main product of translation. The

synthesis of globin depends on the availability of *heme*—the iron-containing prosthetic group that attaches to globin chains to form the final protein product, hemoglobin. Developing erythrocytes normally synthesize globin at a high rate. However, globin synthesis would be wasteful if not enough heme were available to complete the formation of hemoglobin molecules, so erythrocytes have developed a mechanism for adjusting polypeptide synthesis to match heme availability.

This mechanism involves a protein kinase, called *heme-controlled inhibitor* (HCl), whose activity is regulated by heme. HCl is inactive in the presence of heme. But when heme is absent, HCl phosphorylates and inhibits eIF2, one of several proteins required for initiating translation in eukaryotes (page 687). The reduced activity of eIF2 depresses all translational activity, but since globin chains account for more than 90% of the polypeptides made in developing erythrocytes, the main impact of HCl in these cells is on globin synthesis. Other kinases that phosphorylate eIF2 have been detected in a diverse array of cell types, suggesting that phosphorylation of eIF2 is a widely used mechanism for regulating translation.

The use of protein phosphorylation to control translation is not restricted to effects on eIF2. Eukaryotic

initiation factor eIF4F (page 687), a multiprotein complex that binds to the 5' mRNA cap, is also regulated by phosphorylation, although in this case phosphorylation activates rather than inhibits the initiation factor. An example of this type of control is observed in cells infected by adenovirus, which inhibits protein synthesis in infected cells by blocking phosphorylation of eIF4E, the cap-binding subunit of eIF4F. Other viruses inhibit the eIF4F complex by producing proteases that cleave eIF4F into two fragments, one containing the site that binds to the 5' cap of mRNA molecules and the other containing the site that binds to ribosomes. Surprisingly, the ribosome-binding fragment can still initiate the translation of viral (but not cellular) mRNA by binding to the *IRES* sequence (page 687) that lies directly upstream of the start codon of some viral mRNAs. This allows a virus to hijack the translation machinery for translating its own mRNA while simultaneously shutting down the translation of normal cellular mRNAs.

The types of translational control we have discussed so far are relatively nonspecific in that they affect the translation rates of all mRNAs within a cell. An example of a more specific type of translational control is seen with *ferritin*, an iron-storage protein whose synthesis is selectively stimulated in the presence of iron. The key to this selective stimulation lies in the 5' untranslated leader sequence of ferritin mRNA, which contains a 28-nucleotide segment—the **iron-response element (IRE)**—that forms a hairpin loop required for the stimulation of ferritin synthesis by iron. If the IRE sequence is experimentally inserted into a gene whose expression is not normally regulated by iron, translation of the resulting mRNA becomes iron sensitive.

Figure 23-31 shows how the IRE sequence works. When the iron concentration is low, a regulatory protein called the *IRE-binding protein* binds to the IRE sequence in ferritin mRNA, preventing the mRNA from forming an initiation complex with ribosomal subunits. But the IRE-

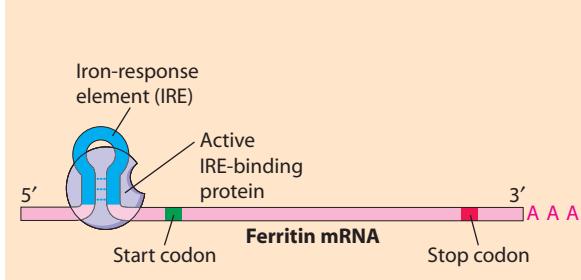

binding protein is an allosteric protein whose activity can be controlled by the binding of iron. When more iron is available, the protein binds an iron atom and undergoes a conformational change that prevents it from binding to the IRE, thereby allowing the ferritin mRNA to be translated. The IRE-binding protein is therefore an example of a **translational repressor** that selectively controls the translation of a particular mRNA. This type of translational control allows cells to respond to specific changes in the environment faster than would be possible through the use of transcriptional control.

Other proteins act as translational repressors but bind the 3' untranslated regions of specific mRNAs. One example of this type of control is the *PUF* proteins, which regulate the translation of proteins important during development. In addition to translational repressor proteins, we will see below that an important class of small RNAs—*microRNAs*—also interact with the 3'-UTR to regulate translation.

Translation Can Also Be Controlled by Regulation of mRNA Degradation

Translation rates are also subject to control by alterations in mRNA stability—in other words, if an mRNA molecule is degraded more rapidly, then less time is available for it to be translated. Degradation rates can be measured by *pulse-chase experiments*, in which cells are first incubated for a brief period of time (the “pulse”) in the presence of a radioactive compound that becomes incorporated into mRNA. The cells are then placed in a nonradioactive medium, and incubation is continued (the “chase”). No additional radioactivity is taken up by the cell during the chase period, so the fate of the radioactivity previously incorporated into mRNA can be measured over time. This approach allows researchers to measure an mRNA’s *half-life*, which is the time required for 50% of the initial (radioactive) RNA to be degraded.

(a) Low iron concentration. IRE-binding protein binds to IRE, so translation of ferritin mRNA is inhibited.

(b) High iron concentration. IRE-binding protein cannot bind to IRE, so translation of ferritin mRNA proceeds.

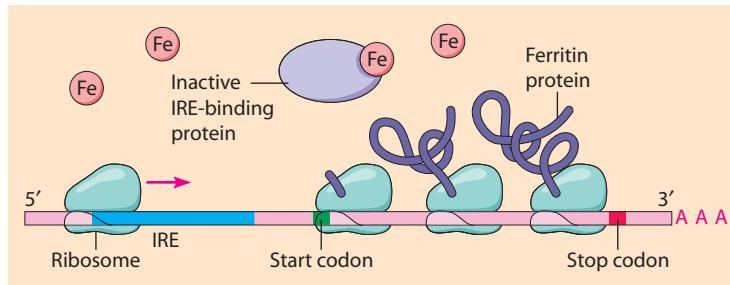

FIGURE 23-31 Translational Control in Response to Iron. (a) An iron response element (IRE) located in the 5' untranslated region of ferritin mRNA can form a hairpin structure that is bound by the IRE-binding protein, which inhibits the initiation of translation. (b) When the iron concentration is high, iron binds to the IRE-binding protein and changes it to a conformation that does not recognize the IRE. Ribosomes can therefore assemble on the ferritin mRNA and translate it.

The half-life of eukaryotic mRNAs varies widely, ranging from 30 minutes or less for some growth factor mRNAs to over 10 hours for the mRNA encoding β -globin. The length of the poly(A) tail is one factor that plays a role in controlling mRNA stability. Messenger RNAs with short poly(A) tails tend to be less stable than mRNAs with longer poly(A) tails. In some cases, mRNA stability is also influenced by specific features of the 3' untranslated region. For example, short-lived mRNAs for several growth factors have particular *AU-rich elements* in this region. The AU-rich sequences trigger removal of the poly(A) tail by degradative enzymes. When an AU-rich element is transferred to the 3' end of a normally stable globin message using recombinant DNA techniques, the hybrid mRNA acquires the short half-life typical of a growth factor mRNA.

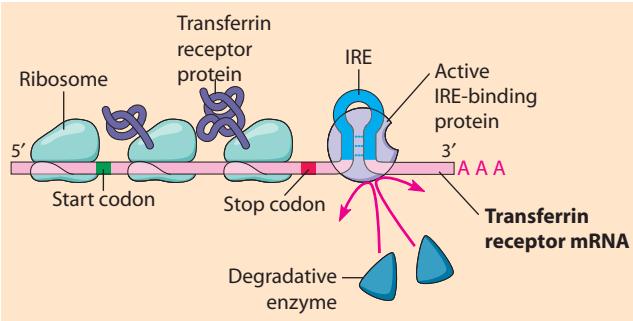

Another way of regulating mRNA stability is illustrated by the action of iron, which, in addition to participating in translational control as just described, plays a role in controlling mRNA degradation as well. The uptake of iron into mammalian cells is mediated by a plasma membrane receptor protein called the *transferrin receptor*. When iron is scarce, synthesis of the transferrin receptor is stimulated by a mechanism that protects transferrin receptor mRNA from degradation, thereby making more mRNA molecules available for translation. As shown in **Figure 23-32**, this control mechanism involves an IRE (similar to the one in ferritin mRNA) located in the 3' untranslated region of transferrin receptor mRNA. When intracellular iron levels are low and increased uptake of iron is necessary, the IRE-binding protein binds to this IRE and protects the mRNA from degradation. When iron levels in the cell are high and additional uptake is not necessary, the IRE-binding protein binds an iron atom and dissociates from the mRNA, allowing the mRNA to be degraded.

Two general mechanisms exist for degrading mRNAs that have been targeted for destruction. The main difference is whether the mRNA is degraded in the 3' \rightarrow 5' or the 5' \rightarrow 3' direction. In the 3' \rightarrow 5' pathway, shortening of the poly(A) tail and removal of poly(A)-binding proteins from the 3' end of the mRNA is followed by degradation of the RNA chain by the cytoplasmic **exosome**, a complex of several 3' \rightarrow 5' exonucleases. When the exosome eventually arrives at the 5' end of the mRNA, the 5' cap is destroyed by a cap-degrading enzyme. In contrast, the 5' \rightarrow 3' pathway involves shortening of the poly(A) tail at the 3' end followed by immediate removal of the cap from the 5' end. The mRNA is then degraded by 5' \rightarrow 3' exonucleases. The enzymes involved in this 5' \rightarrow 3' pathway are concentrated in cytoplasmic structures called *mRNA processing bodies*, or simply **P bodies**. In addition to their role in mRNA degradation, P bodies can serve as temporary storage sites for nontranslated mRNAs and for recruitment of proteins involved in RNA interference, to which we now turn.

RNA Interference Utilizes Small RNAs to Silence the Expression of Genes Containing Complementary Base Sequences

Regulatory proteins like IRE-binding and PUF proteins, which bind to specific mRNAs, are not the only molecules used by cells for controlling mRNA activity. Individual mRNAs are also controlled by a class of small RNA molecules that inhibit the expression of mRNAs containing sequences related to sequences found in the small RNAs. Such RNA-mediated inhibition, known as **RNA interference (or RNAi)**, is based on the ability of small RNAs to trigger mRNA degradation, or inhibit mRNA translation, or inhibit transcription of the gene coding for a particular mRNA.

(a) Low iron concentration. IRE-binding protein binds to the IRE of transferrin receptor mRNA, thereby protecting the mRNA from degradation. Synthesis of transferrin receptor therefore proceeds.

(b) High iron concentration. IRE-binding protein cannot bind to IRE, so mRNA is degraded and synthesis of transferrin receptor is thereby inhibited.

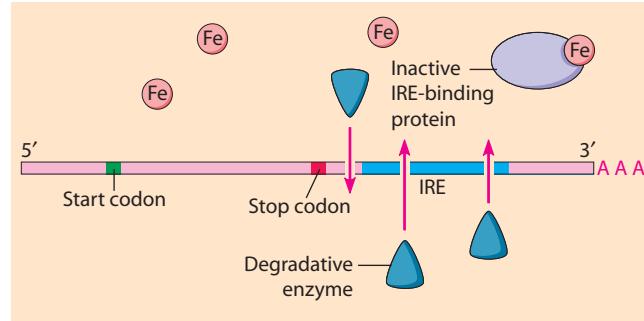

FIGURE 23-32 Control of mRNA Degradation in Response to Iron. Degradation of the mRNA coding for the transferrin receptor, a protein required for iron uptake, is regulated by the same IRE-binding protein shown in Figure 23-31. (a) When the intracellular iron concentration is low, the IRE-binding protein binds to an IRE in the 3' untranslated region of the transferrin receptor mRNA, protecting the mRNA from degradation and allowing the transferrin receptor protein to be synthesized. (b) When iron levels are high, iron atoms bind to the IRE-binding protein, causing it to leave the IRE. The mRNA is then vulnerable to attack by degradative enzymes.

The first type of RNA interference to be discovered occurs in response to the presence of double-stranded RNA. For example, if plants are infected with viruses that produce double-stranded RNA as part of their life cycle, the infected cells limit the infection by reducing the expression of viral genes. Moreover, the effect is not limited to viral genes. If a normal plant gene is inserted into a virus using genetic engineering techniques, cells infected with the virus reduce expression of their own copy of the same gene. The causal role played by double-stranded RNA in this type of gene silencing was demonstrated in 1998 by Andrew Fire and Craig Mello, who reported that injecting double-stranded RNA into worms greatly reduces the levels of RNA transcripts that contain sequences complementary to those present in the double-stranded RNA. Because their studies laid the groundwork for a burgeoning new field of biology related to the roles played by small RNAs in the control of gene expression, Fire and Mello were awarded a Nobel Prize in 2006.

Figure 23-33 illustrates how double-stranded RNAs knock down the expression of specific genes. First, a cytoplasmic ribonuclease known as **Dicer** cleaves the double-stranded RNA into short fragments about 21–22 base pairs in length. The resulting double-stranded fragments, called **siRNAs** (small interfering, or silencing, RNAs), then combine with a group of proteins to form an inhibitor of gene expression called a **RISC** (RNA-induced silencing complex). This particular type of RISC is known as an **siRISC** because its siRNA component determines which gene will be targeted for silencing.

After being incorporated into an siRISC, one of the two strands of the siRNA is degraded. The remaining single-stranded RNA then binds the siRISC via complementary base pairing to a target mRNA molecule. If pairing between the siRNA and the mRNA is a perfect match (or very close), mRNA degradation is initiated by **Slicer**, a ribonuclease component of the siRISC that cleaves the mRNA in the middle of the complementary site. If the match between the siRNA and mRNA is imperfect, translation of the mRNA may be inhibited without the mRNA being degraded. And in some cases, the siRISC may enter the nucleus and be guided by its siRNA to complementary nuclear DNA sequences. After associating with these gene sequences, the siRISC silences their expression by stimulating DNA methylation and/or recruiting an enzyme that adds methyl groups to histones, thereby triggering the formation of a transcriptionally inactive, condensed form of chromatin (heterochromatin).

RNA interference originally may have evolved to protect cells from viruses that utilize double-stranded RNA. However, it also turns out to be a powerful laboratory tool that allows scientists to selectively knock down expression of any gene they wish to study. Since complete genome sequences are now available for a variety of organisms, the function of each individual gene can be systematically explored by using RNA interference to turn it off. Researchers simply synthesize (or purchase) short

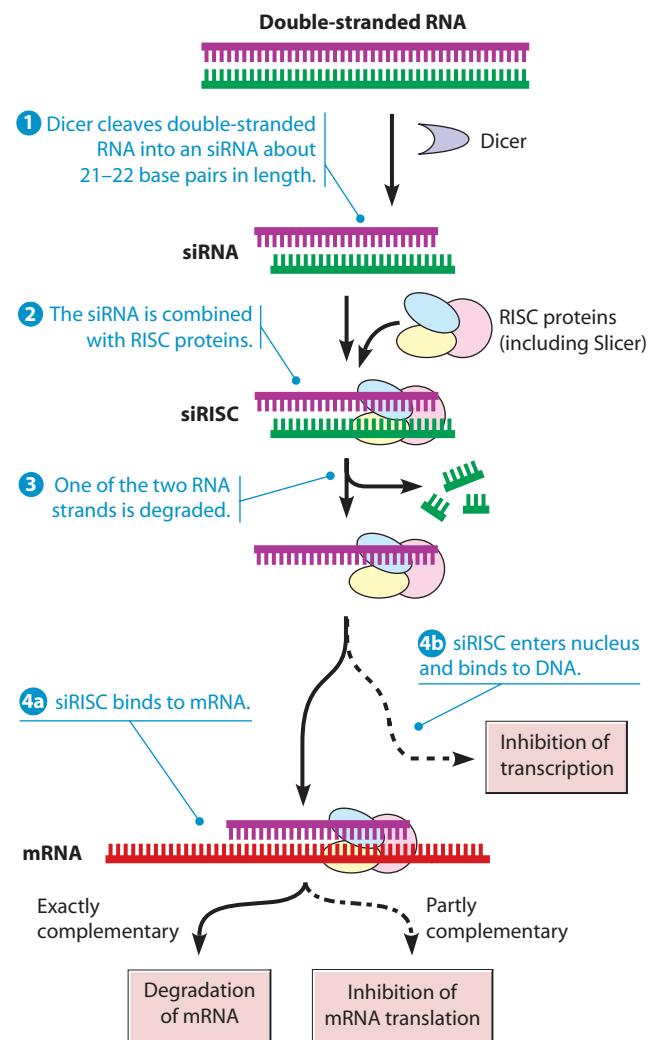

FIGURE 23-33 RNA Interference by Double-Stranded RNA.

RNA. When a cell encounters double-stranded RNA, Dicer cleaves it into an siRNA, about 21–22 base pairs in length, that is subsequently combined with RISC proteins to form an siRISC. After degradation of one of the two siRNA strands, the remaining strand binds the siRISC via complementary base pairing to either a target mRNA molecule in the cytoplasm (**4a**) or to a target DNA sequence in the nucleus (**4b**), thereby silencing gene expression at either the translational or transcriptional level. The most common situation (indicated by the solid arrows) is an exact complementary match between the siRNA and a corresponding mRNA, which triggers mRNA cleavage by Slicer, an enzyme component of the siRISC.

siRNAs that are complementary to sequences present in the genes they wish to silence. Introducing these synthetic siRNAs into cells allows individual genes to be turned off one at a time. To illustrate the extraordinary power of this approach, RNAi has already been used to study the roles of 98% of the roughly 20,000 protein coding genes in the worm *C. elegans* by turning them off one by one.

Another potential application of siRNAs is to use them for silencing genes involved in various diseases. For example, studies in mice have shown that injecting animals with siRNAs directed against a gene involved in cholesterol metabolism can reduce cholesterol levels in the

blood. Although questions concerning safety, side effects, and effectiveness remain to be answered, the therapeutic use of siRNAs as drugs for treating or preventing human diseases is thought to have a bright future.

MicroRNAs Produced by Normal Cellular Genes Silence the Translation of Developmentally Important Messenger RNAs

The finding that gene expression can be silenced by introducing double-stranded RNAs into cells raises the question of whether any normal genes produce RNAs that function in a comparable fashion. The search for such molecules has led to the discovery of **microRNAs (miRNAs)**, a class of single-stranded RNAs about 21–22 nucleotides in length that are produced by genes found in almost all eukaryotes. These microRNAs bind to and regulate the expression of messenger RNAs produced by genes that are separate from the genes that produce the microRNAs.

As shown in **Figure 23–34**, genes that produce microRNAs are initially transcribed into longer RNA molecules called *primary microRNAs (pri-miRNAs)*, which fold into hairpin loops. These looped pri-miRNAs are converted into mature miRNAs by sequential processing. First, a nuclear enzyme called **Drosha** cleaves the pri-miRNAs into smaller hairpin RNAs, called *precursor microRNAs (pre-miRNAs)*, roughly 70 nucleotides long. Next the pre-miRNAs are exported to the cytoplasm, where Dicer cleaves the hairpin loop to produce two complementary short RNA molecules 21–22 nucleotides long.

One of the two short RNAs is the mature microRNA, which joins with a group of proteins to form an **miRISC**. Each miRISC inhibits the expression of messenger RNAs containing a base sequence complementary to that of the microRNA residing within the miRISC. The interactions between miRISCs and their targeted messenger RNAs take place mainly in cytoplasmic P bodies (page 748). Sometimes the microRNA in a particular miRISC is exactly complementary to a sequence present in a targeted messenger RNA. In such cases, the targeted message is destroyed by a mechanism similar to that observed with siRNAs. It is more common, however, for microRNAs to exhibit partial complementarity to sites in messenger RNA. Rather than triggering messenger RNA degradation, the binding of miRISCs to partially complementary sites inhibits translation of the targeted message. This inhibitory effect usually requires the binding of multiple miRISCs to different, partially complementary sites within a given messenger RNA. Such inhibition is not necessarily permanent, however. Changing cellular conditions can trigger the release of a messenger RNA from inhibiting miRISCs, accompanied by movement of the messenger RNA from P bodies to actively translating ribosomes.

Current estimates suggest that genes coding for microRNAs account for up to 5% of the total number of genes in eukaryotic genomes. In mammals, this corresponds to the presence of about 1000 microRNA genes.

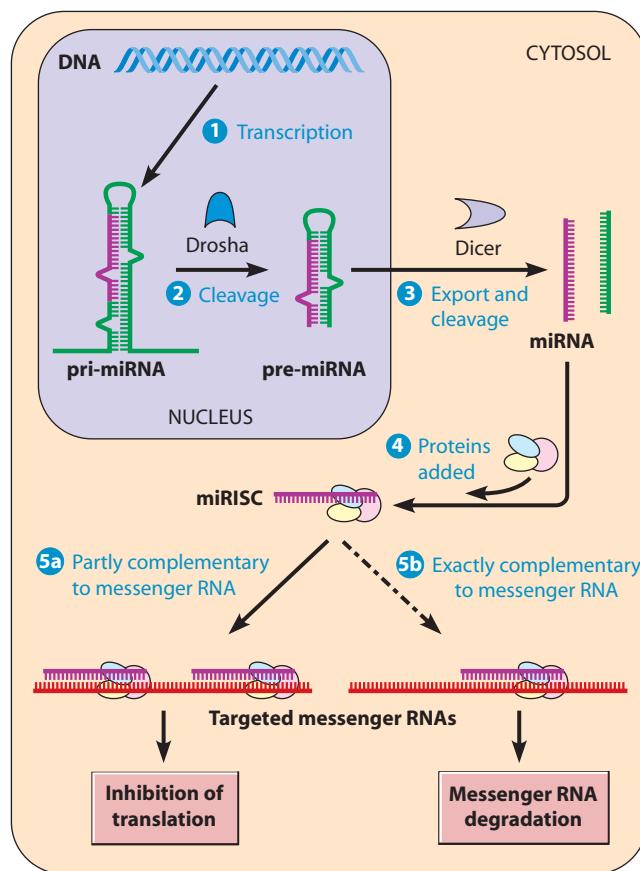

FIGURE 23–34 Translational Silencing by microRNAs.

MicroRNAs are produced by a multistep process in which ① a microRNA gene is first transcribed into a primary transcript (pri-miRNA) that folds into a hairpin loop. ② The nuclear enzyme Drosha cleaves pri-miRNA into a smaller (roughly 70 nucleotide) hairpin RNA (pre-miRNA), which is ③ exported from the nucleus and cleaved by Dicer to release a microRNA (miRNA) molecule that is 21–22 nucleotides long. ④ The miRNA then joins with RISC proteins to form an miRISC, which is directed by its miRNA to messenger RNAs containing sequences complementary to those in the miRNA. ⑤a Most commonly, multiple miRISCs bind to the same messenger RNA through partly complementary sequences and together inhibit translation. ⑤b Occasionally the miRNA is exactly complementary to a site within a particular messenger RNA, resulting in messenger RNA degradation by a mechanism similar to that observed with siRNAs.

The microRNA produced by each of these genes is capable of binding to target sites in about 200 different messenger RNAs, and many messenger RNAs are targeted by several microRNAs acting in combination. MicroRNAs appear to play important roles during embryonic development, especially in the formation of specialized cell types such as neurons, immune cells, and skeletal and heart muscle cells. One way of uncovering the developmental roles played by microRNAs has been to use the gene knockout technique (page 638) to eliminate specific microRNA genes from mouse embryos. In one such experiment, deleting a microRNA gene called *miR-1-2* led to severe heart defects that caused more than half the mice to die during embryonic development or within the first few

months of life. At least a dozen of the mRNAs targeted for regulation by the *miR-1-2* microRNA have been tentatively identified. Included in this group are mRNAs coding for transcription factors that regulate muscle cell development and an mRNA coding for a subunit of a potassium channel that helps maintain the resting membrane potential.

Posttranslational Control Involves Modifications of Protein Structure, Function, and Degradation

After translation of an mRNA molecule has produced a polypeptide chain, there are still many ways of regulating the activity of the polypeptide product. This brings us to the final level of controlling gene expression, namely, the various **posttranslational control** mechanisms that are available for modifying protein structure and function (see Figure 23-10, step 5). Included in this category are reversible structural alterations that influence protein function, such as protein phosphorylation and dephosphorylation, as well as permanent alterations such as proteolytic cleavage. Other posttranslational events subject to regulation include the guiding of protein folding by chaperone proteins, the targeting of proteins to intracellular or extracellular locations, and the interaction of proteins with regulatory molecules or ions, such as cAMP or Ca^{2+} . These kinds of posttranslational events are discussed elsewhere in other contexts, but we again mention them here to emphasize that the flow of information in the cell is not complete until a properly functioning gene product is available.

So far we have focused on control mechanisms that influence gene expression by affecting the rate of protein production from each gene. But the amount of any given protein present in a cell is influenced by its rate of degradation as well as its rate of production. Thus, regulating the rate of protein degradation is another important means for influencing gene expression.

The relative contributions made by the rates of protein synthesis and degradation in determining the final concentration of any protein in a cell are summarized by the equation

$$P = \frac{k_{\text{syn}}}{k_{\text{deg}}} \quad (23-1)$$

where P is the concentration of a given protein present, k_{syn} is the rate order constant for its synthesis, and k_{deg} is the rate order constant for its degradation. As we saw with mRNAs (p. 748), rate constants for degradation are often expressed in the form of a half-life. The half-lives of cellular proteins range from as short as a few minutes to as long as several weeks. Such differences in half-life can dramatically affect the ability of different proteins to respond to changing conditions.

A striking example is provided by the behavior of liver cells exposed to the steroid hormone cortisone, which stimulates the synthesis of various metabolic enzymes. When researchers examined the impact of cortisone on two liver enzymes involved in amino acid metabolism, *tryptophan pyrrolase* and *arginase*, they noticed a pronounced difference: The concentration of tryptophan pyrrolase quickly increased tenfold, whereas the concentration of arginase increased only slightly. At first glance, such data would seem to indicate that cortisone selectively stimulates the synthesis of tryptophan pyrrolase. In fact, cortisone stimulates the synthesis of both tryptophan pyrrolase and arginase to about the same extent. The explanation for the apparent paradox is that tryptophan pyrrolase has a much shorter half-life (larger k_{deg}) than does arginase. Using the mathematical relationship summarized in Equation 23-1, calculations show that the concentration of a protein exhibiting a short half-life (large k_{deg}) changes more dramatically in response to alterations in synthetic rate than does the concentration of a protein with a longer half-life. For this reason, enzymes that are important in metabolic regulation tend to have short half-lives, allowing their intracellular concentrations to be rapidly increased or decreased in response to changing conditions.

Although the factors determining the rates at which various proteins are degraded are not completely understood, it is clear that the process is subject to regulation. In rats deprived of food, for example, the amount of the enzyme arginase in the liver doubles within a few days without any corresponding change in the rate of arginase synthesis. The explanation for the observed increase is that the arginase degradation rate slows dramatically in starving rats. This effect is highly selective; most proteins are degraded more rapidly, not more slowly, in starving animals.

Ubiquitin Targets Proteins for Degradation by Proteasomes

The preceding example raises the question of how the degradation of individual proteins is selectively regulated. The most common method for targeting specific proteins for destruction is to link them to **ubiquitin**, a small protein chain containing 76 amino acids. Ubiquitin is joined to target proteins by a process that involves three components: a *ubiquitin-activating enzyme* (E1), a *ubiquitin-conjugating enzyme* (E2), and a *substrate recognition protein*, or *ubiquitin ligase* (E3). As shown in Figure 23-35, ubiquitin is first activated by attaching it to E1 in an ATP-dependent reaction. The activated ubiquitin is then transferred to E2 and subsequently linked, in a reaction facilitated by E3, to a lysine residue in a target protein. Additional molecules of ubiquitin are then added in sequence, forming short chains.

These ubiquitin chains serve as targeting signals that are recognized by large, protein-degrading structures called **proteasomes**. Proteasomes are the predominant proteases (protein-degrading enzymes) of the cytosol and

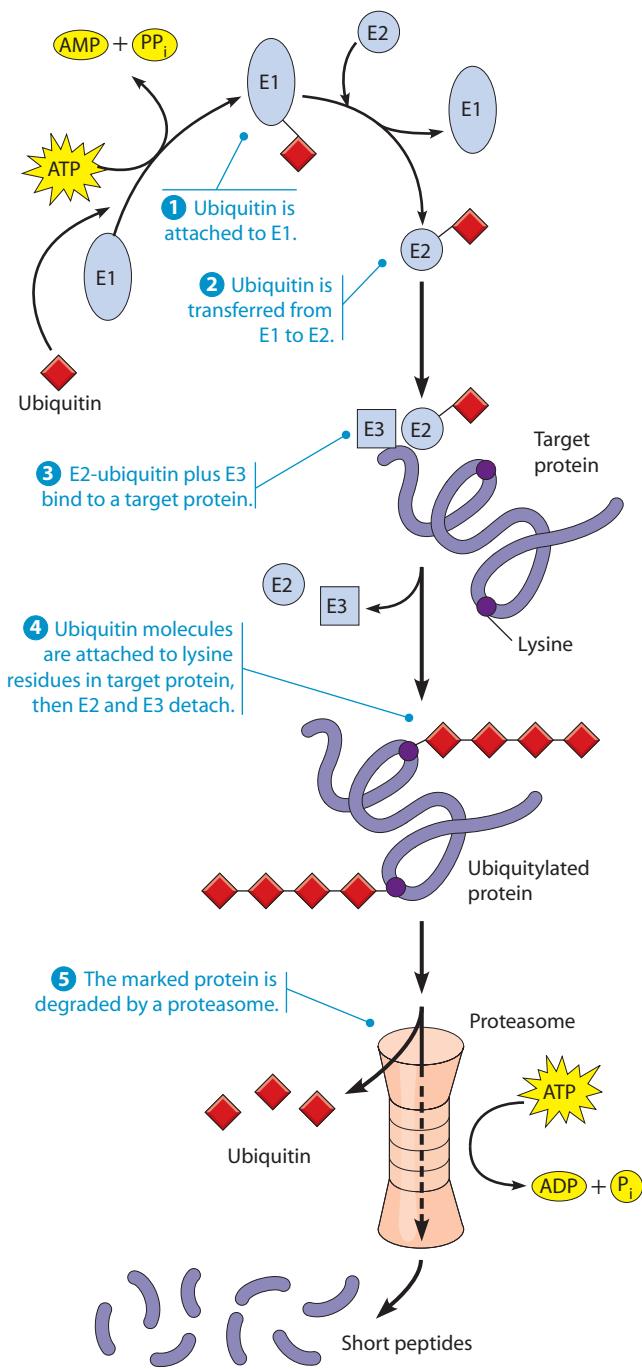

FIGURE 23-35 Ubiquitin-Proteasome System for Regulated Protein Degradation. Ubiquitin is attached to lysine in targeted proteins through the sequential action of a ubiquitin-activating enzyme (E1), a ubiquitin-conjugating enzyme (E2), and a ubiquitin ligase (E3). A proteasome then degrades the targeted protein into short peptides.

are often present in high concentration, accounting for up to 1% of all cellular protein. Each proteasome has a molecular weight of roughly 2 million and consists of half a dozen proteases associated with several ATPases and a binding site for ubiquitin chains. Shaped like a short cylinder, the proteasome binds to ubiquitylated proteins and removes their ubiquitin chains. The proteins are then

fed into the central channel of the proteasome and their peptide bonds are hydrolyzed in an ATP-dependent process, generating small peptide fragments that are released from the other end of the cylinder.

The key to regulating protein degradation lies in the ability to select particular proteins for ubiquitylation. This selectivity stems in part from the existence of multiple forms of E3, each directing the attachment of ubiquitin to different target proteins. One feature recognized by the various forms of E3 is the amino acid present at the N-terminus of a potential target protein. Some N-terminal amino acids cause proteins to be rapidly ubiquitylated and degraded; other amino acids make proteins less susceptible.

Internal amino acid sequences called **degrons** also allow particular proteins to be selected for destruction. For example, we saw in Chapter 19 that progression through the final stages of mitosis is controlled by the anaphase-promoting complex, which targets selected proteins, such as mitotic cyclin, for degradation. The anaphase-promoting complex accomplishes this task by functioning as a ubiquitin ligase (E3) that binds to target proteins containing a particular type of degron, promoting ubiquitylation of these target proteins by E2 and their subsequent degradation by proteasomes. Besides participating in such selective mechanisms for degrading specific proteins at appropriate times, proteasomes play a role in general, ongoing mechanisms for eliminating defective proteins from cells. It has been reported that up to 30% of newly synthesized proteins are defective and so are immediately tagged with ubiquitin, triggering their destruction by proteasomes.

In addition to ubiquitylation, proteins can undergo a related posttranslational modification, through the addition of *small ubiquitin-related modifiers* (SUMOs). These peptides are ubiquitin-like polypeptides that are conjugated to cellular proteins in a manner similar to ubiquitylation, using similar enzymes. SUMOylation appears to have numerous effects, including altering protein stability, movement into and out of the nucleus, and regulation of transcription factor function.

Although the ubiquitin-proteasome system is the primary mechanism used by cells for degrading proteins, it is not the only means available. You learned in Chapter 12 that lysosomes contain digestive enzymes that degrade all major classes of macromolecules, including proteins. Lysosomes can take up and degrade cytosolic proteins by an infolding of the lysosomal membrane, creating small vesicles that are internalized within the lysosome and broken down by the organelle's hydrolytic enzymes. This process of **microautophagy** tends to be rather nonselective in the proteins it degrades. The result is a slow, continual recycling of the amino acids found in most of a cell's protein molecules. Under certain conditions, however, such nonselective degradation of proteins would be detrimental to the cell. For example, during prolonged fasting, nonselective degradation of cellular proteins could lead to depletion of critical enzymes or regulatory

proteins. Under these conditions, lysosomes preferentially degrade proteins containing a targeting sequence that consists of glutamine flanked on either side by a tetrapeptide composed of very basic, very acidic, or very hydrophobic amino acids. Proteins exhibiting this sequence are targeted for selective degradation, presumably because they are dispensable to the cell.

A Summary of Eukaryotic Gene Regulation

You have now seen that eukaryotic gene regulation encompasses a broad array of control mechanisms operating at five distinct levels (refer again to Figure 23-10 for a visual summary). The first level of regulation, *genomic control*, includes DNA alterations (amplification, deletion, rearrangements, and methylation), chromatin decondensation and condensation, histone modifications such as methylation and acetylation, and changes in HMG proteins. The second level, *transcriptional control*, involves interactions between regulatory transcription factors and various types of DNA control elements, permitting specific genes to be turned on and off in different tissues and in response to changing conditions. The third level involves control of *RNA processing*

and *nuclear export* by mechanisms such as alternative splicing and regulated export of mRNAs through nuclear pores. The fourth level, *translational control*, includes mechanisms for modifying the activity of protein synthesis factors and for controlling the translation and degradation of specific mRNAs through the use of translational repressors and microRNAs. Finally, the fifth level involves various *posttranslational control* mechanisms for reversibly or permanently altering protein structure and function, as well as mechanisms for controlling protein degradation rates. Thus, when you read that a particular alteration in cellular function or behavior is based on a “change in gene expression,” you should understand that the underlying explanation might involve mechanisms operating at any one or more of these levels of control.

Because eukaryotes have larger genomes than prokaryotes do, and because they package their DNA into chromatin fibers that are separated from ribosomes by a nuclear envelope, several of the control mechanisms summarized in the preceding paragraph are truly unique to eukaryotes. Most of the control mechanisms discovered in eukaryotes, however, have counterparts in at least some prokaryotes as well.

SUMMARY OF KEY POINTS

Bacterial Gene Regulation

- Rather than being active at all times, most genes are expressed as needed. In bacteria, genes with related functions are often clustered into operons that can be turned on and off in response to changing cellular needs.
- Operons that encode catabolic enzymes are generally inducible—that is, their transcription is turned on by the presence of substrate. Operons that encode anabolic enzymes are typically repressible; transcription is turned off in the presence of end-product. Both types of regulation involve allosteric repressor proteins that bind to the operator and prevent transcription. Some operons also have control sites where the binding of activator proteins, such as catabolite activator protein (CAP), can activate transcription.
- Certain operons, such as those for amino acid biosynthesis, produce mRNAs with a leader sequence that attenuates transcription when the corresponding amino acid is available. Leader sequences in mRNAs may also contain riboswitches that bind to small molecules, thereby altering hairpin loop configurations that affect the termination of transcription or the initiation of translation.

Eukaryotic Gene Regulation: Genomic Control

- Most of the cells in a multicellular organism contain the same genes, although amplification, deletion, rearrangement, and

epigenetic regulation via methylation can cause localized changes in DNA sequence and expression.

- Gene transcription is associated with uncoiling of chromatin fibers. A histone code consisting of various combinations of methyl, acetyl, and phosphate groups is read by other proteins as a set of signals for modifying chromatin structure and gene activity.

Eukaryotic Gene Regulation: Transcriptional Control

- The initiation of eukaryotic transcription is controlled by regulatory transcription factors that bind to DNA control sequences, including proximal control elements that lie close to the core promoter and enhancers and silencers that act at distances up to several hundred thousand base pairs away from the promoter. Enhancers do not act on the promoter itself but instead bind to activator proteins, which in turn interact with coactivator proteins, including Mediator, that loosen chromatin packing and serve as a bridge to the RNA polymerase complex at the promoter.
- DNA response elements allow nonadjacent genes to be regulated in a coordinated fashion. For example, hormone response elements coordinate the expression of genes activated by specific hormones, and the heat-shock response element coordinates the expression of genes activated by elevated temperatures and other stresses.

Eukaryotic Gene Regulation: Posttranscriptional Control

- Eukaryotes utilize a diverse array of posttranscriptional control devices, including alternative splicing to generate multiple mRNAs from the same gene; general, as well as mRNA-specific, mechanisms to regulate translation and degradation of mRNA; and posttranslational modifications of protein structure, activity, and degradation.

- Proteins that bind to specific DNA and RNA sequences play a key role in many of the mechanisms used by cells for controlling the expression of specific genes. In addition, two classes of small RNA molecules (siRNAs and microRNAs) regulate the expression of specific genes through a process known as RNA interference. By binding to complementary sequences in specific messenger RNAs (or in some cases, DNA), these small RNAs silence the translation and/or transcription of individual genes.

MAKING CONNECTIONS

In Chapters 18 through 22, you learned how genetic information contained in molecules of DNA is stored, replicated, and transcribed into messenger RNA, which in turn directs the synthesis of specific proteins. This chapter has shown how these steps can be regulated in ways that allow cells to precisely control the expression of individual genes and the proteins they produce. Some of the mechanisms used for controlling gene expression are triggered by changes in intracellular conditions. Other mechanisms are responses to extracellular molecules whose effects on gene expression are mediated by signal transduction pathways, as described in Chapter 14. The various approaches

for controlling gene expression help ensure that the amount and activity of each protein in a cell are carefully coordinated with the needs of that cell and (for multicellular organisms) with the needs of the organism the cell resides in. Since proteins are responsible for most of the properties we associate with living cells and organisms, disruptions in any of the steps involved in storing and expressing genetic information may have dire consequences. In the next and final chapter, we will see how such disruptions can lead to the formation of cancer cells that threaten the very existence of the organism in which they arise.

PROBLEM SET

More challenging problems are marked with a •.

23-1 Laboring with lac. Most of what we know about the *lac* operon of *E. coli* has come from genetic analysis of various mutants. In the following list are the genotypes of seven strains of *E. coli*. For each strain, indicate whether the *Z* gene product will be expressed in the presence of lactose and whether it will be expressed in the absence of lactose. Explain your reasoning in each case.

- (a) $I^+P^+O^+Z^+$
- (b) $I^sP^+O^+Z^+$
- (c) $I^+P^+O^cZ^+$
- (d) $I^-P^+O^+Z^+$
- (e) $I^sP^+O^cZ^+$
- (f) $I^+P^-O^+Z^+$
- (g) Same as part a, but with glucose present

23-2 The Pickled Prokaryote. *Pickelensia hypothetica* is an imaginary prokaryote that converts a wide variety of carbon sources to ethanol when cultured anaerobically in the absence of ethanol. When ethanol is added to the culture medium, however, the organism obligingly shuts off its own production of ethanol and makes lactate instead. Several mutant strains of *Pickelensia* have been isolated that differ in their ability to synthesize ethanol. Class I mutants cannot synthesize ethanol at all. Mutations of this type map at two loci, *A* and *B*. Class II mutants, on the other hand, are constitutive for ethanol synthesis: They continue to produce ethanol whether it is present

in the medium or not. Mutations of this type map at loci *C* and *D*. Strains of *Pickelensia* constructed to be diploid for the ethanol operon have the following genotypes and phenotypes:

$$\begin{array}{ll} A^+B^-C^+D^+/A^-B^+C^+D^+ & \text{inducible} \\ A^+B^+C^+D^-/A^+B^+C^+D^+ & \text{inducible} \\ A^+B^+C^+D^+/A^+B^+C^-D^+ & \text{constitutive} \end{array} \quad (23-2)$$

- (a) Identify each of the four genetic loci of the ethanol operon.
- (b) Indicate the expected phenotype for each of the following partially diploid strains:

- i. $A^-B^+C^+D^+/A^-B^+C^+D^-$
- ii. $A^+B^-C^+D^+/A^-B^+C^+D^-$
- iii. $A^+B^+C^+D^-/A^-B^-C^-D^+$
- iv. $A^-B^+C^-D^+/A^+B^-C^+D^+$

- **23-3 Regulation of Bellicose Catabolism.** The enzymes bellicose kinase and bellicose phosphate dehydrogenase are coordinately regulated in the bacterium *Hokus focus*. The genes encoding these proteins, *belA* and *belB*, are contiguous segments on the genetic map of the organism. In her pioneering work on this system, Professor Jean X. Pression established that the bacterium can grow with the monosaccharide bellicose as its only carbon and energy source, that the two enzymes involved in bellicose catabolism are synthesized by the bacterium only when bellicose is present in the medium, and that enzyme production is turned off in the presence of glucose. She identified a number of mutations that reduce or eliminate enzyme production and showed these could be grouped into

two classes. Class I mutants are in *cis*-acting elements, whereas those in class II all map at a distance from the genes coding for the enzymes and are *trans*-acting. Thus far, the only constitutive mutations Pression has found are deletions that connect *belA* and *belB* to new DNA at the upstream side of *belA*. The following is a list of conclusions she would like to draw from her observations. Indicate in each case whether the conclusion is consistent with the data (C), inconsistent with the data (I), or irrelevant to the data (X).

- (a) Bellicose can be metabolized by *H. focus* cells to yield ATP.
- (b) Enzyme production by genes *belA* and *belB* is under positive control.
- (c) Phosphorylation of bellicose makes the sugar less permeable to transport across the plasma membrane.
- (d) The operator for the bellicose operon is located upstream from the promoter.
- (e) Some of the mutations in class I may be in the promoter.
- (f) Some of the mutations in class II may be in the operator.
- (g) Class II mutations may include mutations in the gene that encodes CAP.
- (h) The constitutive deletion mutations connect genes *belA* and *belB* to a new promoter.
- (i) Expression of the bellicose operon is subject to regulation by attenuation.

23-4 Attenuation in 25 Words or Less. Complete each of the following statements about attenuation of the *trp* operon of *E. coli* in 25 words or less.

- (a) The leader sequence can be considered to be a *conditional terminator* because . . .
- (b) When the gene product of the operon is not needed, the 5' end of the mRNA forms a secondary structure that . . .
- (c) Implicit in our understanding of the mechanism of attenuation is the assumption that ribosomes follow RNA polymerase very closely. This "tailgating" is essential to the model because . . .
- (d) Measurements of rates of synthesis indicate that translation normally proceeds faster than transcription. This supports the proposed mechanism for attenuation because . . .
- (e) If the operon encoding the enzymes in the biosynthetic pathway for amino acid X is subject to this type of attenuation, the leader sequence probably encodes a polypeptide that . . .
- (f) Attenuation makes sense as a mechanism for regulating operons that code for enzymes involved in amino acid biosynthesis because . . .
- (g) Attenuation of this type is not a likely mechanism for regulating gene expression in eukaryotes because . . .

23-5 Positive and Negative Control. Assume you have a culture of *E. coli* cells growing on medium B, which contains both lactose and glucose. At time *t*, 33% of the cells are transferred to medium L, which contains lactose but not glucose; 33% are transferred to medium G, which contains glucose but not lactose; and the remaining cells are left in medium B. For each of the following statements, indicate with an L if it is true of the cells transferred to medium L, with a G if it is true of the cells transferred to medium G, with a B if it is true of the cells

left in medium B, and with an N if it is true of none of the cells. In some cases, more than one letter may be appropriate.

- (a) The rate of glucose consumption per cell is approximately the same after time *t* as before.
- (b) The rate of lactose consumption is higher after time *t* than before.
- (c) The intracellular cAMP level is lower after time *t* than before.
- (d) Most of the *lac* operator sites have *lac* repressor proteins bound to them.
- (e) Most of the catabolite activator proteins exist as CAP-cAMP complexes.
- (f) Most of the *lac* repressor proteins exist as repressor-glucose complexes.
- (g) The rate of transcription of the *lac* operon is greater after time *t* than before.
- (h) The *lac* operon has both CAP and the repressor protein bound to it.

23-6 Enhancers. An enhancer may increase the frequency of transcription initiation for its associated gene when . . . (Indicate true or false for each statement, and explain your answer.)

- (a) . . . it is located 1000 nucleotides upstream of the gene's core promoter.
- (b) . . . it is in the gene's coding region.
- (c) . . . no promoter is present.
- (d) . . . it causes looping out of the intervening DNA.
- (e) . . . it causes alternative splicing of the DNA.

23-7 Gene Amplification. The best-studied example of gene amplification involves the genes coding for ribosomal RNA during oogenesis in *Xenopus laevis*. The unamplified number of ribosomal RNA genes is about 500 per haploid genome. After amplification, the oocyte contains about 500,000 ribosomal RNA genes per haploid genome. This level of amplification is apparently necessary to allow the egg cell to synthesize the 10^{12} ribosomes that accumulate during the two months of oogenesis in this species. Each ribosomal RNA gene consists of about 13,000 base pairs, and the genome size of *Xenopus* is about 2.7×10^9 base pairs per haploid genome.

- (a) What fraction of the total haploid genome do the 500 copies of the ribosomal RNA genes represent?
- (b) What is the total size (in base pairs) of the genome after amplification of the ribosomal RNA genes? What proportion of this do the amplified ribosomal RNA genes represent?
- (c) Assume that all the ribosomal RNA genes in the amplified oocyte are transcribed continuously to generate the number of ribosomes needed during the two months of oogenesis. How long would oogenesis have to extend if the genes had not been amplified?
- (d) Why do you think genes have to be amplified when the gene product needed by the cell is an RNA but not usually when the desired gene product is a protein?

• **23-8 Steroid Hormones.** Steroid hormones are known to increase the expression of specific genes in selected target cell types. For example, testosterone increases the production of a

protein called α 2-microglobulin in the liver, and hydrocortisone (a type of glucocorticoid) increases the production of the enzyme tyrosine aminotransferase in the liver.

- (a) Based on your general knowledge of steroid hormone action, explain how these two steroid hormones are able to selectively influence the production of two different proteins in the same tissue.
- (b) Prior to the administration of testosterone or hydrocortisone, liver cells are exposed to either puromycin (an inhibitor of protein synthesis) or α -amanitin (an inhibitor of RNA polymerase II). How would you expect such treatments to affect the actions of testosterone and hydrocortisone?
- (c) Suppose you carry out a domain-swap experiment in which you use recombinant DNA techniques to exchange the zinc finger domains of the testosterone receptor and glucocorticoid receptors with each other. What effects would you now expect testosterone and hydrocortisone to have in cells containing these altered receptors?
- (d) If recombinant DNA techniques are used to substitute a testosterone response element for the glucocorticoid response element that is normally located adjacent to the tyrosine aminotransferase gene in liver cells, what effects would you expect testosterone and hydrocortisone to have in such genetically altered cells?

23-9 Homeotic Genes in *Drosophila*. Homeotic genes are considered crucial to early development in *Drosophila* because . . . (Indicate true or false for each statement, and explain your answer.)

- (a) . . . they encode proteins containing zinc finger domains.
- (b) . . . mutations in homeotic genes are always lethal.
- (c) . . . they control the expression of many other genes required for development.
- (d) . . . homeodomain proteins act by influencing mRNA degradation.

23-10 Hox Genes in Mammals. *Hox* genes are known to influence the identity of body parts in mammals, similar to their role in flies. Mario Capecchi's laboratory has made many knockout mouse strains in which individual *Hox* genes are knocked out. The phenotype of many of these knockouts is extremely mild, especially when compared with the corresponding mutants in flies, which often die. How can you explain this difference?

• **23-11 Protein Degradation.** You learned in Chapter 19 that mitotic cyclin is an example of a protein that is selectively degraded at a particular point in the cell cycle, namely the onset of anaphase. Suppose that you use recombinant DNA techniques to create a mutant form of mitotic cyclin that is not degraded at the onset of anaphase.

- (a) Sequence analysis of the mutant mitotic cyclin shows that it is missing a stretch of nine amino acids near one end of the molecule. Based on this information, discuss at least three possible explanations of why this form of mitotic cyclin is not degraded at the onset of anaphase.
- (b) What kinds of experiments could you carry out to distinguish among these various possible explanations?
- (c) Suppose that you discover cells containing a mutation in a second protein and learn that this mutation also prevents mitotic cyclin from being degraded at the onset of mitosis, even when mitotic cyclin is normal. The degradation of other proteins appears to proceed normally in such cells. A mutation in what kind of protein might explain such results?

23-12 Levels of Control. Assume liver and kidney tissues from the same mouse each contain about 10,000 species of cytosolic mRNA, but only about 25% of these are common to the two tissues.

- (a) Suggest an experimental approach that might be used to establish that some of the mRNA molecules are common to both tissues, but others are not.
- (b) One possible explanation for the data is that differential transcription occurs in liver and kidney nuclei. What is another possible explanation? Describe an experiment that would enable you to distinguish between these possibilities.
- (c) If all mRNA molecules had been shown to be common to both liver and kidney and yet the two tissues were known to be synthesizing different proteins, what level of control would you have to assume was operating?

• **23-13 More About Levels of Control.** If sea urchin zygotes are exposed to *actinomycin D*, an inhibitor of RNA synthesis, during the early stages of embryonic development, protein synthesis and development continue until the embryos form a hollow ball of cells, or blastula, with hundreds of cells. However, if the same inhibitor is added later during embryonic development, protein synthesis is severely depressed and normal embryonic development halts. How might you explain these observations?

Cancer Cells

Anyone familiar with the events occurring inside living cells must feel a sense of awe at the complexities involved. Given the vast number of activities that need to be coordinated in every cell, it is not surprising that malfunctions occasionally arise. Cancer—the second-leading cause of death after cardiovascular disease—is a prominent example of a disease that arises from such abnormalities in cell function. If current trends continue, almost half the population of the United States will eventually develop some form of the disease and cancer will become the most common cause of death.

Although our understanding of the cellular defects that underlie cancer is still incomplete, we now know that gene mutations and changes in gene expression play a central role. In this chapter we will see how these genetic changes contribute to the aberrant properties of cancer cells. As we do so, it will become apparent that explaining the behavior of cancer cells requires an intimate knowledge of how normal cells behave and, conversely, that investigating the biology of cancer cells has deepened our understanding of normal cells.

Uncontrolled Cell Proliferation and Survival

The term *cancer*, which means “crab” in Latin, was coined by Hippocrates in the fifth century B.C. to describe diseases in which tissues grow and spread unrestrained throughout the body, eventually choking off life. Cancers can originate in almost any organ. Depending on the cell type involved, they are grouped into several different categories. **Carcinomas**, which account for about 90% of all cancers, arise from the *epithelial cells* that cover external and internal body surfaces. Lung, breast, and colon cancer are the most frequent cancers of this type. **Sarcomas** develop from supporting tissues such as bone, cartilage, fat, and muscle. Finally, **lymphomas** and **leukemias** arise from

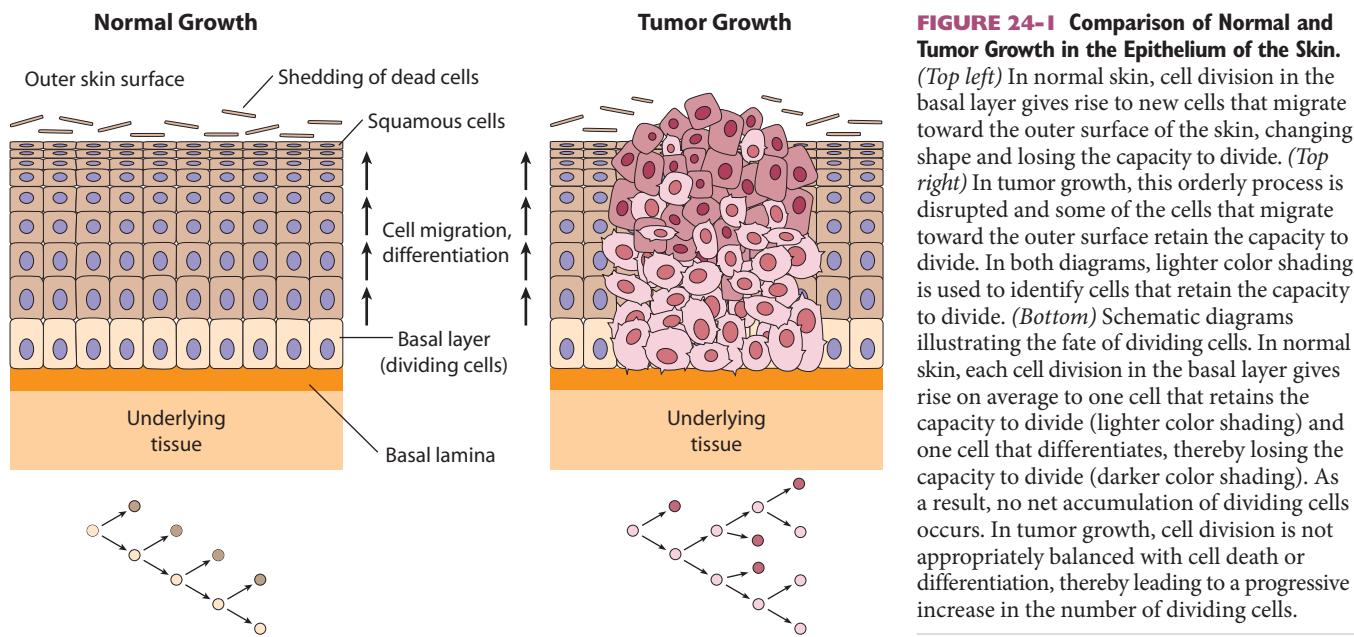

cells of blood and lymphatic origin, with the term *lymphoma* being used for tumors that grow as solid masses of tissue and the term *leukemia* being reserved for cases in which the cancer cells proliferate mainly in the bloodstream.

Based on such differences in their sites of origin and the specific cell type involved, more than a hundred different types of cancer can be distinguished from one another. But no matter where cancer arises and what cell type is involved, the danger posed by the disease comes from a combination of two properties: the ability of cells to proliferate in an uncontrolled way and their ability to spread through the body. We will begin the chapter by describing these two properties that make cancer a potentially lethal disease.

Tumors Arise When the Balance Between Cell Division and Cell Differentiation or Death Is Disrupted

A cancer is an abnormal type of tissue growth in which some cells divide and accumulate in an uncontrolled, relatively autonomous way, leading to a progressive increase in the number of dividing cells. The resulting mass of growing tissue is called a **tumor** (or *neoplasm*). Although tumors have escaped from the normal controls on cell proliferation, tumor cells do not always divide more rapidly than normal cells. The crucial issue is not the rate of cell division but rather the balance between cell division and cell differentiation or cell death.

Cell differentiation is the process by which cells acquire the specialized properties that distinguish different types of cells from each other (page 722). As cells acquire these specialized traits, they generally lose the capacity to divide. To illustrate, let us briefly consider cell division and differentiation in the skin, where new cells continually replace aging cells that are being shed from the outer body surfaces. The new replacement cells are generated by cell divisions occurring in the *basal layer* of the skin

(**Figure 24-1, left**). On average, each time a basal cell divides, it gives rise to two cells with different fates. One cell stays in the basal layer and retains the capacity to divide, whereas the other cell loses the capacity to divide and differentiates as it leaves the basal layer and moves toward the outer skin surface. During the differentiation process, the migrating cell gradually flattens and begins to make *keratin*, the structural protein that imparts mechanical strength to the outer layers of the skin. Eventually the cell dies and is shed from the outer skin surface.

Thus in normal skin, one of the two cells produced by each cell division retains the ability to divide, while the other cell leaves the basal layer, loses the capacity to divide, and finally dies. This arrangement ensures that there is no increase in the number of dividing cells. The cell divisions occurring in the basal layer simply generate new cells to replace the ones that are continually being lost from the outer skin surface. A similar phenomenon occurs in bone marrow, where cell division creates new blood cells to replace the aging blood cells that are being destroyed. It also occurs in the gastrointestinal tract lining, where cell division creates new cells to replace the ones being shed from the inner surface of the stomach and intestines. In each of these situations, cell division is carefully balanced with cell differentiation and death so that no net accumulation of dividing cells takes place.

In tumors, this finely balanced arrangement is disrupted and cell division is uncoupled from cell differentiation and death. As a result, some cell divisions give rise to two cells that both continue to divide, thereby feeding a progressive increase in the number of dividing cells (see Figure 24-1, right). If the cells are dividing rapidly, the tumor will grow quickly; if the cells are dividing more slowly, tumor growth will be slower. But regardless of how fast or slow the cells divide, the tumor will continue to grow because new cells are being produced in greater numbers than

FIGURE 24-1 Comparison of Normal and Tumor Growth in the Epithelium of the Skin.

(Top left) In normal skin, cell division in the basal layer gives rise to new cells that migrate toward the outer surface of the skin, changing shape and losing the capacity to divide. (Top right) In tumor growth, this orderly process is disrupted and some of the cells that migrate toward the outer surface retain the capacity to divide. In both diagrams, lighter color shading is used to identify cells that retain the capacity to divide. (Bottom) Schematic diagrams illustrating the fate of dividing cells. In normal skin, each cell division in the basal layer gives rise on average to one cell that retains the capacity to divide (lighter color shading) and one cell that differentiates, thereby losing the capacity to divide (darker color shading). As a result, no net accumulation of dividing cells occurs. In tumor growth, cell division is not appropriately balanced with cell death or differentiation, thereby leading to a progressive increase in the number of dividing cells.

needed. As the dividing cells accumulate, the normal organization and function of the tissue gradually become disrupted.

Based on differences in their growth patterns, tumors are classified as either benign or malignant. **Benign tumors** grow in a confined local area and are rarely dangerous. In contrast, **malignant tumors** are capable of invading surrounding tissues, entering the bloodstream, and spreading to distant parts of the body. The term **cancer** refers to any malignant tumor—that is, any tumor that can spread from its original location to other sites. Because the ability to grow in an uncontrolled way and spread to distant locations makes cancer a potentially life-threatening disease, it is important to understand the mechanisms that give rise to these traits.

Cancer Cell Proliferation Is Anchorage Independent and Insensitive to Population Density

Cancer cell proliferation exhibits several traits that distinguish it from normal cell proliferation. One trait, of course, is the ability to form tumors. This trait can be demonstrated experimentally by injecting cells into *nude mice*, which lack a functional immune system that would normally attack and destroy foreign cells. Normal human cells injected into such animals will not grow, whereas cancer cells will proliferate and form tumors.

Cancer cells also exhibit other growth properties that distinguish them from normal cells. For example, normal cells don't grow well in culture if they are suspended in a liquid medium or in a semisolid material such as soft agar. But when provided with a solid surface they can attach to, normal cells become anchored to the surface, spread out, and begin to proliferate. In contrast, cancer cells grow well not only when they are anchored to a solid surface but

also when they are freely suspended in a liquid or semi-solid medium. Cancer cells are therefore said to exhibit **anchorage-independent growth**.

When growing in the body, most normal cells meet the anchorage requirement by binding to the extracellular matrix through cell surface proteins called *integrins* (page 494). If attachment to the matrix is prevented using chemicals that block the binding of integrins to the matrix, normal cells usually lose the ability to divide and often self-destruct by *apoptosis* (a type of cell death described on page 591). Triggering apoptosis in the absence of proper anchorage is one of the safeguards that prevents normal cells from floating away and setting up housekeeping in another tissue. Because cancer cells are anchorage independent, they circumvent this safeguard.

Cancer cells also differ from normal cells in their response to crowded conditions in culture. When normal cells are grown in culture, they divide until the surface of the culture vessel is covered by a single layer of cells. Once this *monolayer stage* is reached, cell division stops—a phenomenon referred to as **density-dependent inhibition of growth**. Cancer cells exhibit reduced sensitivity to density-dependent inhibition of growth and thus do not stop dividing when they reach the monolayer stage. Instead, cancer cells continue to divide and gradually begin piling up on one another.

Cancer Cells Are Immortalized by Mechanisms That Maintain Telomere Length

When most normal cells are grown in culture, they divide a limited number of times. For example, freshly isolated human fibroblasts divide about 50–60 times in culture and then stop dividing, undergo various degenerative changes, and may even die (**Figure 24-2**). Under similar conditions, cancer cells exhibit no such limit and continue dividing indefinitely, behaving as if they were immortal. A striking example is provided by *HeLa cells*, which were obtained in 1951 from a uterine cervical cancer that had been surgically removed from a woman named Henrietta

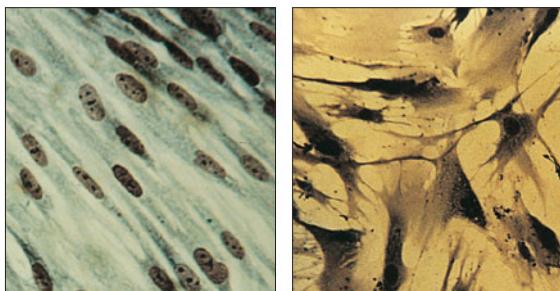

FIGURE 24-2 Microscopic Appearance of Young and Old Human Fibroblasts. (Left) Young fibroblasts that have divided only a few times in culture exhibit a thin, elongated shape. (Right) After dividing about 50 times, the cells stop dividing and undergo degenerative changes. Note the striking difference in appearance between the young (dividing) and older (nondividing) cells.

Lacks (hence the term *HeLa* cells). Although she died of cancer that same year, some of her tumor cells had been placed in culture after surgery. These cancer cells began to proliferate and have continued to do so for over 50 years, dividing more than 20,000 times with no signs of stopping.

Why can cancer cells divide indefinitely in culture when most normal human cells divide only 50–60 times? The answer is related to the telomeric DNA sequences that are lost from the ends of each chromosome every time DNA replicates (page 565). If a normal cell divides too many times, its telomeres become too short to protect the ends of the chromosomes and a pathway is triggered that halts cell division (and may even destroy the cell by apoptosis). This response to telomere shortening prevents excessive proliferation of adult cells and helps explain why normal fibroblasts divide only 50–60 times in culture.

In cancer cells, the telomere-imposed limit is overcome by mechanisms that replenish some of the missing telomere sequences. Most cancer cells accomplish this feat by producing *telomerase*, the enzyme that adds telomeric DNA sequences to the ends of DNA molecules (page 565). An alternative mechanism for maintaining telomere length employs enzymes that exchange DNA sequence information between chromosomes. By one mechanism or the other, cancer cells maintain telomere length above a critical threshold and thereby retain the capacity to divide indefinitely.

Defects in Signaling Pathways, Cell Cycle Controls, and Apoptosis Contribute to Uncontrolled Proliferation

Mechanisms that maintain telomere length play a permissive role in allowing cancer cells to continue dividing, but they do not actually cause cells to divide. The defects driving the uncontrolled proliferation of cancer cells can be traced to a variety of signaling pathways and control mechanisms that normally maintain the proper balance between cell division and death. For example, you learned in Chapters 14 and 19 that cell proliferation is regulated by protein *growth factors* that bind to cell surface receptors and activate signaling pathways within the targeted cells. While cells do not usually divide unless they are stimulated by the proper growth factor, cancer cells circumvent this restraining mechanism through alterations in signaling pathways (to be described shortly) that create a constant signal to divide.

Disruptions in cell cycle control also contribute to the unrestrained proliferation of cancer cells. In Chapter 19 we saw that the commitment to proceed through the cell cycle is made at the *restriction point*, which controls progression from G1 into S phase. If normal cells are grown under suboptimal conditions (for example, insufficient growth factors, high cell density, lack of anchorage, or inadequate nutrients), the cells become arrested at the restriction point and stop dividing. In comparable situa-

tions, cancer cells continue to proliferate; if conditions are extremely adverse, as occurs with extreme nutritional deprivation, they eventually die at random points in the cell cycle rather than arresting in G1. This abnormal behavior occurs because cell cycle controls do not function properly in cancer cells. Besides failing to respond appropriately to external signals, cancer cells are also unresponsive to internal conditions, such as DNA damage, that would normally trigger checkpoint mechanisms to halt the cell cycle.

Another factor influencing the growth of cancers is the rate at which cells die. If the normal mechanisms for triggering cell death are disrupted, proliferating cells will accumulate faster than they do when cell death is occurring at an appropriate rate. Cell death is controlled mainly by pathways that trigger apoptosis to get rid of unnecessary or defective cells. Since cancer cells fit the definition of unnecessary or defective cells—that is, they grow in an uncontrolled way and exhibit DNA and chromosomal damage—why aren't cancer cells killed by apoptosis? The answer is that cancer cells have various ways of blocking the pathways that trigger apoptosis; this allows them to survive and proliferate under conditions that would normally cause cell death. For certain kinds of cancer, uncontrolled growth arises primarily from a failure to undergo apoptosis rather than increased cell division.

How Cancers Spread

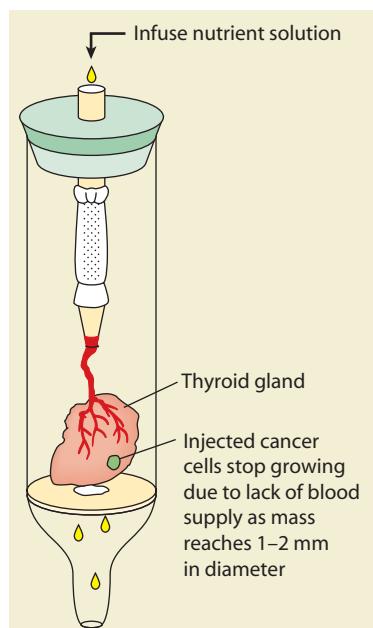

Although uncontrolled proliferation is a defining feature of cancer cells, it is not the property that makes cancer so dangerous. After all, the cells of benign tumors also

proliferate in an uncontrolled way, but such tumors remain in their original location and are usually easy to remove (unless they arise in surgically inaccessible locations). The hazards posed by cancer cells come from uncontrolled proliferation *combined with* the ability to spread throughout the body, which makes complete surgical removal impractical. Roughly 90% of all cancer deaths are caused by the spread of cancer rather than by the primary tumor itself. We will now examine the mechanisms that make this spreading of cancer cells possible.

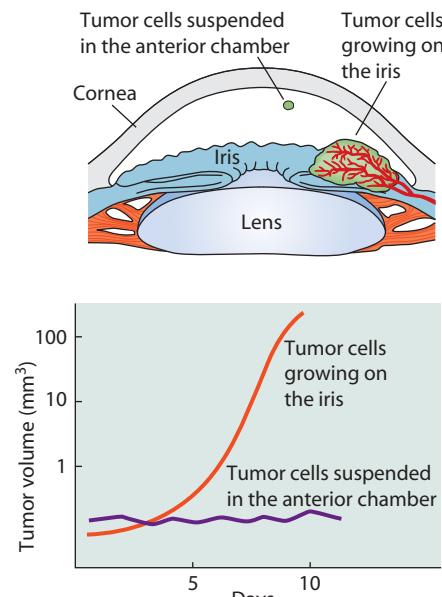

Angiogenesis Is Required for Tumors to Grow Beyond a Few Millimeters in Diameter

For more than 100 years, scientists have known that tumors possess a dense network of blood vessels. Initially these were thought to be preexisting vessels that had expanded in response to the tumor's presence or were part of an inflammatory response designed to defend the host against the tumor. But in 1971, Judah Folkman proposed a new idea regarding the role of these blood vessels. He suggested that tumors release signaling molecules that trigger **angiogenesis**—that is, growth of blood vessels—in the surrounding host tissues, and that these new vessels are required for tumors to grow beyond a tiny, localized clump of cells.

This idea initially emerged from studies involving cancer cells grown in isolated organs under artificial laboratory conditions. In one experiment, a normal thyroid gland was removed from a rabbit and placed in a glass chamber, a small number of cancer cells were injected into the gland, and a nutrient solution was pumped into the organ to keep it alive (**Figure 24-3a**). Under these

(a) Cancer cells grown in an isolated thyroid gland

(b) Cancer cells grown on the iris or in the anterior chamber of the eye

FIGURE 24-3 Two Experiments Showing the Requirement for Angiogenesis. (a) Cancer cells were injected into an isolated rabbit thyroid gland that was kept alive by pumping a nutrient solution into its main blood vessel. The tumor cells fail to link up to the organ's blood vessels, and the tumor stops growing when it reaches a diameter of roughly 1–2 millimeters. (b) Cancer cells were either injected into the liquid-filled anterior chamber of a rabbit's eye, where there are no blood vessels, or they were placed directly on the iris. Tumor cells in the anterior chamber, nourished solely by diffusion, remain alive but stop growing before the tumor reaches a millimeter in diameter. In contrast, blood vessels quickly infiltrate the cancer cells implanted on the iris, allowing the tumors to grow to thousands of times their original mass. Tumor angiogenesis in a living mouse

conditions, the cancer cells divided for a few days but suddenly stopped growing when the tumor reached a diameter of 1–2 mm. Virtually every tumor stopped growing at exactly the same size, suggesting that some kind of limitation allowed them to grow only so large.

When tumor cells were removed from the thyroid gland and injected back into animals, cell division resumed and massive tumors developed. Why did the tumors stop growing at a tiny size in the isolated thyroid gland and yet grow in an unrestrained way in live animals? On closer examination, a possible explanation became apparent. The tiny tumors, alive but dormant in the isolated thyroid gland, had failed to link up with the organ's blood vessels. As a result, the tumors stopped growing when they reached a diameter of 1–2 mm. When injected into live animals, these same tumors became infiltrated with blood vessels and grew to an enormous size.

To test the idea that blood vessels are needed to sustain tumor growth, Folkman implanted cancer cells in the anterior chamber of a rabbit's eye, where there is no blood supply. As shown in Figure 24-3b, these cancer cells survived and formed tiny tumors. But blood vessels from the nearby iris could not reach the cells and the tumors soon stopped growing. When the same cells were implanted directly on the iris tissue, blood vessels from the iris quickly infiltrated the tumor cells and each tumor grew to thousands of times its original size. Once again, it appeared that tumors need a blood supply to grow beyond a tiny mass.

Blood Vessel Growth Is Controlled by a Balance Between Angiogenesis Activators and Inhibitors

If tumors require blood vessels to sustain their growth, how do they ensure that this need is met? The first hint came from studies in which cancer cells were placed inside a chamber surrounded by a filter possessing tiny pores that cells cannot pass through. When such chambers are implanted into animals, new capillaries proliferate in the surrounding host tissue. In contrast, normal cells placed in the same type of chamber do not stimulate blood vessel growth. Such results suggest that cancer cells produce molecules that diffuse through the tiny pores in the filter and activate angiogenesis in the surrounding host tissue.

Subsequent investigations have revealed that the main angiogenesis-activating molecules are proteins called *vascular endothelial growth factor* (*VEGF*) and *fibroblast growth factor* (*FGF*). *VEGF* and *FGF* are produced by many kinds of cancer cells, as well as by certain normal cells. When cancer cells release these proteins into the surrounding tissue, they bind to receptor proteins on the surface of the *endothelial cells* that form the lining of blood vessels. This binding activates a signaling pathway that causes the endothelial cells to divide and to secrete protein-degrading enzymes called *matrix metalloproteinases*

(*MMPs*). The *MMPs* break down the extracellular matrix, thereby permitting the endothelial cells to migrate into the surrounding tissues. As they migrate, the proliferating endothelial cells become organized into hollow tubes that develop into new blood vessels.

Although many tumors produce *VEGF* and/or *FGF*, these signaling molecules are not the sole explanation for the activation of angiogenesis. For angiogenesis to proceed, these molecules must overcome the effects of angiogenesis *inhibitors* that normally restrain the growth of blood vessels. More than a dozen naturally occurring inhibitors of angiogenesis have been identified, including the proteins *angiostatin*, *endostatin*, and *thrombospondin*. A finely tuned balance between the concentration of angiogenesis inhibitors and angiogenesis activators determines whether a tumor will induce the growth of new blood vessels. When tumors trigger angiogenesis, it is usually accomplished by an increase in the production of angiogenesis activators and a simultaneous decrease in the production of angiogenesis inhibitors.

Cancer Cells Spread by Invasion and Metastasis

Once angiogenesis has been triggered at an initial tumor site, the stage is set for the cancer cells to spread throughout the body. This ability to spread is based on two distinct mechanisms: invasion and metastasis. **Invasion** refers to the direct migration and penetration of cancer cells into neighboring tissues, whereas **metastasis** involves the ability of cancer cells to enter the bloodstream (or other body fluids) and travel to distant sites, where they form tumors—called *metastases*—that are not physically connected to the primary tumor.

The ability of a tumor to metastasize depends on a complex cascade of events, beginning with angiogenesis. The events following angiogenesis can be grouped into three main steps. First, cancer cells invade surrounding tissues and penetrate through the walls of lymphatic and blood vessels, thereby gaining access to the bloodstream. Second, the cancer cells are transported by the circulatory system throughout the body. And third, cancer cells leave the bloodstream and enter various organs, where they establish new metastatic tumors (Figure 24-4). If cells from the initial tumor fail to complete any of these steps, or if any of the steps can be prevented, metastasis will not occur. It is therefore crucial to understand how the properties of cancer cells make these three steps possible.

Changes in Cell Adhesion, Motility, and Protease Production Allow Cancer Cells to Invade Surrounding Tissues and Vessels

The first step in metastasis involves the invasion of surrounding tissues and vessels by cancer cells (see Figure 24-4, step ①). This means that unlike the cells of benign tumors or most normal cells, which remain together at the

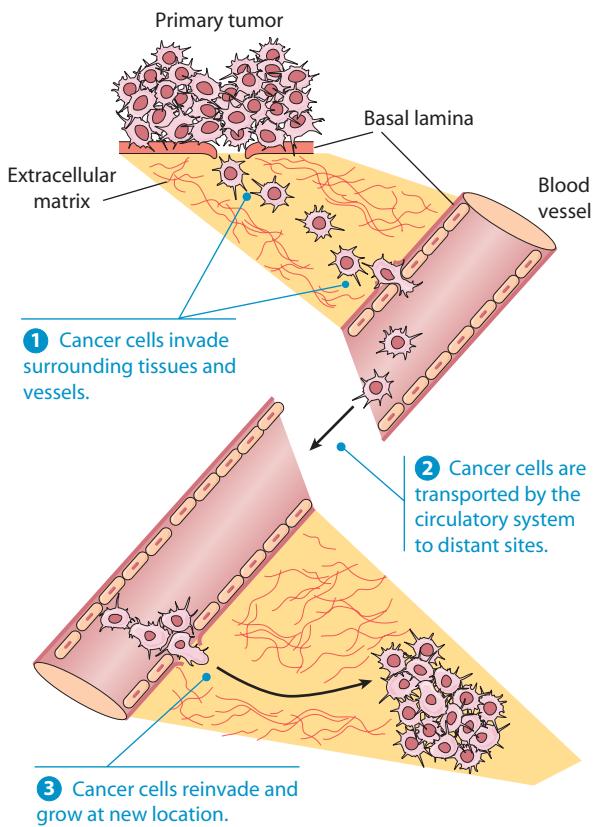

FIGURE 24-4 Stages in the Process of Metastasis. Only a small fraction of the cells in a typical cancer successfully carry out all three steps involved in metastasis: ① invasion into surrounding tissues and vessels, ② transportation via the circulatory system, and ③ reinvade and growth at a distant site.

site where they are formed, cancer cells can leave their initial location and invade surrounding tissues, eventually entering the circulatory system.

Several mechanisms make this invasive behavior possible. The first involves changes in the cell surface proteins that cause cells to adhere to one another. Such proteins are often missing or defective in cancer cells, which allows cells to separate from the main tumor more readily. One crucial molecule is *E-cadherin* (page 479), a cell-cell adhesion protein whose loss underlies the reduced adhesiveness of many epithelial cancers. Highly invasive cancers usually have less *E-cadherin* than do normal cells. Restoring *E-cadherin* to isolated cancer cells lacking this molecule has been shown to inhibit their ability to form invasive tumors when the cells are injected back into animals.

A second factor underlying invasive behavior is the increased motility of cancer cells, which is stimulated by signaling molecules produced by surrounding host tissues or by the cancer cells themselves. Some of these signaling molecules can act as *chemoattractants* that serve as guiding signals that attract migrating cancer cells. Activation of the Rho family GTPases (see description of Rho, Rac, and Cdc42 on page 440) plays a central role in the stimulation of cell motility that leads to invasion and metastasis.

Another trait contributing to invasion is the ability of cancer cells to produce *proteases* that degrade protein-containing structures that would otherwise act as barriers to cancer cell movement. A critical barrier encountered by most cancers is the *basal lamina*, a dense layer of protein-containing material that separates epithelial layers from underlying tissues (see Figure 17-20). Before epithelial cancers, which account for 90% of all human malignancies, can invade adjacent tissues, the basal lamina must first be breached. Cancer cells break through this barrier by secreting proteases, which degrade the proteins that form the backbone of the basal lamina.

One such protease is *plasminogen activator*, an enzyme that converts the inactive precursor *plasminogen* into the active protease *plasmin*. Because high concentrations of plasminogen are present in most tissues, small amounts of plasminogen activator released by cancer cells can quickly catalyze the formation of large quantities of plasmin. The plasmin performs two tasks: (1) It degrades components of the basal lamina and the extracellular matrix, thereby facilitating tumor invasion, and (2) it cleaves inactive precursors of matrix metalloproteinases, produced mainly by surrounding host cells, into active enzymes that also degrade the basal lamina and extracellular matrix.

After proteases allow cancer cells to penetrate the basal lamina, they facilitate cancer cell migration by degrading the extracellular matrix of the underlying tissues. The cancer cells migrate until they reach tiny blood or lymphatic vessels, which are also surrounded by a basal lamina. The proteases then digest holes in this second basal lamina, allowing cancer cells to pass through it (and through the layer of endothelial cells that form the vessel's inner lining) to finally gain entry into the circulatory system.

Relatively Few Cancer Cells Survive the Voyage Through the Bloodstream

Cancer cells that penetrate the walls of tiny blood vessels gain entry to the bloodstream, which then transports the cells to distant parts of the body (see Figure 24-4, step ②). If cancer cells instead penetrate the walls of lymphatic vessels, the cells are first carried to regional lymph nodes, where they may become lodged and grow. For this reason, regional lymph nodes are a common site for the initial spread of cancer. However, lymph nodes have numerous interconnections with blood vessels, so cancer cells that initially enter into the lymphatic system eventually flow into the bloodstream.

Regardless of their initial entry route, the net result is often large numbers of cancer cells in the bloodstream. Even a tiny malignant tumor weighing only a few grams can release several million cancer cells into the circulation each day. However, the bloodstream is a relatively inhospitable place for most cancer cells and fewer than one in a thousand cells survives the trip to a potential site of

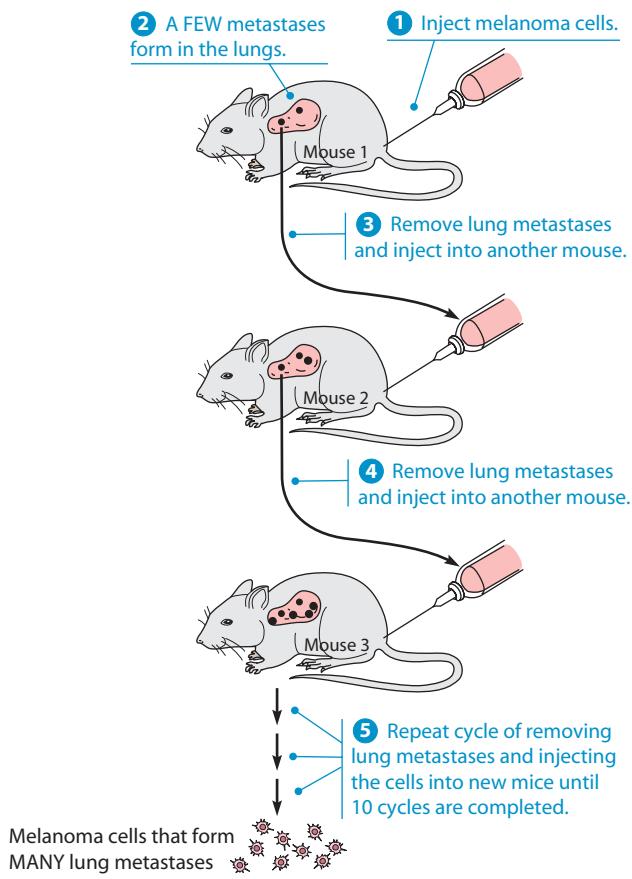

FIGURE 24-5 Selection of Melanoma Cells Exhibiting an Enhanced Ability to Metastasize. Mouse melanoma cells were injected into the tail vein of a mouse. After a small number of metastases arose in the lungs, cells from these lung tumors were removed and injected into another mouse. When this cycle was repeated ten times, the final population of melanoma cells produced many more lung metastases than were produced by the original cells.

metastasis. Are these few successful cells simply a random representation of the original tumor cell population, or do they represent cells that are especially well suited for metastasizing? **Figure 24-5** illustrates an experiment designed to address these questions. In this experiment, mouse melanoma cells were injected into the bloodstream of healthy mice to study their ability to metastasize. A few weeks later, metastases appeared in a variety of locations but mainly in the lungs. Cells from the lung metastases were removed and injected into another mouse, leading to the production of more lung metastases. By repeating this procedure many times in succession, researchers eventually obtained a population of cancer cells that formed many more metastases than did the original tumor cell population.

The most straightforward interpretation is that the initial melanoma consisted of a heterogeneous population of cells with differing properties and that repeated isolation and reinjection of cells derived from successful metastases gradually selected for those cells that were best suited for metastasizing. To test this hypothesis, further

experiments have been performed in which single cells were isolated from a primary melanoma and each isolated cell was allowed to proliferate in culture into a separate population of cells. Such cell populations, each derived from a single initial cell, are called **clones**. When injected into animals, some of the cloned cells produced few metastases, some produced numerous metastases, and some fell in between. Since each clone was derived from a different cell in the original tumor, the results confirmed that the cells of the primary tumor differed in their ability to metastasize.

Blood-Flow Patterns and Organ-Specific Factors Determine the Sites of Metastasis

Some cancer cells circulating in the bloodstream eventually exit through the wall of a tiny vessel and invade another organ, where they form metastases that may be located far from the initial tumor (see Figure 24-4, step ③). Although the bloodstream carries cancer cells throughout the entire body, metastases develop preferentially at certain sites. One factor responsible for this specificity is related to blood-flow patterns. Based solely on size considerations, circulating cancer cells are most likely to become lodged in *capillaries* (tiny vessels with a diameter no larger than a single blood cell). After becoming stuck in capillaries, cancer cells penetrate the walls of these tiny vessels, enter the surrounding tissues, and seed the development of new tumors. For example, consider primary tumors originating in most organs. After the cancer cells enter the bloodstream, the first capillary bed they encounter will be in the lungs. As a result, the lungs are a frequent site of metastasis for many kinds of cancer. However, blood-flow patterns do not always favor the lungs. For cancers of the stomach and colon, cancer cells entering the bloodstream are first carried to the liver, where the vessels break up into a bed of capillaries. As a result, the liver is a common site of metastasis for these cancers.

While blood-flow patterns are important, they do not always explain the observed distribution of metastases. As early as 1889, Stephen Paget proposed that circulating cancer cells have a special affinity for the environment provided by particular organs. Paget's idea, referred to as the "seed and soil" hypothesis, is based on the analogy that when a plant produces seeds, they are carried by the wind in all directions but grow only if they fall on congenial soil. According to this view, cancer cells are carried to a variety of organs by the bloodstream, but only a few sites provide an optimal growth environment for each type of cancer. Supporting evidence has come from a systematic analysis of the sites where metastases tend to arise. For roughly two-thirds of the human cancers examined, the rates of metastasis to various organs can be explained solely on the basis of blood-flow patterns. In the remaining cases, some cancers metastasize to particular organs less frequently than expected and others metastasize to particular organs more frequently than expected.

Why do cancer cells grow best at particular sites? The answer is thought to involve interactions between cancer cells and the microenvironment in the organs they are delivered to. One example involves prostate cancer, which commonly metastasizes to bone (a pattern that would not be predicted by blood-flow patterns). The reason for this preference was uncovered by experiments in which prostate cancer cells were mixed with cells from various organs—including bone, lung, and kidney—and the cell mixtures were then injected into animals. It was found that the ability of prostate cancer cells to develop into tumors is stimulated by the presence of cells derived from bone but not from lung or kidney. Subsequent studies uncovered the explanation: Bone cells produce specific growth factors that stimulate the proliferation of prostate cancer cells. This is just one of several types of molecular interactions that can influence the ability of cancer cells to grow in particular organs.

The Immune System Influences the Growth and Spread of Cancer Cells

Does the body have any mechanisms for defending against the growth and spread of cancer cells? One possibility is the immune system, which can attack and destroy foreign cells. Of course, cancer cells are not literally “foreign,” but they often exhibit molecular changes that might allow the immune system to recognize the cells as being abnormal. The *immune surveillance theory* postulates that immune destruction of cancer cells is a common event and that cancer simply reflects the occasional failure of an adequate immune response to be mounted against aberrant cells.

Some of the evidence cited in support of this theory involves organ transplant patients, who take immunosuppressive drugs to depress immune function and thereby decrease the risk of immune rejection of the transplanted organ. As predicted by the immune surveillance theory, individuals treated with immunosuppressive drugs develop many cancers at higher rates than normal. The immune surveillance concept has been tested more directly in animals that are genetically altered to introduce specific defects in the immune system. One study used mutant mice containing disruptions in *Rag2*, a gene expressed only in lymphocytes. The mutant mice, which have no functional lymphocytes (and hence no immune response), exhibit an increased cancer rate both for spontaneous cancers and for cancers induced by injecting animals with chemicals that cause cancer.

Although such results indicate that the immune system helps protect mice from developing cancer, how relevant are these findings to humans? If the immune system plays a major role in protecting us from cancer, we would expect a dramatic increase in cancer rates in AIDS patients with severely depressed immune function. While AIDS does cause higher rates for a few types of cancer, especially Kaposi’s sarcoma and lymphomas, increases are

not seen for the more common forms of cancer. Most of the cancers that occur at increased rates in people with AIDS are caused by viruses (whose role in cancer is covered later in the chapter). Such observations suggest that the immune system may help protect humans from virus-induced cancers, but it is less successful in defending against the more common types of cancer.

The reason for this failure is that cancers find ways of evading destruction by the immune system. One way is based on the fact that tumors are heterogeneous populations of cells that express different *antigens* (substances that trigger an immune response). Those cells containing antigens that elicit a strong immune response are likely to be attacked and destroyed, while cells that either lack or produce smaller quantities of such antigens are more likely to survive and proliferate. So as tumors grow, there is a continual selection for cells that elicit a weaker immune response.

Cancer cells have also devised ways of actively confronting and overcoming the immune system. For example, some cancer cells produce molecules that kill or inhibit the function of T lymphocytes (immune cells involved in destroying foreign or defective cells). Tumors may also surround themselves with dense supporting tissue that shields them from immune attack. And some cancer cells simply divide so quickly that the immune system cannot kill them fast enough to keep tumor growth in check. Consequently, the larger a tumor grows, the easier it becomes to overwhelm the immune system.

The Tumor Microenvironment Influences Tumor Growth, Invasion, and Metastasis

We have now encountered several examples in which tumor behavior is influenced by interactions between tumor cells and the surrounding *tumor microenvironment*, which includes various kinds of normal cells, extracellular molecules, and components of the extracellular matrix. For example, angiogenesis is triggered by growth factors released by tumor cells that act on normal endothelial cells in the surrounding tissue, thereby stimulating the proliferation of new blood vessels. Proteases produced both by tumor cells and surrounding normal cells facilitate invasion by degrading components of the extracellular matrix and the basal lamina. The motility of cancer cells and the direction in which they migrate is influenced by signaling molecules made by normal cells in the surrounding tissues. Penetration through capillaries involves adhesion of cancer cells to molecules present in the basal lamina. And finally, the growth of metastases at distant sites is stimulated by growth factors and other molecules produced by cells residing in the organs being invaded.

The tumor microenvironment can also contain cells and molecules that hinder invasion and metastasis. For example, normal cells of the immune system may attack cancer cells, and other cells in the tumor microenvironment often produce *TGF β* , a potent inhibitor of proliferation for many cell types (page 413). Cancer cells may in turn acquire

mutations that allow them to continue growing in the presence of TGF β . Sometimes cancer cells even start secreting TGF β themselves, which inhibits the growth of surrounding normal cells and allows the cancer cells to reproduce and invade surrounding tissues more rapidly because of the decreased competition from neighboring cells. These are just a few of numerous examples in which interactions with the tumor microenvironment influence the ability of cancer cells to grow, invade neighboring tissues, and metastasize to distant sites.

What Causes Cancer?

The uncontrolled proliferation of cancer cells, combined with their ability to metastasize to distant sites, makes cancer a potentially life-threatening disease. What causes the emergence of cells with such destructive properties? People often view cancer as a mysterious disease that strikes randomly and without known cause, but this misconception fails to consider the results of thousands of scientific investigations, some dating back more than 200 years. The inescapable conclusion emerging from these studies is that cancers are commonly caused by environmental agents and lifestyle factors, most of which act by triggering DNA mutations.

Epidemiological Data Have Allowed Many Causes of Cancer to Be Identified

The first indication that a particular agent may cause cancer usually comes from *epidemiology*—the branch of science that investigates the frequency and distribution of diseases in human populations. Epidemiological studies

have revealed that cancers arise with differing frequencies in different parts of the world. To list just a few examples, stomach cancer is frequent in Japan, breast cancer is prominent in the United States, and liver cancer is common in Africa and Southeast Asia. To determine whether differences in heredity or environment are responsible for such differences, scientists have examined cancer rates in people who move from one country to another. For example, in Japan the incidence of stomach cancer is greater and the incidence of colon cancer is lower than in the United States; however, when Japanese families move to the United States, their cancer rates come to resemble those in the United States, indicating that cancer rates are determined more by environmental and lifestyle factors than by heredity.

Epidemiological data have played an important role in identifying these environmental and lifestyle factors. A striking example involves lung cancer, which has increased more than tenfold in frequency in the United States since 1900 (Figure 24-6). Investigations into the possible causes for this lung cancer epidemic have revealed that most people who develop lung cancer have one trait in common: a history of smoking cigarettes. As might be expected if cigarettes were responsible, heavy smokers develop lung cancer more frequently than light smokers do, long-term smokers develop lung cancer more frequently than short-term smokers do, and lung cancer rates fall after cigarette smokers quit smoking. Besides causing lung cancer, smoking is linked to most cancers of the mouth, pharynx, and larynx, as well as to some cancers of the esophagus, stomach, pancreas, uterine cervix, kidney, bladder, and colon. About half of all people who smoke will be killed by the cancers and cardiovascular diseases

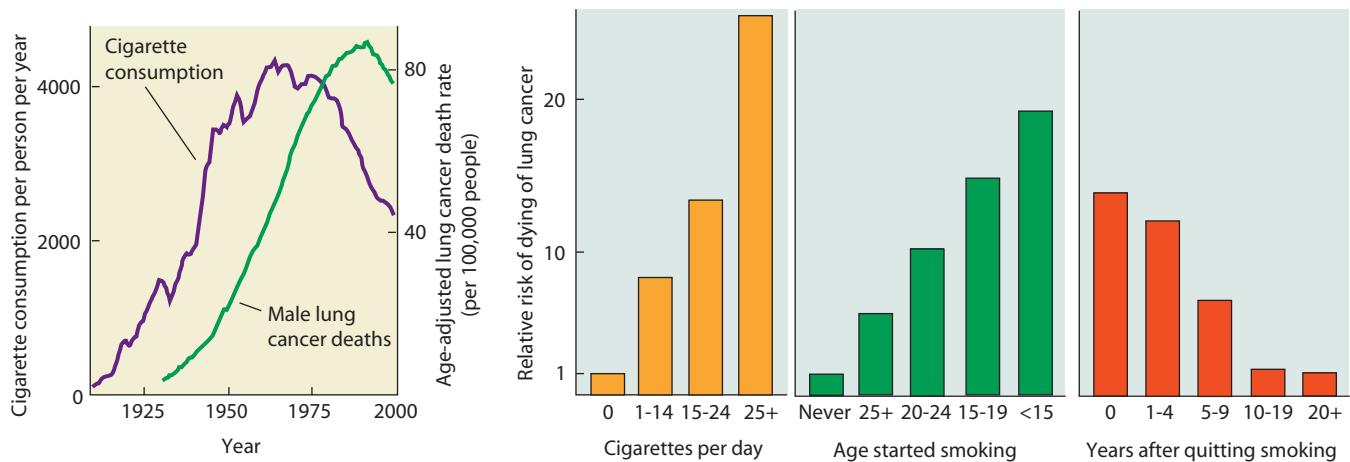

FIGURE 24-6 Cigarette Smoking and Lung Cancer. The graph on the left shows that an increase in cigarette smoking in the United States during the first half of the twentieth century was followed by an explosive growth in lung cancer deaths. A time lag of about 25 years transpired between the increase in smoking rates and the subsequent increase in cancer deaths, which is typical of the time required for most human cancers to develop after exposure to a cancer-causing agent. The bar graphs on the right show that lung cancer rates increase as a function of the number of cigarettes smoked per day, that long-term smokers develop lung cancer more frequently than do short-term smokers, and that lung cancer rates fall after cigarette smokers quit smoking.

caused by smoking, losing an average of 10–15 years of life. This premature loss of life includes about 130,000 deaths per year from lung cancer in the United States alone.

Although the connection between cigarette smoking and cancer was first suggested by epidemiological studies, proof of a cause-and-effect relationship requires direct experimental evidence. Such evidence has come from laboratory studies showing that cigarette smoke contains several dozen chemicals that cause cancer when administered to animals. Knowing that cigarette smoke causes cancer has given society a powerful tool for reducing the number of cancer deaths. After the government began to publicize the dangers of tobacco smoke in the 1960s, smoking rates in the United States stopped growing and began to decline (see Figure 24-6). This decline is one of the main reasons why cancer death rates have slowly begun to fall during the past decade.

Many Chemicals Can Cause Cancer, Often After Metabolic Activation in the Liver

The idea that certain chemicals, such as those found in tobacco smoke, can cause cancer was first proposed more than 200 years ago. In 1761 a London doctor, John Hill, reported that people who routinely used snuff (a powdered form of tobacco that is inhaled) experience an abnormally high incidence of nasal cancer. A few years later another British physician, Percival Pott, observed an elevated incidence of scrotum cancer among men who had served as chimney sweepers in their youth. Because they fit into narrow spaces more readily than adults did, young boys of the time were commonly employed to clean chimney flues. Pott speculated that the chimney soot became dissolved in the natural oils of the scrotum, irritated the skin, and eventually triggered the development of cancer. This conjecture led to the discovery that wearing protective clothing and bathing regularly could prevent scrotum cancer in chimney sweepers.

In the years since these pioneering observations, the list of known and suspected **carcinogens** (cancer-causing agents) has grown to include hundreds of different chemicals. Chemicals are usually labeled as carcinogens because humans or animals develop cancer when exposed to them. This does not mean, however, that each chemical causes cancer through its own direct action. For example, consider the behavior of *2-naphthylamine*, a potent carcinogen that causes bladder cancer in industrial workers and is present in tobacco smoke. As might be expected, feeding *2-naphthylamine* to laboratory animals induces a high rate of bladder cancer. But if *2-naphthylamine* is implanted directly into an animal's bladder, cancer rarely develops. The explanation for the apparent discrepancy is that when *2-naphthylamine* is ingested (by animals) or inhaled (by humans), it passes through the liver and is metabolized into other chemicals that are the actual causes of cancer. Placing *2-naphthylamine* directly in an

animal's bladder bypasses this metabolic activation, and so cancer does not arise.

Many carcinogens share this need for metabolic activation before they can cause cancer. Substances exhibiting such behavior are more accurately called **precarcinogens**, a term applied to any chemical that is capable of causing cancer only after it has been metabolically activated. Most precarcinogens are activated by liver proteins that are members of the *cytochrome P450* enzyme family. Members of this enzyme family catalyze the oxidation of ingested foreign chemicals, such as drugs and pollutants, to make the molecules less toxic and easier to excrete from the body. However, in some cases these oxidation reactions inadvertently convert foreign chemicals into carcinogens—a phenomenon known as *carcinogen activation*.

DNA Mutations Triggered by Chemical Carcinogens Lead to Cancer

Once it was known that chemicals can cause cancer, the question arose as to how they work. The idea that carcinogenic chemicals act by triggering DNA mutations was first proposed around 1950, but there was little supporting evidence because nobody had systematically compared the mutagenic potency of different chemicals with their ability to cause cancer. The need for such information inspired Bruce Ames to develop a simple laboratory test for measuring a chemical's mutagenic activity. This procedure, called the **Ames test**, uses bacteria as a test organism because they can be quickly grown in enormous numbers in culture. The bacteria are a special strain that cannot synthesize the amino acid *histidine*. As shown in **Figure 24-7**, the bacteria are placed in a culture dish containing a growth medium lacking histidine, along with the chemical being tested for mutagenic activity. Normally, the bacteria would not grow in the absence of histidine. However, if the chemical being tested is mutagenic, it will trigger random mutations, some of which might restore the ability to synthesize histidine. Each bacterium acquiring such a mutation will grow into a visible colony, so the total number of colonies is a measure of the mutagenic potency of the substance being tested.

Because many chemicals that cause cancer do not become carcinogenic until after they have been modified by liver enzymes, the Ames test includes a step in which the chemical being tested is first incubated with an extract of liver cells to mimic the reactions that normally occur in the liver. The resulting chemical mixture is then tested for its ability to cause bacterial mutations. When the Ames test is performed in this way, a strong correlation is observed between a chemical's ability to cause mutations and its ability to cause cancer.

Carcinogenic chemicals inflict DNA damage in several ways, including binding to DNA and disrupting normal base-pairing; generating crosslinks between the two strands of the double helix; creating chemical linkages

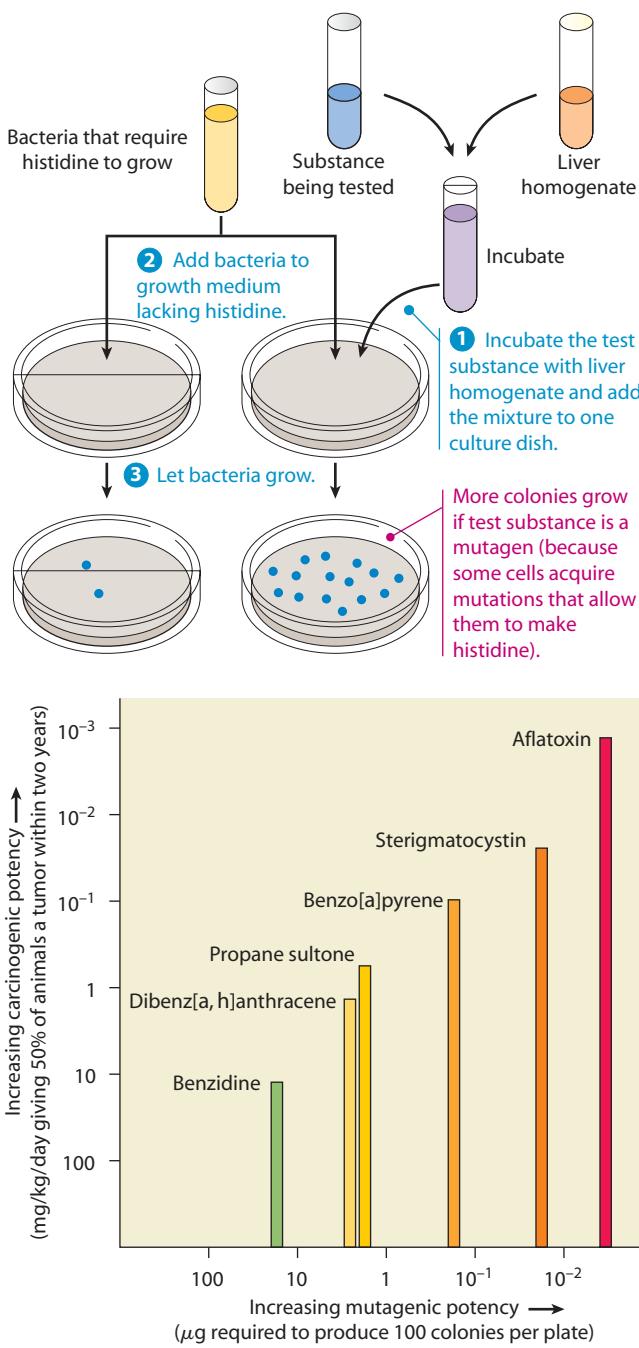

FIGURE 24-7 Ames Test for Identifying Potential Carcinogens.

The Ames test is based on the rationale that most carcinogens are mutagens. (Top) The ability of chemicals to induce mutations is measured in bacteria that cannot synthesize the amino acid histidine. When placed in a growth medium lacking histidine, the only bacteria that can grow are those that have acquired a mutation allowing them to make histidine. The number of bacterial colonies that grow is therefore related to the mutagenic potency of the substance being tested. Chemicals studied with the Ames test are first incubated with a liver homogenate because many chemicals become carcinogenic only after they have undergone biochemical modification in the liver. (Bottom) The bar graph shows that substances exhibiting strong mutagenic activity in the Ames test also tend to be strong carcinogens. Among this particular group of substances, aflatoxin is the most potent mutagen and the most potent carcinogen. Note that the data are plotted on logarithmic scales to permit aflatoxin to be shown on the same graph as benzidine, which is about 10,000 times weaker than aflatoxin as a mutagen and carcinogen.

between adjacent bases; hydroxylating or removing individual DNA bases; and causing breaks in one or both DNA strands. In some cases, the mutational role of specific chemicals in causing cancer has been linked to effects on specific genes. For example, the *polycyclic aromatic hydrocarbons* found in tobacco smoke preferentially bind to specific regions of the *p53* gene and trigger unique mutations in which the base T is substituted for the base G. As we will see later in the chapter, mutations in the *p53* gene play a key role in the development of many kinds of cancer.

Cancer Arises Through a Multistep Process Involving Initiation, Promotion, and Tumor Progression

Although mutation plays a prominent role, the development of cancer requires multiple steps. Early evidence for this idea came from studying the ability of coal tar components, such as *dimethylbenz[a]anthracene* (DMBA), to cause cancer in laboratory animals. These studies showed that feeding mice a single dose of DMBA rarely causes tumors to develop. However, if a mouse that has been fed a single dose of DMBA is later treated with a substance that causes skin irritation, cancer develops in the treated area (Figure 24-8). The irritant most commonly used for triggering tumor formation is a plant-derived substance called *croton oil*, which is enriched in compounds called *phorbol esters*. Croton oil does not cause cancer by itself, nor does cancer arise if DMBA is administered *after* the croton oil. These observations indicate that

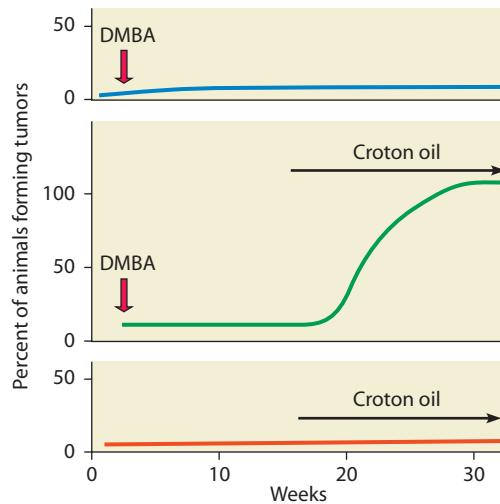

FIGURE 24-8 Evidence for Initiation and Promotion Stages During Cancer Development. (Top) Mice given a single dose of DMBA (dimethylbenz[a]anthracene) do not form tumors. (Middle) Painting their skin with croton oil twice a week after DMBA treatment leads to the appearance of skin tumors. If the croton oil application is stopped a few weeks into the treatment (data not shown), the tumors regress. (Bottom) Croton oil alone does not produce skin tumors. These data are consistent with the conclusion that DMBA is an initiator and croton oil is a promoting agent.

DMBA and croton oil play two different roles, known as **initiation** and **promotion**. During initiation, normal cells are converted to a precancerous state, and promotion then stimulates the altered cells to divide and form tumors.

A year or more can transpire after feeding animals a single dose of DMBA and yet tumors will still develop if an animal's skin is then irritated with croton oil. This means that a single DMBA treatment can create a permanently altered, initiated state in cells located throughout the body, and that subsequent administration of croton oil acts on these altered cells to promote tumor development. The ability of chemicals to act as initiators correlates with their ability to cause DNA damage, suggesting that the permanently altered, initiated state is based on the ability of initiators to cause *DNA mutation*.

In contrast, promotion is a gradual process requiring prolonged or repeated exposure to a promoting agent. Investigation of a wide variety of promoting agents, such as the phorbol esters in croton oil, has revealed that their main shared property is the ability to stimulate *cell proliferation*. Not all tumor promoters are foreign substances. Hormones and growth factors that stimulate normal cell proliferation may inadvertently behave as tumor promoters if they act on a cell that has already sustained an initiating mutation.

When a cell with an initiating mutation is exposed to a promoting agent (or natural growth regulator) that causes the initiated cell to proliferate, the number of mutant cells increases. As proliferation continues, natural selection tends to favor cells exhibiting enhanced growth rate and invasive properties, eventually leading to the formation of a malignant tumor. The time required for promotion contributes to the lengthy delay that often transpires between exposure to an initiating carcinogen and the development of cancer.

Initiation and promotion are followed by a third stage, known as **tumor progression** (Figure 24-9). During tumor progression, tumor cell properties gradually change over time as cells acquire more aberrant traits and become increasingly aggressive. The driving force for tumor progression is that cells exhibiting traits that confer a selective advantage—for example, increased growth rate, increased invasiveness, ability to survive in the bloodstream, resistance to immune attack, ability to grow in other organs, resistance to drugs, evasion of apoptosis, and so forth—will be more successful than cells lacking these traits and so will gradually tend to predominate.

While it is easy to see why cells exhibiting such traits tend to prevail through natural selection, this does not explain how the aberrant traits originate in the first place. One way new traits arise is through additional DNA mutations that occur after the original, initiating mutation. New traits can also be produced by changes in the expression of normal genes. As you learned in Chapter 23, numerous *epigenetic* mechanisms exist for activating or inhibiting the activity of normal genes without mutating

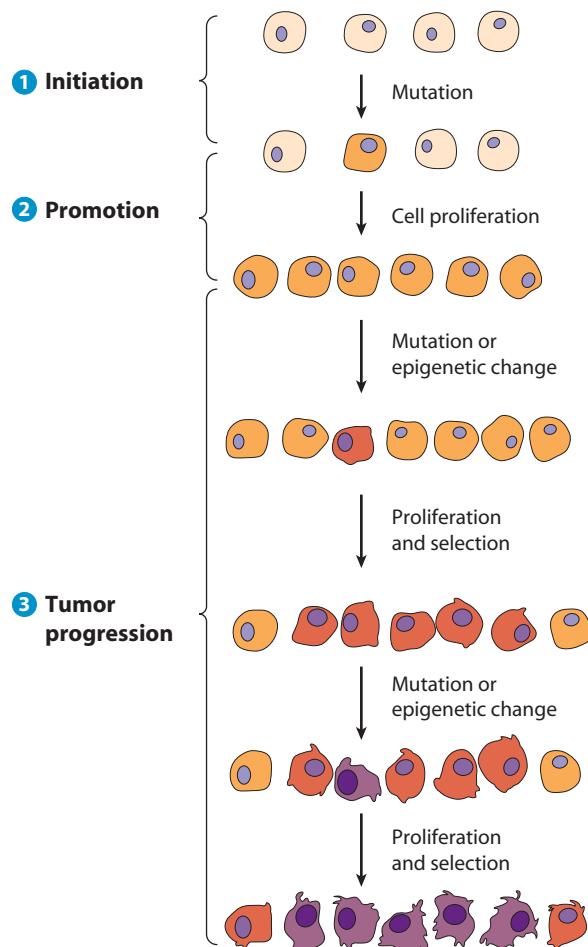

FIGURE 24-9 Main Stages in Cancer Development. Cancer arises by a multistep process involving ① an initiation event based on DNA mutation, ② a promotion stage in which the initiated cell is stimulated to proliferate, and ③ tumor progression, in which mutations and changes in gene expression create variant cells exhibiting enhanced growth rates or other aggressive properties that give certain cells a selective advantage. Such cells tend to outgrow their companions and become the predominant cell population in the tumor. During tumor progression, repeated cycles of this selection process create a population of cells whose properties gradually change over time.

them. Thus, tumor progression is made possible by a combination of DNA mutations and epigenetic changes that don't require mutation, accompanied by natural selection of those cells that acquire advantageous properties through these mechanisms.

Ionizing and Ultraviolet Radiation Also Cause DNA Mutations That Lead to Cancer

Chemicals are not the only DNA-damaging agents that can cause cancer. Shortly after the discovery of X-rays by Wilhelm Roentgen in 1895, it was noticed that people working with this type of radiation developed cancer at abnormally high rates. Animal studies subsequently confirmed that X-rays create DNA mutations and cause cancer in direct proportion to the dose administered.

A similar type of radiation is emitted by many radioactive elements. An early example of the cancer hazards posed by radioactivity occurred in the 1920s in a New Jersey factory that produced glow-in-the-dark watch dials. A luminescent paint containing the radioactive element *radium* was used for painting the dials, and this paint was applied with a fine-tipped brush that the workers frequently wetted with their tongues. As a result tiny quantities of radium were inadvertently ingested and became concentrated in their bones, triggering bone cancer.

Elevated cancer rates caused by exposure to radioactivity have also been reported in people exposed to radioactive fallout from nuclear explosions. The most dramatic incidents occurred in the Japanese cities of Hiroshima and Nagasaki after atomic bombs were dropped there in 1945. Another episode affected people around the Chernobyl nuclear power plant in the former Soviet Union (now Ukraine), which exploded in 1986.

X-rays and related forms of radiation emitted by radioactive elements are called **ionizing radiation** because they remove electrons from molecules, thereby generating highly reactive ions that create various types of DNA damage, including single- and double-strand breaks. **Ultraviolet radiation (UV)** is another type of radiation that causes cancer by damaging DNA. The ability of the UV radiation in sunlight to cause cancer was first deduced from the observation that skin cancer is most prevalent in people who spend long hours in the sun, especially in tropical regions where the sunlight is intense. UV radiation is absorbed mainly by the skin, where it imparts enough energy to trigger *pyrimidine dimer* formation—that is, the formation of covalent bonds between adjacent pyrimidine bases in DNA, as shown in Figure 19-17. If the damage is not repaired, distortion of the double helix causes improper base pairing during DNA replication, which in turn produces distinctive mutation patterns. For example, a CC→TT mutation (conversion of two adjacent cytosines to thymines) is a unique product of UV exposure and can be used as a distinctive “signature” to identify mutations caused by sunlight.

The existence of such signature mutations provided a way to prove that UV-induced mutations cause skin cancer. One of the first genes to be studied was the *p53* gene (page 588), which is known to be mutated in many human cancers. When the *p53* gene of skin cancer cells is examined using DNA sequencing techniques, mutations exhibiting a distinctive UV signature (such as CC→TT) are frequently observed. In contrast, when *p53* mutations are detected in other types of cancer, they do not exhibit the UV signature (**Figure 24-10**).

Such observations confirm that the *p53* mutations seen in skin cancer cells are triggered by sunlight, but they don't prove that these mutations actually cause the cancers to arise. Is it possible that the mutations are simply an irrelevant, random by-product of long-term exposure to sunlight? This question has been resolved by examining

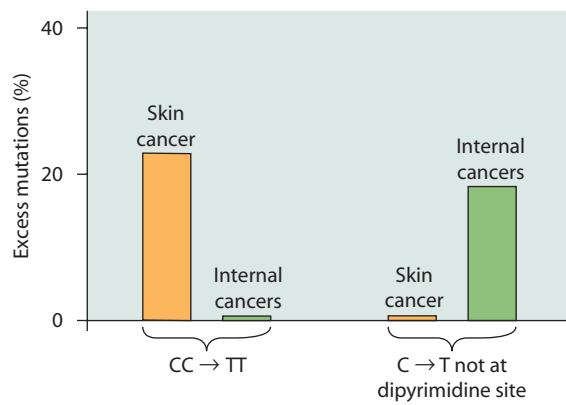

FIGURE 24-10 Incidence of Two Types of *p53* Mutations in Skin Cancer and Internal Cancers. The two bars on the left represent the frequency of CC→TT mutations, which are triggered by UV radiation. The two bars on the right represent the frequency of C→T mutations not located at dipyrimidine sites, which are not caused by UV radiation. Note that the UV-triggered type of mutation occurs in the *p53* gene of skin cancers (squamous cell carcinomas) but not in cancers of internal organs. Mutation frequencies are plotted relative to what would be expected to occur randomly.

the precise distribution of UV-induced mutations within the *p53* gene. In Chapter 21, it was pointed out that changes in the third base of a codon often do not alter the amino acid being specified by that codon (see Figure 21-6). If the *p53* mutations detected in skin cancers are simply a random by-product of sunlight exposure, then mutations in a codon's third base that do not change an amino acid should be as frequent as mutations in the first or second base that do change an amino acid. In fact, DNA sequencing has revealed that the *p53* mutations seen in skin cancer cells are not randomly distributed. Instead, they preferentially involve base changes that alter amino acids in the *p53* protein, as would be expected if these mutations are involved in the mechanism by which sunlight causes cancer.

Viruses and Other Infectious Agents Trigger the Development of Some Cancers

Although the carcinogenic properties of chemicals and radiation were recognized by the early 1900s, the possibility that infectious agents might also cause cancer was not widely appreciated because cancer does not usually behave like a contagious disease. However, in 1911 Peyton Rous performed experiments on sick chickens brought to him by local farmers that showed for the first time that cancer can be caused by a virus. These chickens had cancers of connective tissue origin, or *sarcomas*. To investigate the origin of the tumors, Rous ground up the tumor tissue and passed it through a filter with pores so small that not even bacterial cells could pass through. When he injected the cell-free extract into healthy chickens, they developed sarcomas. Since no cancer cells had been injected into the healthy chickens, Rous concluded that sarcomas can be transmitted by an agent that is smaller

than a bacterial cell. This was the first time anyone had detected an **oncogenic virus**—that is, a virus that causes cancer. Although Rous's findings were initially greeted with skepticism, an 87-year-old Rous finally received the Nobel Prize in 1966—more than 50 years after his discovery of the first cancer virus!

It is now clear that dozens of viruses can cause cancer in animals, and a smaller number have been linked to human cancers. The first human example was uncovered by Denis Burkitt, a British surgeon working in Africa in the late 1950s. At certain times of the year, Burkitt noted large outbreaks of lymphocytic cancers of the neck and jaw. Because this cancer, now known as **Burkitt lymphoma**, occurred in periodic epidemics localized to specific geographical regions, Burkitt proposed that it was transmitted by an infectious agent. Burkitt's ideas attracted the attention of two virologists, named Epstein and Barr, whose electron microscopic studies of Burkitt lymphoma cells revealed a virus now called the **Epstein–Barr virus (EBV)**. The following evidence supports the idea that EBV can play a role in Burkitt lymphoma: (1) EBV DNA and proteins are often found in tumor cells obtained from patients with Burkitt lymphoma but not in normal cells from the same individuals; (2) adding EBV to normal human lymphocytes in culture causes the cells to acquire some of the properties of cancer cells; and (3) injecting EBV into monkeys causes lymphomas to arise.

In addition to EBV, several other viruses have been linked to human cancers. Among these are the *hepatitis B* and *hepatitis C* viruses, which trigger some liver cancers; *human T-cell lymphotropic virus-I (HTLV-I)*, which causes adult T-cell leukemia and lymphoma; and the sexually transmitted *human papillomavirus (HPV)*, which is associated with uterine cervical cancer. Moreover, viruses are not the only infectious agents that can cause cancer. Chronic infection with the bacterium *Helicobacter pylori* (*H. pylori*)—a common cause of stomach ulcers—can trigger stomach cancer, and flatworm infections have been linked to a small number of bladder and bile duct cancers.

Knowing the identity of such infectious agents opens the door for new cancer prevention strategies. For example, antibiotics that kill *H. pylori* are helpful in preventing stomach cancer, and vaccines against hepatitis B and HPV can reduce the incidence of liver and cervical cancers, respectively. The HPV vaccine, which first became available in 2006, illustrates the difficulties that often hinder the development of such vaccines. Scientists have known for more than 100 years that cervical cancer is caused by a sexually transmitted agent, but HPV was not identified as the responsible agent until the 1980s. The difficulty in making this identification arose because HPV is not a single virus but rather a heterogeneous family of related viruses containing more than 100 different subtypes (HPV 1, HPV 2, HPV 3, and so forth). After tests were developed for distinguishing the various subtypes, it became clear that cervical cancer is linked to infection with certain high-risk forms of the virus—mainly HPV 16,

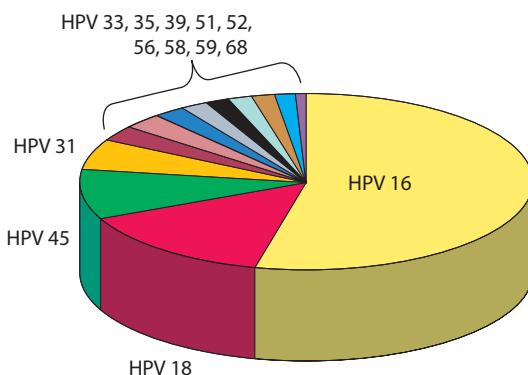

FIGURE 24-11 Prevalence of Various Subtypes of HPV in Cervical Cancers. About 90% of all cancers of the uterine cervix involve infection with at least one of the subtypes of HPV shown in this chart.

HPV 18, and a few others (Figure 24-11). The first HPV vaccine was therefore targeted against HPV subtypes 16 and 18, which gives the vaccine the potential to prevent about 70% of all cervical cancers. This vaccine also protects against two other HPV subtypes that cause genital warts.

Although the infectious agents that cause cancer include a diverse collection of viruses, bacteria, and parasites, their mechanisms of action can be grouped into two main categories. One involves those agents—such as the hepatitis B and C viruses, *H. pylori*, and parasitic flatworms—that cause tissue destruction and chronic inflammation. Under these conditions, cells of the immune system infiltrate the tissue and attempt to kill the infectious agent. Unfortunately, the mechanisms used by immune cells to fight infections often produce mutagenic chemicals, such as oxygen *free radicals* (highly reactive forms of oxygen containing an unpaired electron). The net result is an increased likelihood that cancer-causing mutations will arise when cells proliferate to repair the damaged tissue.

The other mechanism used by infectious agents to cause cancer is based on the ability of certain viruses to stimulate the proliferation of infected cells. Some viruses trigger cell proliferation through the direct action of viral genes, whereas other viruses alter the behavior of host cell genes. In either case, the types of genes involved play a role not just in viral cancers but in cancers caused by chemicals and radiation as well. We will therefore proceed to a discussion of cancer-related genes and the ways in which they act.

Oncogenes and Tumor Suppressor Genes

A large body of evidence points to the central role played by DNA mutations in cancer development. As we have just seen, some cancer-causing mutations are triggered by chemicals, radiation, or infectious agents. Others are spontaneous mutations, DNA replication errors, or in

certain cases, inherited mutations. But despite these differences in origin, the result is always the mutation of genes involved in controlling cell proliferation and survival. We will now describe the two main classes of affected genes: *oncogenes* and *tumor suppressor genes*.

Oncogenes Are Genes Whose Products Can Trigger the Development of Cancer

An **oncogene** is a gene whose *presence* can trigger the development of cancer. Some oncogenes are introduced into cells by cancer-causing viruses, while others arise from the mutation of normal cellular genes. In either case, oncogenes code for proteins that stimulate excessive cell proliferation and/or promote cell survival by inhibiting apoptosis.

The first oncogene to be discovered was in the *Rous sarcoma virus*, which causes cancer in chickens (page 770) and has only four genes. Mutational studies revealed that mutant viruses with defects in one of these genes, called *src*, are still able to infect cells and reproduce normally but can no longer cause cancer. In other words, a functional copy of the *src* gene must be present for cancer to arise. Similar approaches subsequently led to the identification of oncogenes in dozens of other viruses.

Evidence for the existence of oncogenes in cancers not caused by viruses first came from studies in which DNA isolated from human bladder cancer cells was introduced into a strain of cultured mouse cells called *3T3 cells*. The DNA was administered under conditions that stimulate **transfection**—that is, uptake of the foreign DNA into the cells and its incorporation into their chromosomes. After being transfected with the cancer cell DNA, some of the mouse *3T3* cells proliferated excessively. When these cells were injected back into mice, the animals developed cancer. Scientists therefore suspected that a human gene taken up by the mouse cells had caused the cancer. To confirm the suspicion, gene cloning techniques were applied to DNA isolated from the mouse cancer cells. This resulted in identification of the first human oncogene: a mutant *RAS* gene coding for an abnormal form of Ras, the protein whose role in growth signaling was described in Chapters 14 and 19. (*Important Note:* The names of human genes—for example, *RAS*—are generally written in italicized capital letters, while the names of the proteins they produce—for example, Ras—are written without italics and often with only an initial capital letter.)

RAS was just the first of more than 200 human oncogenes to be discovered. While these oncogenes are defined as genes that can cause cancer, a single oncogene is usually not sufficient. For example, in the transfection experiments described in the preceding paragraph, introducing the *RAS* oncogene caused cancer only because the mouse *3T3* cells used in these studies already possess a mutation in another cell cycle control gene. If freshly isolated normal mouse cells are used instead of *3T3* cells, intro-

ducing the *RAS* oncogene by itself will not cause cancer; however, *RAS* together with other oncogenes that target the p53 pathway will cause cancer. This observation illustrates an important principle: *Multiple mutations are usually required to convert a normal cell into a cancer cell*.

Proto-oncogenes Are Converted into Oncogenes by Several Distinct Mechanisms

How do human cancers, most of which are not caused by viruses, come to acquire oncogenes? The answer is that oncogenes arise by mutation from normal cellular genes called **proto-oncogenes**. Despite their harmful-sounding name, proto-oncogenes are not bad genes that are simply waiting for an opportunity to foster the development of cancer. Rather, they are normal cellular genes that make essential contributions to the regulation of cell growth and survival. The term *proto-oncogene* simply implies that if and when the structure or activity of a proto-oncogene is disrupted by certain kinds of mutations, the mutant form of the gene can cause cancer. The mutations that convert proto-oncogenes into oncogenes are created through several distinct mechanisms, which are summarized in **Figure 24-12** and briefly described next.

1. Point Mutation. The simplest mechanism for converting a proto-oncogene into an oncogene is a point mutation—that is, a single nucleotide substitution in DNA that causes a single amino acid substitution in the protein encoded by the proto-oncogene. The most frequently encountered oncogenes of this type are the *RAS* oncogenes that code for abnormal forms of the Ras protein. Point mutations create abnormal, hyperactive forms of the Ras protein that cause the Ras pathway to be continually activated, thereby leading to excessive cell proliferation. *RAS* oncogenes have been detected in several human cancers, including those of the bladder, lung, colon, pancreas, and thyroid. A point mutation can be present at any of several different sites within a *RAS* oncogene, and the particular site involved appears to be influenced by the carcinogen that caused it.

2. Gene Amplification. The second mechanism for creating oncogenes utilizes gene amplification (page 723) to increase the number of copies of a proto-oncogene. When the number of gene copies is increased, it causes the protein encoded by the proto-oncogene to be produced in excessive amounts, although the protein itself is normal. For example, about 25% of human breast and ovarian cancers have amplified copies of the *ERBB2* gene, which codes for a growth factor receptor. The existence of multiple copies of the gene leads to the production of too much receptor protein, which in turn causes excessive cell proliferation.

3. Chromosomal Translocation. During chromosomal translocation, a portion of one chromosome is physically

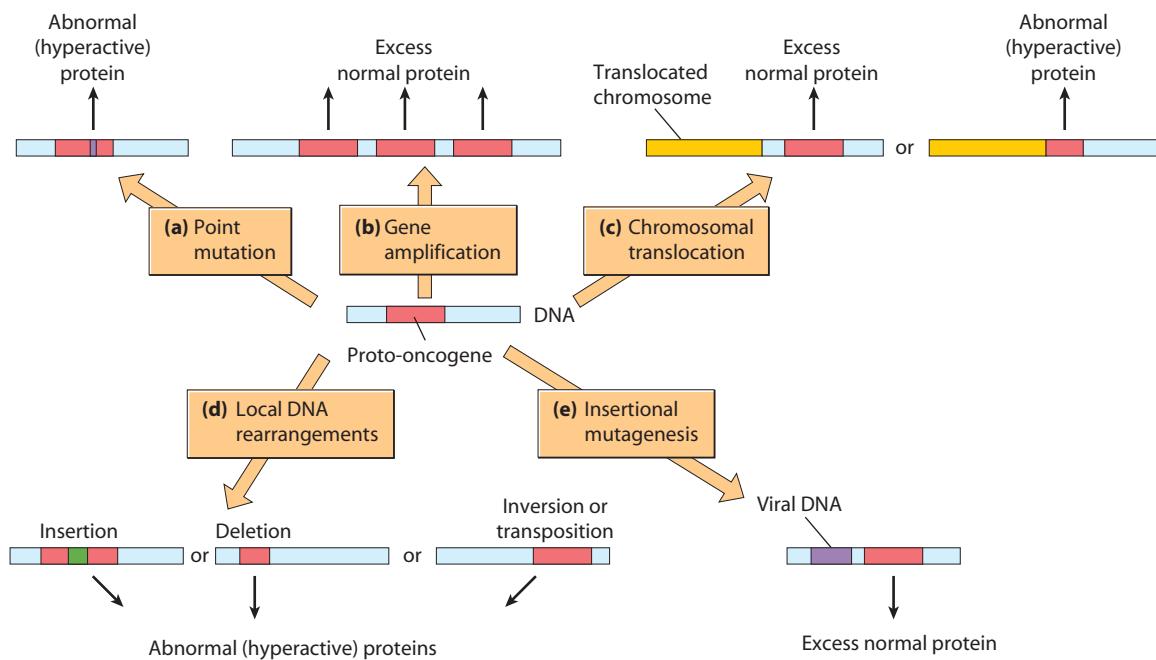

FIGURE 24-12 Five Mechanisms for Converting Proto-oncogenes into Oncogenes. Some oncogenes produced by these mechanisms code for abnormal proteins, whereas others produce normal proteins in excessive amounts. (a) Point mutation involves a single nucleotide substitution that creates an oncogene coding for an abnormal protein differing in a single amino acid from the normal protein produced by the proto-oncogene. (b) Gene amplification creates multiple gene copies, thereby leading to excessive production of a normal protein. (c) Chromosomal translocations move chromosome segments from one chromosome to another. This may either fuse two genes together to form an oncogene coding for an abnormal protein, or it may place a proto-oncogene next to a highly active gene, thereby causing the translocated proto-oncogene to become more active. (d) Local DNA rearrangements such as insertions, deletions, inversions, and transpositions can disrupt the structure of proto-oncogenes and cause them to produce abnormal proteins. (e) Insertional mutagenesis occurs when viral DNA is integrated into a host chromosome near a proto-oncogene. The inserted DNA may stimulate the expression of the proto-oncogene and cause it to produce too much protein.

removed and joined to another chromosome. A classic example occurs in Burkitt lymphoma, a type of cancer associated with the Epstein–Barr virus (EBV). Infection with EBV stimulates cell proliferation, but this is not sufficient to cause cancer by itself. The disease arises only when a translocation involving chromosome 8 happens to occur in one of these proliferating cells. In the most frequent translocation, a proto-oncogene called *MYC* is

moved from chromosome 8 to 14, where it becomes situated next to an intensely active region of chromosome 14 containing genes coding for antibody molecules (Figure 24-13). Moving the *MYC* gene so close to the highly active antibody genes causes the *MYC* gene to likewise become activated, thereby leading to overproduction of the Myc protein—a transcription factor that stimulates cell proliferation. Although the translocated *MYC* gene

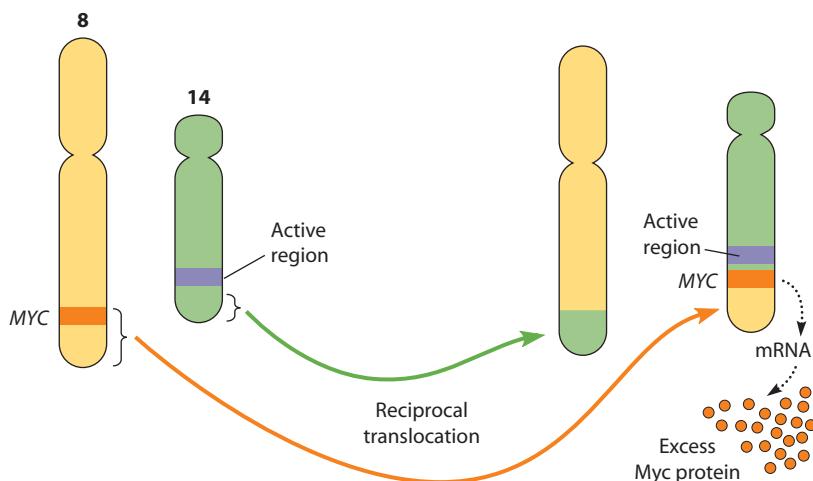

FIGURE 24-13 Chromosome Translocation in Burkitt Lymphoma. In the lymphocytes that give rise to Burkitt lymphoma, a segment of chromosome 8 containing the normal *MYC* gene is frequently exchanged with a segment of chromosome 14. This reciprocal translocation places the normal *MYC* gene adjacent to a very active region of chromosome 14, which contains genes coding for antibody molecules. Moving the *MYC* gene so close to the highly active antibody genes results in activation of the *MYC* gene, leading to an overproduction of Myc protein that stimulates cell proliferation.

sometimes retains its normal structure and codes for a normal Myc protein, it is still an oncogene because its new location on chromosome 14 causes the gene to be overexpressed.

Translocations can also disrupt gene structure and cause abnormal proteins to be produced. One example involves the *Philadelphia chromosome*, an abnormal version of chromosome 22 commonly associated with chronic myelogenous leukemia. The Philadelphia chromosome is created by DNA breakage near the ends of chromosomes 9 and 22, followed by reciprocal exchange of DNA between the two chromosomes. This translocation creates an oncogene called *BCR-ABL*, which contains DNA sequences derived from two different genes (*BCR* and *ABL*). As a result, the oncogene produces a *fusion protein* that functions abnormally because it contains amino acid sequences derived from two different proteins.

4. Local DNA Rearrangements. Another mechanism for creating oncogenes involves local rearrangements in which the base sequences of proto-oncogenes are altered by *deletions*, *insertions*, *inversions* (removal of a sequence followed by reinsertion in the opposite direction), or *transpositions* (movement of a sequence from one location to another). An example encountered in thyroid and colon cancers illustrates how a simple rearrangement can create an oncogene from two normal genes. This example involves two genes, named *NTRK1* and *TPM3*, that reside on the same chromosome. *NTRK1* codes for a receptor tyrosine kinase, and *TPM3* codes for a completely unrelated protein, nonmuscle tropomyosin. In some cancers, a DNA inversion occurs that causes one end of the *TPM3* gene to fuse to the opposite end of the *NTRK1* gene (Figure 24-14). The resulting gene, called the *TRK oncogene*, produces a fusion protein containing the tyrosine kinase site of the receptor joined to a region of the tropomyosin molecule that forms a *coiled coil* (page 444)—a structure that causes two polypeptide chains to join together as a dimer. As a result, the fusion protein forms a permanent dimer and its tyrosine kinase is permanently activated. (Recall from Chapter 14 that receptor tyrosine kinases are normally activated by bringing together two receptor molecules to form a dimer.)

5. Insertional Mutagenesis. Retroviruses—whose life cycles were described on page 648—can sometimes cause cancer even if they have no oncogenes of their own. Retroviruses accomplish this task by integrating their genes into a host chromosome in a region where a proto-oncogene is located. Integration of the viral DNA then converts the host cell proto-oncogene into an oncogene by causing the gene to be overexpressed. This phenomenon, called **insertional mutagenesis**, is frequently encountered in animal cancers but is rare in humans. However, some human cancers may have been inadvertently created this way in gene therapy trials that used retroviruses as vectors for repairing defective genes (page 640).

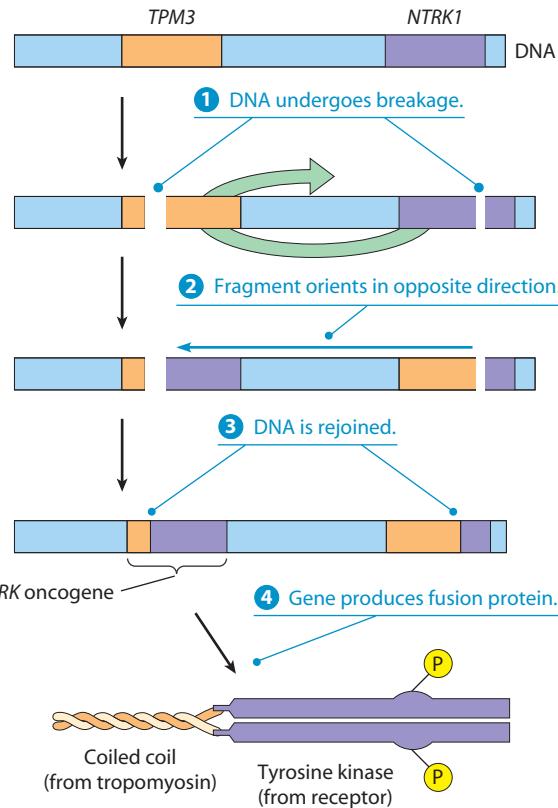

FIGURE 24-14 Origin of the TRK Oncogene. The *TRK* oncogene is created by a chromosomal inversion that brings together segments of two genes residing on the same chromosome, one gene coding for a growth factor receptor with tyrosine kinase activity (*NTRK1*) and the other gene coding for nonmuscle tropomyosin (*TPM3*). The inversion causes one end of the *TPM3* gene to become fused to the opposite end of the *NTRK1* gene. The resulting *TRK* oncogene produces a fusion protein in which the tropomyosin segment causes the receptor region to form a dimer, thereby permanently activating its tyrosine kinase site.

Most Oncogenes Code for Components of Growth-Signaling Pathways

We have just seen that alterations in proto-oncogenes can convert them into oncogenes, which in turn code for proteins that either are structurally abnormal or are produced in excessive amounts. How do these oncogene-encoded proteins cause cancer? Although more than 200 oncogenes have been identified to date, many of the proteins they produce fit into one of six categories: *growth factors*, *receptors*, *plasma membrane GTP-binding proteins*, *non-receptor protein kinases*, *transcription factors*, and *cell cycle or apoptosis regulators* (Table 24-1). These six categories are all related to steps in growth-signaling pathways (e.g., see the steps in the Ras pathway shown in Figure 19-42). The following sections provide examples of how oncogene-produced proteins in each of the six groups contribute to the development of cancer.

I. Growth Factors. Normally, cells will not divide unless they have been stimulated by an appropriate growth

Table 24-1 A Few Examples of Oncogenes Grouped by Protein Function

Oncogene Name	Protein Produced	Oncogene Origin	Common Cancer Type*
1. Growth factors			
<i>v-sis</i>	PDGF	Viral	Sarcomas (monkeys)
<i>COL1A1-PDGFB</i>	PDGF	Translocation	Fibrosarcoma
2. Receptors			
<i>v-erb-b</i>	Epidermal growth factor receptor	Viral	Leukemia (chickens)
<i>TRK</i>	Nerve growth factor receptor	DNA rearrangement	Thyroid
<i>ERBB2</i>	Epidermal growth factor receptor 2	Amplification	Breast
<i>v-mpl</i>	Thrombopoietin receptor	Viral	Leukemia (mice)
3. Plasma membrane GTP-binding proteins			
<i>KRAS</i>	Ras	Point mutation	Pancreas, colon, lung, others
<i>HRAS</i>	Ras	Point mutation	Bladder
<i>NRAS</i>	Ras	Point mutation	Leukemias
4. Nonreceptor protein kinases			
<i>BRAF</i>	Raf kinase	Point mutation	Melanoma
<i>v-src</i>	Src kinase	Viral	Sarcomas (chickens)
<i>SRC</i>	Src kinase	DNA rearrangement	Colon
<i>TEL-JAK2</i>	Jak kinase	Translocation	Leukemias
<i>BCR-ABL</i>	Abl kinase	Translocation	Chronic myelogenous leukemia
5. Transcription factors			
<i>MYC</i>	Myc	Translocation	Burkitt lymphoma
<i>MYCL</i>	Myc	Amplification	Small cell lung cancer
<i>c-myc</i>	Myc	Insertional mutagenesis	Leukemia (chickens)
<i>v-jun</i>	Jun	Viral	Sarcomas (chickens)
<i>v-fos</i>	Fos	Viral	Bone (mice)
6. Cell cycle or apoptosis regulators			
<i>CYCD1</i>	Cyclin	Amplification, translocation	Breast, lymphoma
<i>CDK4</i>	Cdk	Amplification	Sarcomas, glioblastoma
<i>BCL2</i>	Bcl-2	Translocation	Non-Hodgkins lymphoma
<i>MDM2</i>	Mdm2	Amplification	Sarcomas, lung, breast, others

*Cancers are in humans unless otherwise specified. Only the most frequent cancer types are listed.

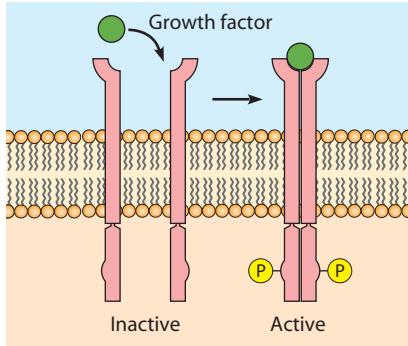

factor. But if a cell possesses an oncogene that produces such a growth factor, the cell may stimulate its own proliferation. One oncogene that functions in this way is the *v-sis* gene ("v" means viral) found in the *simian sarcoma virus*, which causes cancer in monkeys. The *v-sis* oncogene codes for a mutant form of *platelet-derived growth factor* (*PDGF*). When the virus infects a monkey cell whose growth is normally controlled by PDGF, the PDGF produced by the *v-sis* oncogene continually stimulates the cell's own proliferation (in contrast to the normal situation, in which cells are exposed to PDGF only when it is released from surrounding blood platelets).

A PDGF-related oncogene has also been detected in some human sarcomas. These tumors possess a chromosomal translocation that creates a gene in which part of the *PDGF* gene is joined to part of an unrelated gene (the gene coding for collagen). The resulting oncogene produces PDGF in an uncontrolled way, thereby causing cells

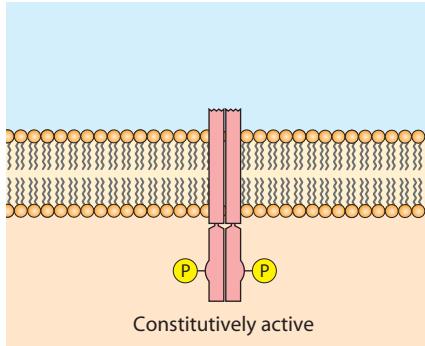

containing the gene to continually stimulate their own proliferation.

2. Receptors. Several dozen oncogenes code for receptors involved in growth-signaling pathways. As described in Chapter 14, many receptors exhibit intrinsic tyrosine kinase activity that is activated only when a growth factor binds to the receptor. Oncogenes sometimes code for mutant versions of such receptors whose tyrosine kinase activity is permanently activated, regardless of the presence or absence of a growth factor. The *TRK* oncogene, which was described in the section on DNA rearrangements, is one example (see Figure 24-14). Another example is the *v-erb-b* oncogene, which is found in a virus that causes a red blood cell cancer in chickens. The *v-erb-b* oncogene produces an altered version of the *epidermal growth factor* (*EGF*) *receptor* that retains tyrosine kinase activity but lacks the EGF binding site. Consequently, the receptor is

(a) Normal receptor. During normal receptor activation, binding of a growth factor to its receptor promotes the clustering of two receptor molecules, thereby causing the tyrosine kinase activity of each receptor to catalyze phosphorylation of the adjacent receptor (autophosphorylation).

(b) Mutant receptor. Some oncogenes code for mutant receptors whose tyrosine kinase is permanently activated. Below is a mutant receptor missing its growth factor binding site, which makes the receptor constitutively active—that is, it exhibits tyrosine kinase activity even in the absence of growth factor.

(c) Amplified receptor. Amplified oncogenes produce normal receptors but in excessive quantities, which also leads to excessive receptor activity.

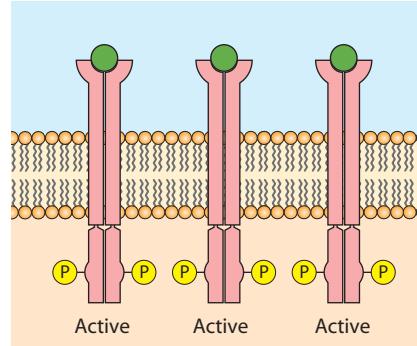

FIGURE 24-15 Receptor Tyrosine Kinases in Normal and Cancer Cells. (a) Normal receptors exhibit tyrosine kinase activity only after a growth factor has bound to them. (b) Some oncogenes code for mutant receptors whose tyrosine kinase is permanently activated. (c) Other oncogenes produce normal receptors but in excessive quantities, which also leads to excessive receptor activity.

constitutively active—that is, it stays active as a tyrosine kinase whether EGF is present or not, whereas the normal form of the receptor exhibits tyrosine kinase activity only when bound to EGF (**Figure 24-15a, b**).

Other oncogenes produce normal receptors but in excessive quantities, which can also lead to hyperactive growth signaling (see Figure 24-15c). An example is provided by the human *ERBB2* gene. As discussed earlier in the chapter, amplification of the *ERBB2* gene in certain breast and ovarian cancers causes it to overproduce a growth factor receptor. The presence of too many receptor molecules causes a magnified response to growth factor and hence excessive cell proliferation.

Some growth-signaling pathways, such as the Jak-STAT pathway described in Chapter 23, utilize receptors that do not possess protein kinase activity. With such receptors, binding of growth factor causes the activated receptor to stimulate the activity of an independent tyrosine kinase molecule. An example of an oncogene that codes for such a receptor occurs in the *myeloproliferative leukemia virus*, which causes leukemia in mice. The oncogene, called *v-mpl*, codes for a mutant version of the receptor for *thrombopoietin*, a growth factor that uses the Jak-STAT pathway to stimulate the production of blood platelets.

3. Plasma Membrane GTP-Binding Proteins. In many growth-signaling pathways, the binding of a growth factor to its receptor leads to activation of the plasma membrane, GTP-binding protein called Ras (page 408). Oncogenes coding for mutant Ras proteins are one of the most common types of genetic abnormality detected in human cancers. The point mutations that create *RAS* oncogenes

usually cause a single incorrect amino acid to be inserted at one of three possible locations within the Ras protein. The net result is a hyperactive Ras protein that retains bound GTP instead of hydrolyzing it to GDP, thereby maintaining the protein in a permanently activated state. In this hyperactive state, the Ras protein continually sends a growth-stimulating signal to the rest of the Ras pathway, regardless of whether growth factor is bound to the cell's growth factor receptors.

4. Nonreceptor Protein Kinases. A common feature shared by many growth-signaling pathways is the use of protein phosphorylation reactions to transmit signals within the cell. The enzymes that catalyze these intracellular phosphorylation reactions are referred to as **nonreceptor protein kinases** to distinguish them from the protein kinases that are intrinsic to cell surface receptors. For example, in the case of the Ras pathway, the activated Ras protein triggers a cascade of intracellular protein phosphorylation reactions, beginning with phosphorylation of the Raf protein kinase and eventually leading to the phosphorylation of MAP kinases (page 590). Several oncogenes code for protein kinases involved in this cascade. An example is the *BRAF* oncogene, which codes for a mutant Raf protein in a variety of human cancers. Oncogenes coding for nonreceptor protein kinases involved in other signaling pathways have been identified as well. Included in this group are oncogenes that produce abnormal versions of the Src, Jak, and Abl protein kinases.

5. Transcription Factors. Some of the nonreceptor protein kinases activated in growth-signaling pathways subsequently

trigger changes in transcription factors, thereby altering gene expression. Oncogenes that produce mutant forms or excessive quantities of various transcription factors have been detected in a broad range of cancers. Among the most common are oncogenes coding for Myc transcription factors, which control the expression of numerous genes involved in cell proliferation and survival. For example, we have already seen how the chromosomal translocation associated with Burkitt lymphoma creates a *MYC* oncogene that produces excessive amounts of Myc protein (see Figure 24-13). Burkitt lymphoma is only one of several human cancers in which the Myc protein is overproduced. In these other cancers, gene amplification rather than chromosomal translocation is usually responsible. For example, *MYC* gene amplification is frequently observed in small-cell lung cancers and to a lesser extent in a wide range of other carcinomas, including 20–30% of breast and ovarian cancers.

6. Cell Cycle and Apoptosis Regulators. In the final step of growth-signaling pathways, transcription factors activate genes coding for proteins that control cell proliferation and survival. The activated genes include those coding for *cyclins* and *cyclin-dependent kinases* (*Cdks*), whose roles in triggering passage through key points in the cell cycle were described in Chapter 19. Several human oncogenes produce proteins of this type. For example, a cyclin-dependent kinase gene called *CDK4* is amplified in some sarcomas, and the cyclin gene *CYCD1* is commonly amplified in breast cancers and is altered by chromosomal translocation in some lymphomas. Such oncogenes produce excessive amounts or hyperactive versions of Cdk–cyclin complexes, which then stimulate progression through the cell cycle (even in the absence of growth factors).

Some oncogenes contribute to the accumulation of proliferating cells by inhibiting apoptosis rather than stimulating cell division. One example involves the gene that codes for the apoptosis-inhibiting protein Bcl-2 (page 594). Chromosomal translocations involving this gene are observed in certain types of lymphomas. The net effect of these translocations is an excessive production of Bcl-2, which inhibits apoptosis and thereby fosters the accumulation of dividing cells. The *MDM2* gene, which codes for the Mdm2 protein that targets p53 for destruction (page 588), can also cause a failure of apoptosis when the gene is amplified or abnormally expressed. Excessive production of Mdm2 leads to a destruction of the p53 protein, thereby inhibiting the p53 pathway that is normally used to trigger cell death by apoptosis.

Most oncogenes code for a protein that falls into one of the six preceding categories. Some of these oncogenes produce abnormal, hyperactive versions of such proteins. Other oncogenes produce excessive amounts of an otherwise normal protein. In either case, the net result is a protein that stimulates the uncontrolled accumulation of dividing cells.

Tumor Suppressor Genes Are Genes Whose Loss or Inactivation Can Lead to Cancer

In contrast to oncogenes, whose *presence* can induce cancer formation, the *loss* or *inactivation* of **tumor suppressor genes** can also lead to cancer. As the name implies, the normal function of such genes is to restrain cell proliferation. In other words, tumor suppressor genes act as brakes on the process of cell proliferation, whereas oncogenes function as accelerators of cell proliferation. Of the roughly 25,000 genes in human cells, only a few dozen exhibit the properties of tumor suppressors. Since losing the function of just one of these genes may lead to cancer, each must perform an extremely important function.

The first indication that cells contain genes whose loss can lead to cancer came from cell fusion experiments in which normal cells were fused with cancer cells. Based on our current understanding of oncogenes, you might expect that the hybrid cells created by fusing cancer cells with normal cells would have acquired oncogenes from the original cancer cell and would therefore exhibit uncontrolled growth, just like a cancer cell. In fact, this is not what happens. Fusing cancer cells with normal cells almost always yields hybrid cells that behave like the normal parent and do not form tumors (Figure 24-16). Such results, first reported in the late 1960s, provided the earliest evidence that normal cells contain genes whose products can suppress tumor growth and reestablish normal growth behavior.

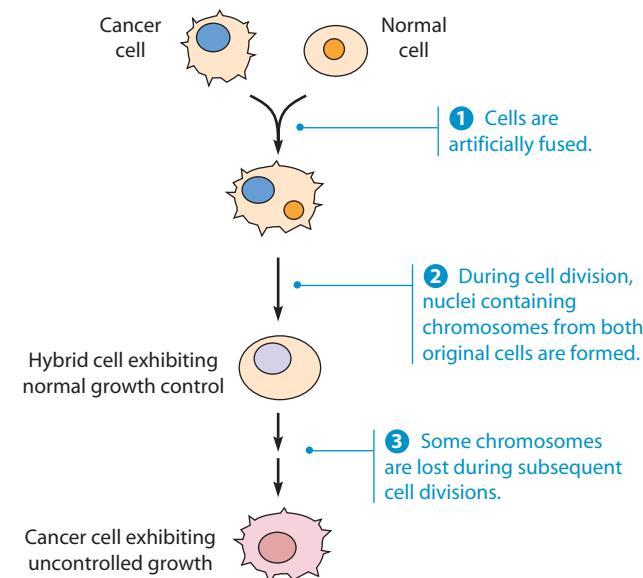

FIGURE 24-16 Fusion of Cancer Cells with Normal Cells.

When cancer cells are artificially fused with normal cells, the resulting hybrid cells do not initially form tumors. After they proliferate for extended periods in culture, the hybrid cells usually revert to the uncontrolled, tumor-forming behavior of the original cancer cells. This reversion is accompanied by the loss of chromosomes that contain tumor suppressor genes.

Although fusing cancer cells with normal cells generally yields hybrid cells that are unable to form tumors, this does not mean these cells are normal. When they are allowed to grow for extended periods in culture, the hybrid cells often revert to the malignant, uncontrolled behavior of the original cancer cells. Reversion to malignant behavior is associated with the loss of certain chromosomes, suggesting that these particular chromosomes contain genes that had been suppressing the ability to form tumors. Such observations eventually led to the naming of the lost genes as “tumor suppressor genes.”

As long as hybrid cells retain both sets of original chromosomes—that is, chromosomes derived from both the cancer cells and the normal cells—the ability to form tumors is suppressed. Tumor suppression is observed even when the original cancer cells possess an oncogene, such as a mutant *RAS* gene, that is actively expressed in the hybrid cells. This means that tumor suppressor genes located in the chromosomes of normal cells can overcome the effects of a *RAS* oncogene present in a cancer cell chromosome. The ability to form tumors reappears only after the hybrid cell loses a chromosome containing a critical tumor suppressor gene.

Although cell fusion experiments provided good evidence for the existence of tumor suppressor genes, identifying these genes has not been easy. By definition, the existence of a tumor suppressor gene does not become apparent until its function has been lost. How do scientists go about finding something whose very existence is unknown until it disappears? One approach involves families that are at high risk for developing cancer. While most cancers are triggered by spontaneous or environmentally induced mutations, about 10–20% of cancer cases can be traced to mutations that are inherited. Such cancers are said to be hereditary, although this designation does not mean that people actually inherit cancer from their parents. What can be inherited, however, is an increased *susceptibility* to developing cancer.

The reason for the increased susceptibility is usually an inherited defect in a tumor suppressor gene. Since tumor suppressor genes are entities whose loss of function is associated with cancer, two successive mutations are typically required—one in each copy of the gene carried on two homologous chromosomes. The probability that two such mutations would occur randomly in the two copies of the same gene is very small. However, if people inherit a mutant (or missing) version of a particular tumor suppressor gene from one parent, they are at much higher risk of developing cancer because only one mutation (in the second copy of that tumor suppressor gene) in a single cell is now needed to begin the progression toward cancer (**Figure 24-17**). In the next section, we will see how the study of such hereditary cancer susceptibilities has facilitated the identification of tumor suppressor genes.

The *RB* Tumor Suppressor Gene Was Discovered by Studying Families with Hereditary Retinoblastoma

The first tumor suppressor gene to be identified was found by studying *hereditary retinoblastoma*, a rare eye cancer that develops in young children who have a family history of the disease. Children with this condition inherit a deletion in a specific region of chromosome 13 from one of their parents. By itself, such a deletion does not cause cancer. But during the many rounds of cell division that occur as the eye grows, an individual retinal cell may occasionally acquire a deletion or mutation in the same region of the second copy of chromosome 13, and cancer arises from such cells. This pattern suggests that (1) chromosome 13 contains a gene that normally inhibits cell proliferation and (2) the deletion or disruption of both copies of the gene must occur before cancer develops. By comparing DNA fragments isolated from chromosome 13 in normal and retinoblastoma cells, the ***RB* gene** was identified as the missing gene.

The *RB* gene codes for the Rb protein, whose role in controlling progression from G1 to S phase of the cell cycle was described in Chapter 19 (see Figure 19-39). The Rb protein is part of the braking mechanism that normally prevents cells from passing through the G1 restriction point and into S phase in the absence of an appropriate signal from a growth factor. Disruption of both copies of the *RB* gene removes this restraining mechanism and opens the door to uncontrolled proliferation. The ability of *RB* mutations to unleash the normal controls on cell proliferation is not limited to hereditary retinoblastoma, the rare eye cancer in which the gene defect was originally identified. Mutations that disrupt the Rb protein have also been detected in nonhereditary retinoblastomas and in several other nonhereditary cancers, including certain forms of lung, breast, and bladder cancer.

The Rb protein is also a target for certain cancer viruses. For example, **human papillomavirus (HPV)**—the virus responsible for uterine cervical cancer—contains an oncogene that produces a protein, called the *E7 protein*, that binds to the Rb protein of infected cells and prevents it from restraining cell proliferation (**Figure 24-18**, ①). Thus, cancers triggered by a loss of functional Rb protein can arise either through mutations that disrupt both copies of the *RB* gene or through the action of viral proteins that bind to and inactivate the Rb protein.

The *p53* Tumor Suppressor Gene Is the Most Frequently Mutated Gene in Human Cancers

Following the discovery of the *RB* gene in the mid-1980s, dozens of additional tumor suppressor genes have been identified. One of the most important is the ***p53* gene** (also called *TP53* in humans), which is mutated in a broad spectrum of tumor types. In fact, almost half of the world’s

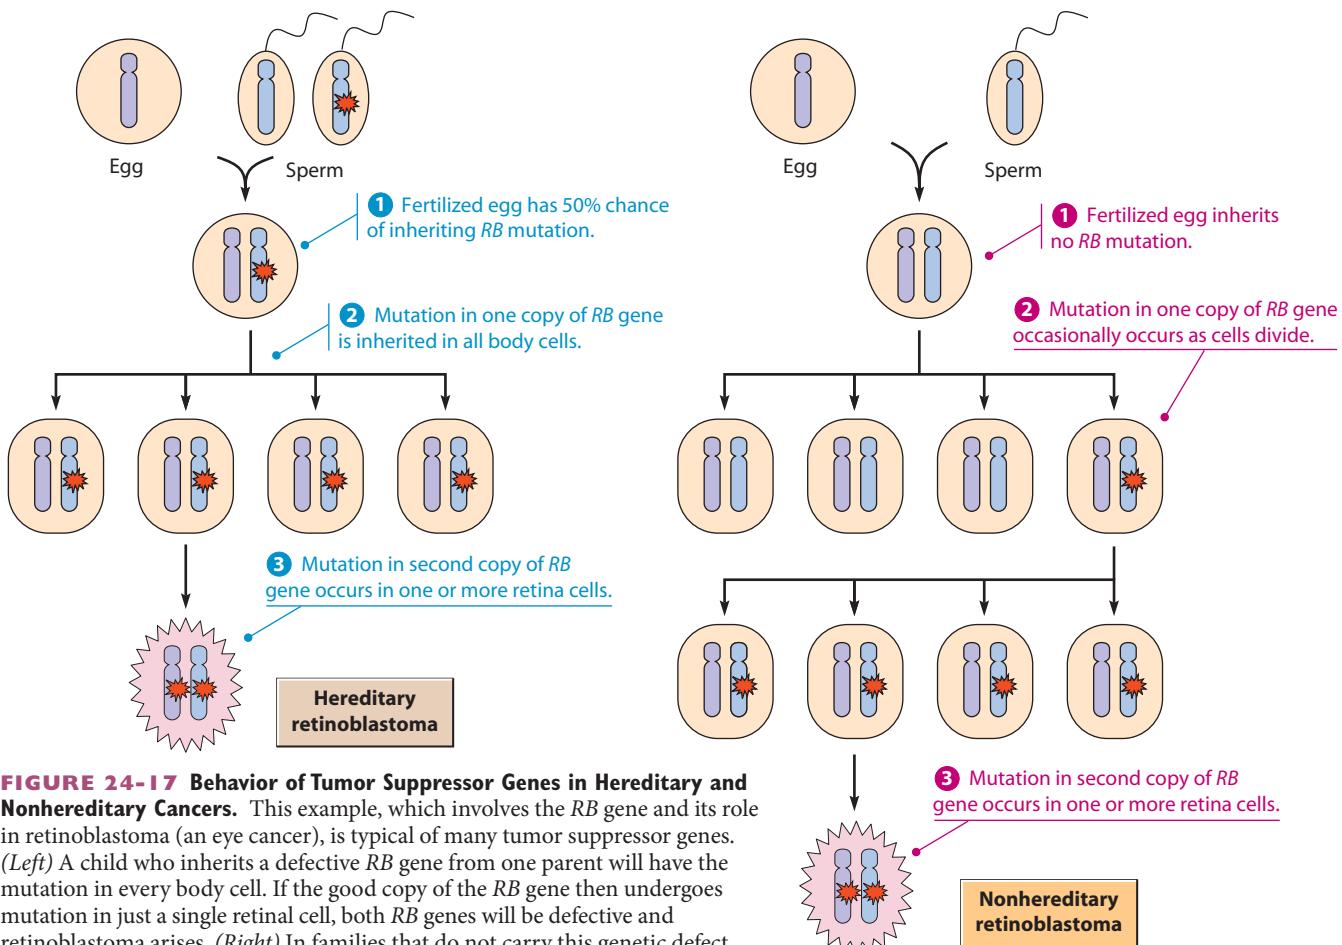

FIGURE 24-17 Behavior of Tumor Suppressor Genes in Hereditary and Nonhereditary Cancers. This example, which involves the *RB* gene and its role in retinoblastoma (an eye cancer), is typical of many tumor suppressor genes. (Left) A child who inherits a defective *RB* gene from one parent will have the mutation in every body cell. If the good copy of the *RB* gene then undergoes mutation in just a single retinal cell, both *RB* genes will be defective and retinoblastoma arises. (Right) In families that do not carry this genetic defect, children are born with two good copies of the *RB* gene. A nonhereditary form of retinoblastoma can still arise, but only in the unlikely event that both copies of the *RB* gene undergo mutation in the same cell.

10 million people diagnosed with cancer each year will have tumors with *p53* mutations, making it the most commonly mutated gene in human cancers.

The *p53* gene codes for the *p53* protein, whose role in responding to DNA damage was described in Chapter 19. When cells are exposed to carcinogenic agents—such as ionizing radiation or toxic chemicals—that cause extensive DNA damage, the altered DNA stimulates the *p53* pathway, which then triggers cell cycle arrest and apoptosis to prevent the genetically damaged cells from proliferating (see Figure 19-40). This protective mechanism is often missing in cancer cells because of mutations that disrupt the *p53* gene. The resulting inactivation of the *p53* pathway leads to a failure of apoptosis that contributes to cancer development by allowing the survival and reproduction of cells containing damaged DNA.

It is therefore not surprising that, as in the case of the *RB* gene, individuals who inherit a defective copy of the *p53* gene from one parent exhibit an increased cancer risk. In this inherited condition, called the *Li-Fraumeni syndrome*, various types of cancer arise by early adulthood due to mutations that inactivate the second, normal

copy of the *p53* gene. Mutations in *p53* are also common in nonhereditary cancers triggered by exposure to DNA-damaging chemicals and radiation. For example, carcinogens present in tobacco smoke cause several kinds of mutations in the *p53* gene in lung cancers, and sunlight causes *p53* mutations in skin cancers. In some cases, mutation in one copy of the *p53* gene is enough to disable the *p53* protein even when the other copy of the *p53* gene is normal. The apparent explanation is that the *p53* protein is a tetramer consisting of four *p53* polypeptide chains, and the presence of even one mutant chain in the tetramer may be enough to prevent the protein from functioning properly.

Like the *Rb* protein, the *p53* protein is a target for certain cancer viruses. For example, in addition to producing the *E7* protein that inactivates *Rb*, the human papillomavirus (HPV) has a second oncogene that produces the *E6* protein, which directs the attachment of ubiquitin to the *p53* protein and thereby targets it for destruction (see Figure 24-18, ②). This means that HPV can block the actions of the proteins produced by both the *RB* and *p53* tumor suppressor genes.

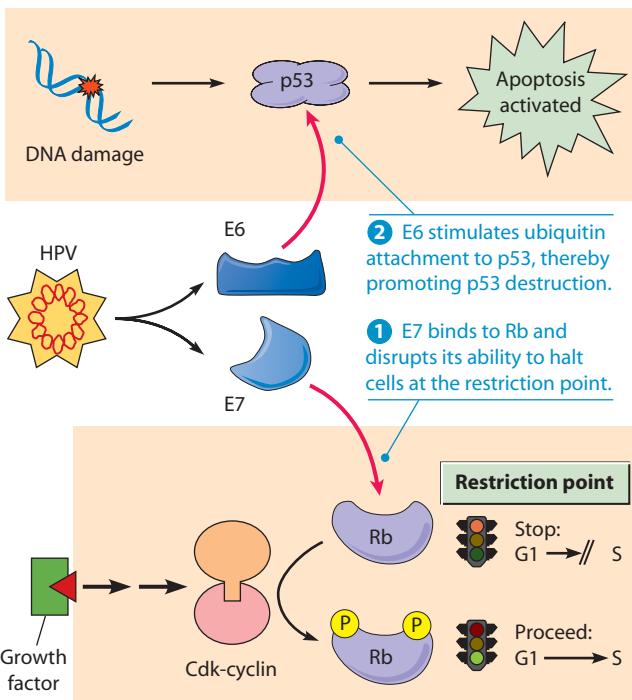

FIGURE 24-18 Oncogenes of the Human Papillomavirus (HPV).

HPV possesses two oncogenes that produce proteins called E6 and E7. ① The E7 protein binds to the cell's normal Rb protein and disrupts its ability to halt cells at the restriction point, thereby contributing to uncontrolled proliferation by permitting unrestrained progression from G1 into S phase. (The mechanism by which the Rb protein normally halts cells at the restriction point is shown in Figure 19-39.) ② The E6 protein promotes the attachment of ubiquitin to the cell's normal p53 protein, thereby promoting p53 destruction. As a result, p53 can no longer trigger apoptosis in cells with damaged DNA.

The APC Tumor Suppressor Gene Codes for a Protein That Inhibits the Wnt Signaling Pathway

Like the *p53* gene, the next tumor suppressor we will consider is a common target for cancer-causing mutations, although in this case cancers arise mainly in one organ: the colon. Mutations affecting the gene in question, called the **APC gene**, are associated with an inherited disease called *familial adenomatous polyposis*. Affected individuals inherit a defective *APC* gene that makes them susceptible to developing thousands of *polyps* (benign tumors) in the colon if the second copy of the *APC* gene undergoes mutation. As a result, the risk of colon cancer arising by age 60 is nearly 100%. Although *familial adenomatous polyposis* is a rare disease, accounting for less than 1% of all colon cancers, *APC* mutations can also arise spontaneously or be triggered by environmental mutagens, and such mutations occur in roughly two-thirds of the more common, nonhereditary forms of colon cancer.

The *APC* gene produces a protein involved in the **Wnt pathway**, which plays a prominent role in controlling

cell proliferation and differentiation during embryonic development. As shown in **Figure 24-19**, the central component of the Wnt pathway is β -catenin (this is the same protein whose role in cadherin-mediated cell adhesion was described in Chapter 17). Normally β -catenin is regulated by a multiprotein *destruction complex* that consists of APC (the protein produced by the *APC* gene) combined with the proteins *axin* and *glycogen synthase kinase 3* (GSK3). When assembled in this APC-*axin*-GSK3 complex, GSK3 catalyzes the phosphorylation of β -catenin. Phosphorylated β -catenin is then linked to ubiquitin, which targets β -catenin for destruction by proteasomes (page 751). The resulting lack of β -catenin makes the Wnt pathway inactive.

The Wnt pathway is turned ON by extracellular signaling molecules called *Wnt proteins*, which bind to and activate *Wnt receptors* located at the cell surface. The activated Wnt receptors bind to *axin*, thereby preventing assembly of the APC-*axin*-GSK3 destruction complex and thus halting the degradation of β -catenin. The β -catenin then enters the nucleus and binds to the *TCF transcription factor*, forming a complex that activates a variety of target genes, including some that stimulate cell proliferation. Among the activated genes are *MYC* and the cyclin gene *CYCD1*—two genes whose ability to function as oncogenes was described earlier in the chapter (see Table 24-1).

Mutations causing abnormal activation of the Wnt pathway have been detected in numerous cancers. Most of these are loss-of-function mutations in the *APC* gene that are either inherited or, more commonly, triggered by environmental mutagens. The resulting absence of functional APC protein prevents the APC-*axin*-GSK3 complex from assembling and β -catenin therefore accumulates, locking the Wnt pathway in the ON position and sending the cell a continuous signal to divide.

Inactivation of Some Tumor Suppressor Genes Leads to Genetic Instability

The normal mutation rate for any given gene is about one in a million per cell division, and yet cancers almost always exhibit mutations in multiple genes—often a dozen or so mutations are necessary to trigger a cancer. How do cancer cells manage to acquire so many mutations if mutation is such a rare event? The apparent explanation is that *mutation rates in cancer cells are hundreds or even thousands of times higher than normal*.

This state, called **genetic instability**, can arise in several different ways. One group of mechanisms involves *disruptions in DNA repair*. For example, inherited defects in genes required for *mismatch repair* (page 569) are responsible for *hereditary nonpolyposis colon cancer* (*HNPPCC*), an inherited syndrome that elevates a person's cancer risk by allowing mutations to accumulate rather than being corrected by mismatch repair. Another hereditary disease,

(a) Normal cell (without Wnt proteins). In the absence of growth-signaling Wnt proteins, β -catenin is targeted for degradation by the axin-APC-GSK3 destruction complex, which catalyzes the phosphorylation of β -catenin. The phosphorylated β -catenin is linked to ubiquitin, thereby marking the phosphorylated β -catenin for degradation by proteasomes. The resulting absence of β -catenin maintains the Wnt pathway in the OFF position.

(b) Normal cell (with Wnt proteins). The Wnt pathway is turned ON by Wnt proteins, which activate cell surface Wnt receptors. The activated receptors bind to axin, thereby preventing assembly of the destruction complex and thus halting β -catenin degradation. The β -catenin enters the nucleus and binds to the TCF transcription factor, forming a complex that activates a variety of genes that control cell proliferation, including *MYC* and *CYCD1* (a cyclin gene).

(c) Cancer cell (regardless of the presence or absence of Wnt proteins). Some cancer cells have loss-of-function mutations in the *APC* gene. In the absence of functional APC protein, the destruction complex cannot form and β -catenin therefore accumulates, entering the nucleus and locking the Wnt pathway in the ON position.

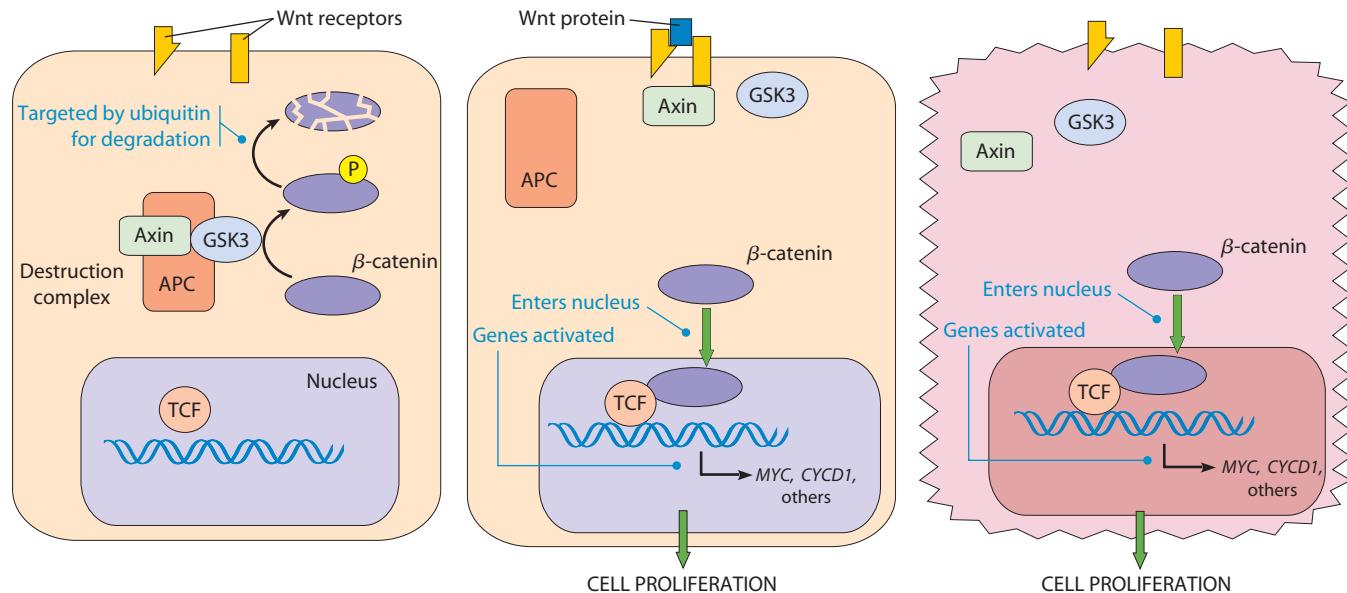

FIGURE 24-19 The Wnt Signaling Pathway. In normal cells, shown in (a) and (b), the Wnt pathway is active only in the presence of Wnt proteins. In cancer cells (c), the Wnt pathway is active regardless of the presence or absence of Wnt proteins.

xeroderma pigmentosum, is caused by inherited defects in genes needed for *excision repair* (page 568). **Box 24A** describes how children who inherit this condition develop an extremely high skin cancer risk because they are unable to repair DNA damage triggered by exposure to sunlight.

Faulty DNA repair is also involved in hereditary forms of breast cancer, which account for about 10% of all breast cancer cases. Most hereditary forms of breast (and ovarian) cancer arise in women who inherit a mutant copy of either the *BRCA1* or *BRCA2* gene, both of which code for proteins involved in repairing double-strand DNA breaks. Breast and ovarian cells defective in either of the BRCA proteins exhibit many chromosomal abnormalities, including translocations, deletions, and broken or fused chromosomes. As a result, women inheriting *BRCA* mutations exhibit a 40–80% lifetime risk for breast cancer and a 15–65% risk for ovarian cancer. Because the risks are so high, women with a family history of breast or ovarian cancer may wish to undergo genetic testing to determine whether they carry a mutant *BRCA1* or *BRCA2* gene.

Genetic instability is not restricted to situations involving hereditary cancer risk. Most cancers are not hereditary, but they still exhibit genetic instability. In some cases, the instability can be traced to mutations in DNA repair genes that either arise spontaneously or are caused by environmental mutagens. Another explanation is that the p53 pathway is defective in most cancer cells, which removes a protective mechanism that would arrest cells at cell cycle checkpoints to allow DNA repair to occur or would trigger apoptosis to destroy cells containing damaged DNA.

Genetic instability can also arise from defects in mitosis that cause *disruptions in chromosome sorting* during cell division, resulting in broken chromosomes and *aneuploidy* (an abnormal number of chromosomes). One reason for improper chromosome sorting is the presence of extra *centrosomes*, the structures that help guide microtubule assembly during spindle formation (page 572). **Figure 24-20** shows a cancer cell with three centrosomes that have assembled a mitotic spindle with three poles. Spindles containing three or more poles, which are rare in normal tissues

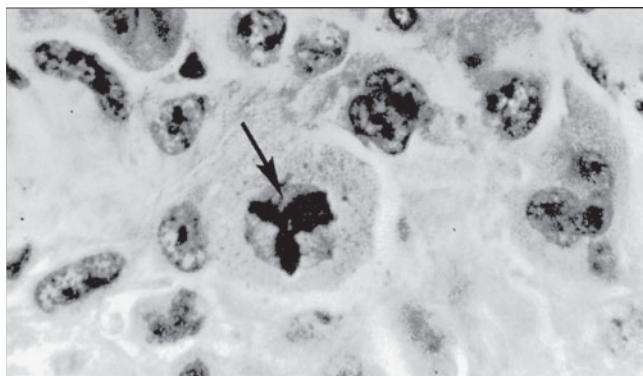

FIGURE 24-20 Abnormal Mitosis in a Cancer Cell. Cancer tissue viewed by light microscopy shows a cell with an abnormal mitotic spindle containing three spindle poles. Such spindles, which cannot separate chromosomes properly, are created by the presence of three centrosomes rather than the normal two.

but common in cancer cells, contribute to aneuploidy because they cannot sort the two sets of chromosomes accurately. Mitosis involving an abnormal spindle often produces cells that are missing certain chromosomes, and such cells are therefore deficient in any tumor suppressor genes that normally reside on the missing chromosomes.

Cancer cells may also exhibit defects in proteins involved in either attaching chromosomes to the spindle or in the *mitotic spindle checkpoint*, whose normal function is to prevent anaphase chromosome separation from beginning before the chromosomes are all attached to the spindle (page 587). For example, some cancers have mutations in genes coding for Mad or Bub proteins, which are central components of the mitotic spindle checkpoint. If Mad or Bub proteins are defective or in short supply, chromosome movements toward the spindle poles may begin before all the chromosomes are properly attached to the mitotic spindle. The result is inaccurate chromosome sorting and the production of aneuploid cells that lack certain chromosomes and possess extra copies of others.

The genes coding for proteins involved in DNA repair and chromosome sorting discussed in this section fit the definition of tumor suppressor genes because their loss or inactivation contributes to cancer development. But such genes are not in the same category as the *RB*, *p53*, and *APC* genes, which produce proteins that restrain cell proliferation and whose loss can directly lead to cancer. To distinguish the two classes of tumor suppressors, genes like *RB*, *p53*, and *APC* are called **gatekeepers** because their loss directly opens the gates to excessive cell proliferation and tumor formation. In contrast, genes involved in DNA repair and chromosome sorting are referred to as **caretakers** because they maintain genetic stability but are not directly involved in controlling cell proliferation and survival. Defects in caretaker genes lead to genetic instability, which in turn allows the accumulation of mutations

Table 24-2 Examples of Tumor Suppressor Genes

Gene	Pathway Affected
Gatekeeper Genes	
<i>APC</i>	Wnt signaling
<i>CDKN2A</i>	Rb and p53 signaling
<i>PTEN</i>	PI3K-Akt signaling
<i>RB</i>	Restriction point control
<i>SMAD4</i>	TGF β -Smad signaling
<i>TGFβ receptor</i>	TGF β -Smad signaling
<i>p53</i>	DNA damage response
Caretaker Genes	
<i>BRCA1, BRCA2</i>	DNA double-strand break repair
<i>MSH2, MSH3, MSH4, MSH5, MSH6, PMS1, PMS2, MLH1</i>	DNA mismatch repair
<i>XPA, XPB, XPC, XPD, XPE, XPF, XPG</i>	DNA excision repair
<i>XPV (POLη)</i>	DNA translesion synthesis

in other genes (including gatekeepers) that then trigger excessive cell proliferation and cause cancer to develop. Genetic instability arising from defective caretaker genes is therefore an early event in the process leading to the development of cancer. **Table 24-2** lists some common tumor suppressor genes, organized on the basis of whether they are caretakers or gatekeepers and grouped according to the pathways they affect.

Cancers Develop by the Stepwise Accumulation of Mutations Involving Oncogenes and Tumor Suppressor Genes

Genome sequencing studies have revealed that a given type of cancer (e.g., breast, lung, or colon cancer) typically involves mutations in about 50–75 different protein-coding genes. A small handful of these genes are mutated frequently in cancer samples of the same type taken from different people, while the rest of the genes are infrequently mutated. The commonly mutated genes affect about a dozen different pathways, most of which are discussed at one point or another in this chapter.

The common mutations involve the inactivation of tumor suppressor genes as well as the conversion of proto-oncogenes into oncogenes. In other words, creating a cancer cell usually requires that the brakes on cell growth (tumor suppressor genes) be released and the accelerators for cell growth (oncogenes) be activated. This principle is well illustrated by the stepwise progression toward malignancy observed in colon cancer. The most common pattern to be detected is the presence of a *KRAS* oncogene (a member of the *RAS* gene family) accompanied by loss-of-function mutations in the tumor suppressor genes

Children of the Moon

The connection between faulty DNA repair and cancer susceptibility was first observed in a rare hereditary disease called **xeroderma pigmentosum**. Individuals who inherit this condition are so sensitive to the sun's ultraviolet (UV) radiation that exposure to a few minutes of daylight is enough to cause severe burning of the skin and skin cancer. Because it is only safe for them to go outside at night, children with xeroderma pigmentosum are sometimes referred to as "children of the moon." In upstate New York there is even a special camp, called *Camp Sundown*, that allows affected children to participate in normal recreational activities but on a different schedule. Outdoor activities begin after sundown and take place during the night, allowing the children to be back indoors and safely behind drawn curtains by sunrise. Scientists from NASA have even designed a special space suit that provides enough sunlight protection to allow children with xeroderma pigmentosum to occasionally play outdoors (**Figure 24A-1**).

FIGURE 24A-1 A Child with Xeroderma Pigmentosum

Playing Outdoors. Because exposure to daylight is dangerous for people with xeroderma pigmentosum, NASA designed a special spacesuit to protect children from the sun's UV radiation.

APC, *SMAD4*, and *p53*. Rapidly growing colon cancers tend to exhibit all four genetic alterations, whereas benign tumors have only one or two.

As shown in **Figure 24-21**, the earliest mutation to be routinely detected is loss of function of the *APC* gene—a mutation that frequently occurs in small polyps before cancer has even arisen. Mutations in *KRAS* and *SMAD4* tend to be seen when the polyps get larger, and mutations in *p53* usually appear when cancer finally develops. However, these mutations do not always occur in the same sequence or with the same exact set of genes. For example, *APC* mutations are found in about two-thirds

The susceptibility to skin cancer that is the hallmark of xeroderma pigmentosum can be traced to inherited defects in DNA repair. In Chapter 19 we saw that the UV radiation in sunlight can damage DNA molecules by triggering *pyrimidine dimer* formation—that is, the formation of covalent bonds between adjacent pyrimidine bases (see Figure 19-17c). If they are not repaired, such mutations can lead to cancer. One way of repairing pyrimidine dimers is through *excision repair*, a process that uses a series of enzymes to excise the damaged region and fill the resulting gap with the correct sequence of nucleotides (see Figure 19-18). In the late 1960s, it was first reported that cells from most individuals with xeroderma pigmentosum are unable to carry out excision repair. As a consequence, DNA mutations accumulate and cancer eventually arises. Subsequent studies revealed that mutations in seven different genes can disrupt excision repair and thereby cause xeroderma pigmentosum. The seven genes, designated *XPA* through *XPG*, each code for an enzyme involved in a different step of the excision repair pathway.

Inherited mutations in an eighth gene, called *XPV*, produce an alternate form of xeroderma pigmentosum in which excision repair remains intact but affected individuals are still susceptible to sunlight-induced cancers. This particular mutation affects the gene for DNA polymerase η (eta), a special form of DNA polymerase that catalyzes the *translesion synthesis* of a new stretch of DNA across regions in which the template strand is damaged (page 568). DNA polymerase η is capable of replicating DNA in regions where pyrimidine dimers are present and correctly inserts the proper bases in the newly forming DNA strand. Thus, inherited defects in DNA polymerase η , like inherited defects in excision repair, hinder the ability to correct pyrimidine dimers created by UV radiation.

The defects in DNA repair inherited by children with xeroderma pigmentosum lead to skin cancer rates that are 2000-fold higher than normal. Affected individuals develop skin cancer at an average age of 8 years old, compared to age 60 for the general population. Although the greatest impact is on skin cancer, the DNA repair defects seen in xeroderma pigmentosum also cause a 20-fold increase in risk for leukemia and cancers of the brain, lung, stomach, breast, uterus, and testes.

of all colon cancers, but this means that the *APC* gene is normal in one out of every three cases. Analysis of tumors containing normal *APC* genes has revealed that many of them possess oncogenes that produce an abnormal, hyperactive form of β -catenin, a protein that—like the *APC* protein—is involved in Wnt signaling (see Figure 24-19). Because *APC* inhibits the Wnt pathway and β -catenin stimulates it, mutations leading to the loss of *APC* and mutations that create hyperactive forms of β -catenin have the same effect: Both enhance cell proliferation by increasing the activity of the Wnt pathway.

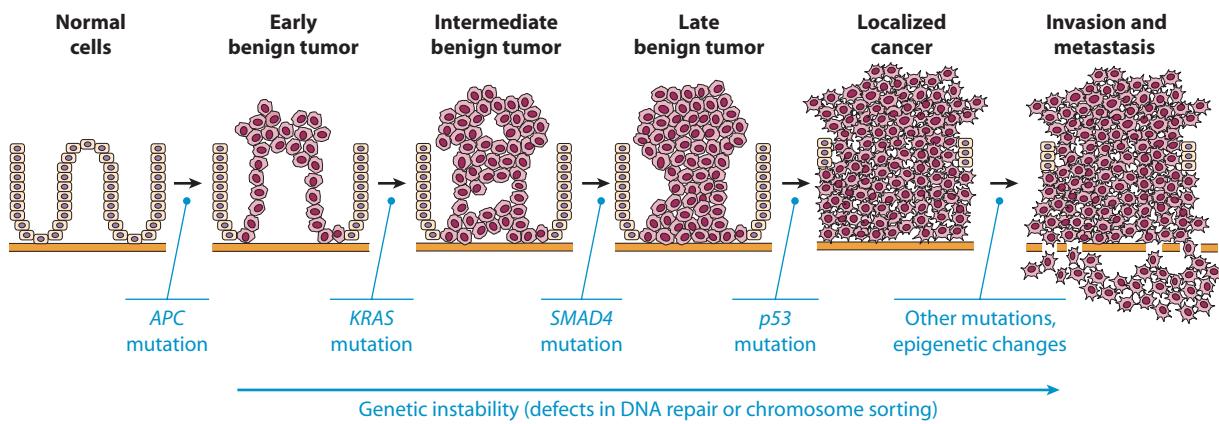

FIGURE 24-21 Stepwise Model for the Development of Colon Cancer. Colon cancer often arises through a stepwise series of mutations involving the *APC*, *KRAS*, *SMAD4*, and *p53* genes. Each successive mutation is associated with increasingly abnormal cell behavior. The early stages in this process produce benign tumors called *polyps*, which protrude from the inner surface of the colon.

 **VIDEOS** www.thecellplace.com Removing a colon polyp

Another pathway frequently disrupted in colon cancer is the *TGF β -Smad pathway* (page 413), which *inhibits* rather than stimulates epithelial cell proliferation. Loss-of-function mutations in genes coding for components of this pathway, such as the *TGF β* receptor or Smad4, are commonly detected in colon cancers. Such mutations disrupt the growth-inhibiting activity of the *TGF β -Smad* pathway and thereby contribute to enhanced cell proliferation.

Overall, the general principle illustrated by the various colon cancer mutations is that different tumor suppressor genes and oncogenes can affect the same pathway, and it is the disruption of particular signaling pathways that is important in cancer rather than the particular gene mutations that cause the disruption.

Epigenetic Changes in Gene Expression Influence the Properties of Cancer Cells

Mutations that create oncogenes or inactivate tumor suppressor genes play central roles in cancer development, but they do not explain all the properties of cancer cells. Many traits exhibited by cancer cells arise not from gene mutations but from *epigenetic changes*—that is, changes in gene expression that do not involve changes in a gene's underlying base sequence.

In Chapter 23, we saw that one mechanism for creating epigenetic changes involves *DNA methylation* at -CG- sites located near gene promoters. Most of these sites are unmethylated in normal cells, but extensive methylation is common in cancer cells, where it leads to *epigenetic silencing* of numerous genes—including tumor suppressor genes. In fact, the tumor suppressor genes of cancer cells are inactivated by DNA methylation at least as often as they are inactivated by DNA mutation. Epigenetic silencing of a tumor suppressor gene can be a critical, initiating event on the road to cancer. For example, individuals who inherit an extensively methylated form of

a DNA mismatch repair gene known as *MLH1* are highly susceptible to developing multiple cancers. Inheriting a methylated tumor suppressor gene may therefore predispose a person to developing cancer just like inheriting a mutated form of the gene does.

Another mechanism for altering gene expression involves *microRNAs*, which bind to and silence the translation of thousands of individual mRNAs (see Figure 23-34). Cancer cells produce excessive amounts of some microRNAs and inadequate amounts of others. Genes that contribute to cancer development by *overproducing* microRNAs are acting as oncogenes. MicroRNA genes in this category include *miR-155*, *miR-17-92*, and *miR-21*. To give one example of how such genes act, the microRNA produced by *miR-17-92* inhibits translation of the messenger RNA coding for *PTEN*, a phosphatase that inhibits PI3K-Akt signaling pathways (page 591). The *miR-17-92* gene is frequently amplified in certain types of cancer, which leads to excessive production of its microRNA and a resulting inhibition of the synthesis of *PTEN*. Depletion of *PTEN* allows the PI3K-Akt pathway to be continually activated, thereby leading to enhanced cell proliferation and survival.

MicroRNAs that are *underproduced* can contribute to cancer development by acting as tumor suppressors. MicroRNA genes in this category include *let-7*, *miR-29*, and the *miR-15a/miR-16-1* cluster. For example, the *miR-15a/miR-16-1* gene cluster is frequently deleted in certain forms of leukemia. One of the normal functions of *miR-15a/miR-16-1* is to inhibit translation of the messenger RNA coding for *Bcl-2*, a protein that inhibits apoptosis (page 594). Deletion of *miR-15a/miR-16-1* can therefore lead to excessive production of *Bcl-2*, which in turn interferes with the ability to carry out apoptosis.

Some microRNAs influence *histone modification* reactions, whose role in regulating gene expression was discussed in Chapter 23. One example involves *miR-101*, a microRNA gene that is frequently deleted in prostate

cancer cells. The microRNA produced by *miR-101* normally inhibits translation of the messenger RNA coding for EZH2, an enzyme that catalyzes histone methylation. Loss of the *miR-101* gene therefore leads to increased production of EZH2, and the resulting increase in histone methylation may play a role in silencing the expression of tumor suppressor genes.

Summing Up: Carcinogenesis and the Hallmarks of Cancer

Since various combinations of mutations and epigenetic changes involving tumor suppressor genes and oncogenes can lead to cancer, you might wonder whether it is possible to provide a unifying overview of the process of *carcinogenesis*—that is, the multistep series of events that convert normal cells into cancer cells. One way of presenting such an overview is provided by **Figure 24-22**, which begins with the four main causes of cancer: chemicals, radiation, infectious agents, and heredity. Through a variety of mechanisms, each of these produces DNA mutations. For cancer to develop, these mutations must involve a stepwise series of changes involving the inactivation of tumor suppressor genes and the conversion of proto-oncogenes into oncogenes. Such mutations, along with epigenetic changes, eventually produce a group of six traits referred to by Douglas Hanahan and Robert Weinberg as the *hallmarks of cancer*. These six traits, described in the following paragraphs, are common to all forms of cancer, but each trait can be acquired through a variety of genetic and epigenetic mechanisms.

1. Self-Sufficiency in Growth Signals. Cells do not normally proliferate unless they are stimulated by an appropriate growth factor. Cancer cells escape this requirement through the action of oncogenes that produce excessive quantities or mutant versions of proteins involved in growth-stimulating pathways (see Table 24-1). One such pathway commonly activated in cancer cells is the Ras

pathway. About 25–30% of all human cancers have mutant Ras proteins that provide an ongoing stimulus for the cell to proliferate independently of growth factors. Mutations affecting other components of the Ras pathway are common as well.

2. Insensitivity to Antigrowth Signals. Normal tissues are protected from excessive cell proliferation by a variety of growth-inhibiting mechanisms. Cancer cells must evade such antigrowth signals if they are to continue proliferating. Most antigrowth signals act during late G1 and exert their effects through the Rb protein, whose phosphorylation regulates passage through the restriction point and into S phase. For example, TGF β normally inhibits proliferation by triggering the TGF β -Smad pathway, which produces Cdk inhibitors that block Rb phosphorylation and thereby prevent passage from G1 into S phase. In cancer cells, the TGF β -Smad pathway is disrupted by a variety of mechanisms, including mutations, epigenetic changes, and interactions with viral proteins. Mutations in the *RB* gene also make cells insensitive to the antigrowth effects of TGF β or any other growth inhibitor that exerts its effects through the Rb protein.

3. Evasion of Apoptosis. The survival of cancer cells depends on their ability to evade the normal fate of genetically damaged cells—destruction by apoptosis. The ability to evade apoptosis is often imparted by mutations in the *p53* tumor suppressor gene, which disrupt the ability of the *p53* pathway to trigger apoptosis in response to DNA damage. The *p53* pathway can also be disrupted by certain oncogenes. An example is the *MDM2* gene, which produces the Mdm2 protein that targets *p53* for destruction (see Figure 19-40). Another oncogene that affects the ability of the *p53* pathway to trigger apoptosis is the *BCL2* gene, which codes for an inhibitor of apoptosis known as the Bcl-2 protein (page 594). *BCL2* oncogenes produce excessive quantities of Bcl-2, resulting in a suppression of apoptosis that allows abnormal cells to

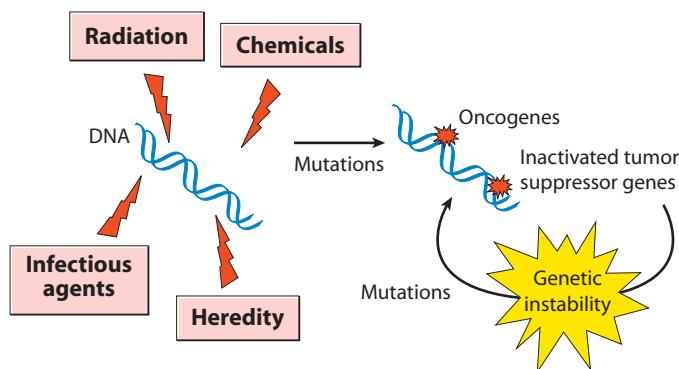

FIGURE 24-22 Overview of Carcinogenesis. The four main causes of cancer (chemicals, radiation, infectious agents, and heredity) trigger initial DNA alterations that can create oncogenes and disrupt tumor suppressor genes. An early result of these changes is genetic instability, which in turn facilitates the acquisition of additional mutations that (along with accompanying epigenetic changes) lead to the six hallmark traits: self-sufficiency in growth signals, insensitivity to antigrowth signals, evasion of apoptosis, limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis.

HALLMARKS OF CANCER

- ① Self-sufficiency in growth signals
- ② Insensitivity to antigrowth signals
- ③ Evasion of apoptosis
- ④ Limitless replicative potential
- ⑤ Sustained angiogenesis
- ⑥ Tissue invasion and metastasis

continue proliferating. Through such mechanisms, cancer cells manage to evade the apoptotic pathways that would otherwise lead to cancer cell destruction.

4. Limitless Replicative Potential. The overall effect of the preceding three traits is to uncouple cancer cells from the mechanisms that normally balance cell proliferation with an organism's need for new cells. However, this would not ensure unlimited proliferation in the absence of a mechanism for replenishing the telomere sequences that are lost from the ends of each chromosome during DNA replication. Telomere maintenance is usually accomplished by activating the gene coding for telomerase, but a few cancer cells activate an alternative mechanism for maintaining telomeres that involves the exchange of sequence information between chromosomes. In either case, cancer cells maintain telomere length above a critical threshold and thereby retain the ability to divide indefinitely.

5. Sustained Angiogenesis. Without a blood supply, tumors will not grow beyond a few millimeters in size. Thus, at some point during early tumor development, cancer cells must trigger angiogenesis. A common strategy involves the activation of genes coding for angiogenesis stimulators combined with the inhibition of genes coding for angiogenesis inhibitors. The mechanisms underlying such changes in gene expression are not well understood, but in some cases they have been linked to the activities of known tumor suppressor genes or oncogenes. For example, the p53 protein activates the gene coding for the angiogenesis inhibitor thrombospondin; hence the loss of p53 function, which occurs in many human cancers, can cause thrombospondin levels to fall. Conversely, RAS oncogenes trigger increased expression of the gene coding for the angiogenesis activator VEGF.

6. Tissue Invasion and Metastasis. The ability to invade surrounding tissues and metastasize to distant sites is the defining trait that distinguishes a cancer from a benign tumor. Three properties exhibited by cancer cells play a crucial role in these events: decreased cell-cell adhesion, increased motility, and the production of proteases that degrade the extracellular matrix and basal lamina. Decreased adhesiveness is often caused by changes in *E-cadherin*, which is lost in the majority of epithelial cancers by either mutation, decreased gene expression, or destruction of E-cadherin itself. Changes in other molecules involved in cancer cell adhesion, motility, and protease production also play roles in invasion and metastasis. The mechanisms underlying these molecular changes differ among tumor types and tissue environments, but they commonly involve activation of genes normally intended for use in embryonic development or wound healing.

The Crucial Enabling Trait: Genetic Instability. To acquire the preceding six traits, cancer cells need to

accumulate more mutations than would be generated by normal mutation rates. Cells must therefore become genetically unstable before enough mutations can accumulate to cause cancer. Genetic instability arises most commonly from mutations that disrupt the ability of the p53 pathway to trigger the destruction of genetically damaged cells. However, mutations in genes coding for proteins involved in DNA repair and chromosome sorting also play a role. Genetic instability is placed in a category separate from the six hallmark traits—which are directly involved in cancer cell proliferation and spread—because genetic instability is a crucial underlying trait that enables cancer cells to accumulate the mutations that permit the six hallmark traits to arise.

Diagnosis, Screening, and Treatment

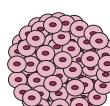

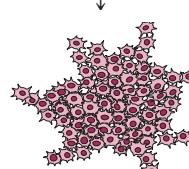

Much progress has been made in recent years in elucidating the genetic and biochemical abnormalities underlying cancer development. One of the hopes for such research is that our growing understanding of the molecular alterations exhibited by cancer cells will eventually lead to improved strategies for cancer diagnosis and treatment.

Cancer Is Diagnosed by Microscopic Examination of Tissue Specimens

Because cancer can arise in almost any tissue, few generalizations are possible regarding disease symptoms. A definitive diagnosis typically requires a *biopsy*, which involves surgical removal of a tiny tissue sample for microscopic examination. Although no single trait is sufficient for visually identifying cancer cells, they usually display several features that together indicate the presence of cancer (**Table 24-3**). For example, cancer cells often exhibit large, irregularly shaped nuclei, prominent nucleoli, a high ratio of nuclear-to-cytoplasmic volume, significant variations in cell size and shape, and a loss of normal tissue organization. To varying extents, cancer cells lose the specialized structural and biochemical properties of the cells normally residing in the tissue of origin. Cancers also have more dividing cells than normal, which means that the *mitotic index* (page 550) will be elevated. And finally, cancers typically have a poorly defined outer boundary, with signs of tumor cells penetrating into surrounding tissues.

If a sufficient number of these abnormal traits are observed, it can be concluded that cancer is present—even if *invasion and metastasis have not yet occurred*. However, the severity of the abnormal traits varies significantly among cancers, even when they arise from the same cell type in the same organ. This variability forms the basis for **tumor grading**, which is the assignment of numbered grades to tumors based on differences in their microscopic appearance. Lower numbers (for example, grade 1) are assigned to tumors whose cells exhibit normal differentiated features, divide slowly, and display only modest abnormalities in the

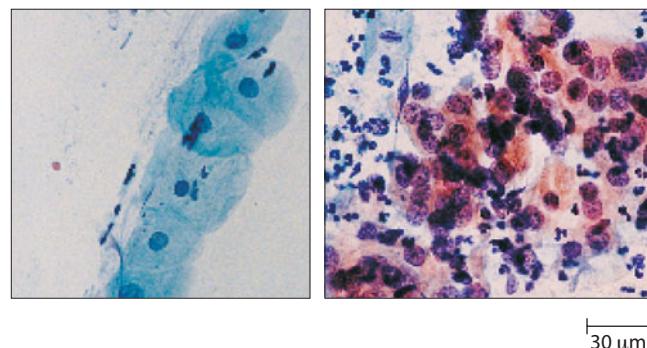

Table 24-3**Some Differences in the Microscopic Traits of Benign and Malignant Tumors**

Trait	Benign	Malignant
Nuclear size	Small	Large
N/C ratio (ratio of nuclear to cytoplasmic volume)	Low	High
Nuclear shape	Regular	Pleomorphic (irregular shape)
Mitotic index	Low	High
Tissue organization	Normal	Disorganized
Differentiation	Well differentiated	Poorly differentiated
Tumor boundary	Well defined ↓ 	Poorly defined ↓ 

traits listed in Table 24-3. Higher numbers (for example, grade 4) are assigned to tumors containing rapidly dividing, poorly differentiated cells that bear less resemblance to normal cells and exhibit severe abnormalities in the traits listed in Table 24-3. The highest-grade cancers contain cells that are so poorly differentiated and abnormal in appearance that they bear no resemblance to the cells of the tissue in which the tumor arose. These high-grade cancers tend to grow and spread more aggressively and respond less to therapy than lower-grade cancers do.

Screening Techniques for Early Detection Can Prevent Cancer Deaths

When cancer is detected before it has spread, cure rates tend to be relatively high, even for cancers that would otherwise have a poor prognosis. A great need therefore exists for screening techniques that can detect cancers at an early stage. One of the most successful screening procedures is the **Pap smear**, a technique for early detection of cervical cancer developed in the early 1930s by George Papanicolaou (for whom it is named). The rationale underlying this procedure is that the microscopic appearance of cancer cells is so distinctive that you can detect the likely presence of cancer simply by examining a small sample of isolated cells. A Pap smear is performed by taking a tiny sample of a woman's vaginal secretions and examining it with a microscope. If the cells in the fluid exhibit unusual features—such as large, irregular nuclei or prominent variations in cell size and shape (**Figure 24-23**)—it is a sign that cancer may be present and further tests need to be done. Because a Pap smear allows cervical cancer to be detected in its early stages before metastasis has occurred, this procedure has prevented hundreds of thousands of cancer deaths.

**FIGURE 24-23 Normal and Abnormal Pap Smears.** (Left)

In a normal Pap smear, the cells are relatively uniform in size and contain small spherical nuclei. (Right) In this abnormal Pap smear, marked variations in cell size and shape are evident, and the nuclei are larger relative to the size of the cells. The abnormalities in these isolated cells suggest they may be derived from a cervical cancer, and further examination of the uterus is therefore required.

The success of the Pap smear has led to the development of screening techniques for other cancers. For example, **mammography** utilizes a special X-ray technique to look for early signs of breast cancer, and **colonoscopy** uses a slender fiber-optic instrument to examine the colon for early signs of colon cancer. The ideal screening test would allow doctors to detect cancers anywhere in the body with one simple procedure, such as a blood test. Prostate cancer is an example of a cancer that can sometimes be detected this way. Men over the age of 50 are often advised to get a **PSA test**, which measures how much *prostate-specific antigen* (PSA) is present in the bloodstream. PSA, which is a protein produced by cells of the prostate gland, normally appears in only tiny concentrations in the blood. If a PSA test reveals a high concentration of PSA, it indicates a possible prostate problem. Further tests are then performed to determine whether cancer is actually present.

Other cancers also release specific proteins into the bloodstream, where their presence might be used to signal the existence of early disease. However, the development of methods for reliably detecting these proteins is still in its infancy, and much work remains to be done before we will know whether cancers can be reliably detected in their early stages by looking for small changes in blood proteins.

Surgery, Radiation, and Chemotherapy Are Standard Treatments for Cancer

Strategies for treating cancer depend both on the type of cancer involved and how far it has spread. The most common approach involves surgery to remove the primary tumor, followed (if necessary) by radiation therapy and/or chemotherapy to destroy any remaining cancer cells.

Radiation therapy uses high-energy X-rays or other forms of ionizing radiation to kill cancer cells. Earlier in the chapter we saw that the DNA damage created by ionizing radiation can cause cancer. Ironically, the same type

of radiation is used in higher doses to destroy cancer cells in people who already have the disease. Ionizing radiation kills cells in two different ways. First, DNA damage caused by radiation activates the p53 signaling pathway, which then triggers apoptosis. However, many cancers have mutations that disable the p53 pathway, so p53-induced apoptosis plays only a modest role in the response of most cancers to radiation treatment. In the second mechanism, radiation kills cells by causing such severe chromosomal damage that it prevents cells from progressing through mitosis, and the cells therefore die while trying to divide.

Most forms of *chemotherapy* use drugs that, like radiation, kill dividing cells. Such drugs can be subdivided into four major categories. (1) *Antimetabolites* inhibit metabolic pathways required for DNA synthesis by acting as competitive inhibitors that bind to enzyme active sites in place of normal substrate molecules. Examples include *fluorouracil*, *methotrexate*, *fludarabine*, *pemetrexed*, and *gemcitabine*. (2) *Alkylating agents* inhibit DNA function by chemically crosslinking the DNA double helix. Examples include *cyclophosphamide*, *chlorambucil*, and *cisplatin*. (3) *Antibiotics* are substances made by microorganisms that inhibit DNA function by either binding to DNA or inhibiting topoisomerases required for DNA replication. Examples include *doxorubicin* and *epirubicin*. (4) *Plant-derived* drugs either inhibit topoisomerases or disrupt the microtubules of the mitotic spindle. Examples include the topoisomerase-inhibitor *etoposide* and the microtubule-disrupting drug, *taxol*.

One problem with such drug (and radiation) treatments is that they are toxic to normal dividing cells as well as to cancer cells. Less toxic approaches are possible for those cancers whose growth requires a specific hormone. For example, many breast cancers require estrogen for their growth. As we saw in Chapter 19, steroid hormones such as estrogen exert their effects by binding to steroid receptor proteins that activate the expression of specific genes. The drug *tamoxifen*, which binds to estrogen receptors in place of estrogen and prevents the receptors from being activated, is useful both in treating breast cancer and in reducing the occurrence of breast cancer in women at high risk for the disease.

A frequent complication with drug therapies is that tumors tend to acquire mutations that make them resistant to the drugs being used. Even when only a single drug is employed, tumors often become resistant to the administered drug and to the effects of several unrelated drugs at the same time. This state, known as multiple drug resistance, arises because cells start producing *multidrug resistance transport proteins* (*ABC transporters*) that actively pump a wide range of chemically dissimilar, hydrophobic drugs out of the cell (page 211).

Drug resistance may also arise because tumors consist of a heterogeneous mixture of cells that are not equally sensitive to anticancer drugs. A growing body of evidence suggests that in some types of cancer only a small population of cells—known as *cancer stem cells* or *cancer-initiating*

cells—proliferate indefinitely and produce the rest of the cells found in tumors. If treatments that destroy most of the tumor cells leave behind a small number of cancer stem cells, these cells may be enough to regenerate the tumor after treatment is stopped. Researchers are therefore trying to identify drugs that selectively destroy cancer stem cells because those are the cells that fuel tumor growth.

Using the Immune System to Target Cancer Cells

The use of surgery, radiation, or chemotherapy—either alone or in various combinations—can cure or prolong survival times for many types of cancer, especially when cancer is diagnosed early. However, some of the more aggressive types of cancer (such as those involving the lung, pancreas, or liver) are difficult to control in these ways, and similar difficulties are encountered when cancer is diagnosed in its later stages. In an effort to develop better approaches for treating such cancers, scientists have been trying to find ways to selectively seek out and destroy cancer cells without damaging normal cells in the process.

One strategy for introducing such selectivity into cancer treatment is to exploit the ability of the immune system to recognize cancer cells. This approach, called **immunotherapy**, was first proposed in the 1800s after doctors noticed that tumors occasionally regress in people who develop bacterial infections. Since infections trigger an immune response, subsequent attempts were made to build on this observation by utilizing live or dead bacteria to provoke the immune system of cancer patients. Although the approach has not worked as well as initially hoped, some success has been seen with *bacillus Calmette-Guérin* (BCG)—a bacterial strain that does not cause disease but elicits a strong immune response at the site where it is introduced into the body. BCG is useful in treating early stage bladder cancers that are localized to the bladder wall. After the primary tumor has been surgically removed, inserting BCG into the bladder elicits a prolonged activation of immune cells that in turn leads to lower rates of cancer recurrence.

While it demonstrates the potential usefulness of immune stimulation, BCG must be administered directly into the bladder to provoke an immune response at the primary tumor site. To treat cancers that have already metastasized to unknown locations, an immune response must be stimulated wherever cancer cells might have traveled. Normal proteins that the body produces to stimulate the immune system are sometimes useful for this purpose. *Interferon alpha* and *interleukin-2* (*IL-2*) are two such proteins that have been successfully used as cancer treatments.

Attempts are also under way to develop therapeutic *vaccines* that introduce cancer cell antigens into patients to stimulate the immune system to selectively attack cancer cells. One such vaccine, called *Provenge*, uses an antigen commonly found in prostate cancer cells combined with antigen-processing cells obtained from the patient's blood.

Monoclonal Antibodies and Cancer Treatment

One way the immune system operates is by producing **antibodies**, which are soluble proteins that bind to substances, referred to as **antigens**, that provoke an immune response. To function as an antigen, a substance must usually be recognized as being “foreign”—that is, different from molecules normally found in a person’s body. Antibody molecules recognize and bind to specific antigens with extraordinary precision, making them ideally suited for targeting antigens that are unique to, or preferentially concentrated in, cancer cells.

For many years, the use of antibodies for treating cancer was hampered by the lack of a reproducible method for producing large quantities of pure antibody molecules directed against the same antigen. Then in 1975, Georges Köhler and César Milstein solved the problem by devising the procedure shown in **Figure 24B-1**. In this technique, mice are first injected with an antigen of interest, and antibody-producing lymphocytes are isolated from the animals a few weeks later. Within such a lymphocyte population, each lymphocyte produces a single type of antibody directed against one particular antigen. To facilitate the selection and growth of individual lymphocytes, they are fused with cells that divide rapidly and have an unlimited life span when grown in culture. Individual hybrid cells are then selected and grown to form a series of clones called *hybridomas*. The antibodies produced by hybridomas are referred to as **monoclonal antibodies** because each one is a pure antibody produced by a cloned population of lymphocytes.

To obtain monoclonal antibodies that might be useful for treating cancer, human cancer tissue is injected into mice to stimulate an immune response. Hybridomas are then created using lymphocytes from the immunized animals, and the hybridomas are analyzed to determine which ones produce antibodies directed against antigens present in the cancer tissue. Because the antibodies are derived from mice and might be destroyed by a person’s immune system, they are usually made more humanlike by replacing large parts of the mouse antibody molecule with corresponding sequences derived from human antibodies. When the resulting antibodies are injected into individuals with cancer, they bind to cancer cells and their presence can in theory trigger an immune attack against the cells containing the bound antibody. Although this approach does not yet work for most cancers, one promising success has been achieved with *non-Hodgkins lymphoma*. Antibodies that target the *CD20* antigen found on the surface of these lymphoma cells are now among the standard treatments for this particular type of cancer.

Antibodies can also serve as delivery vehicles by linking them to radioactive molecules or to other toxic substances that are too lethal to administer alone. Attaching such substances to antibodies allows the toxins to be selectively concentrated at tumor sites without accumulating to toxic levels elsewhere in the body. Finally,

many antibodies have been developed that bind to and inactivate specific proteins involved in the signaling pathways that drive cancer cell proliferation. The monoclonal antibody *Herceptin*, described on page 790, is an example of an anticancer drug that works in this way.

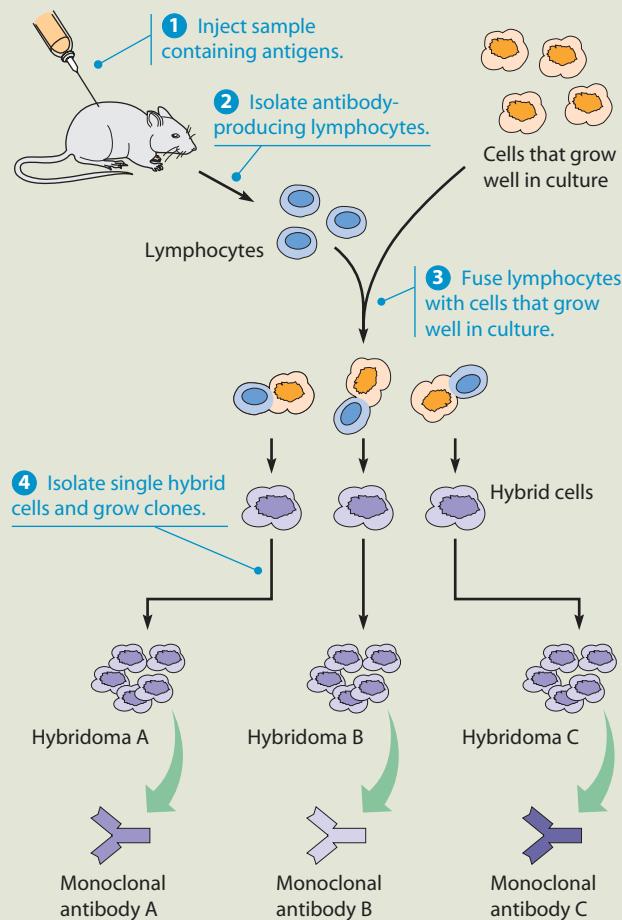

FIGURE 24B-1 Monoclonal Antibody Technique for Producing Pure Antibodies. A sample containing an antigen of interest is injected into mice to stimulate antibody formation. Antibody-producing lymphocytes isolated from the animal are then fused with cells that grow well in culture, and the resulting hybrid cells are used to create a series of cloned cell populations (hybridomas) that each make a single type of antibody. Extensive screening may be required to find a hybridoma that makes an antibody directed against a particular antigen of interest.

Human clinical trials suggest that Provenge is more effective than chemotherapy in prolonging the survival of men with prostate cancer, and the vaccine was approved by the FDA in 2010 for use as a standard treatment for prostate cancer.

Yet another way of using the immune system to fight cancer is with *antibodies*, which are proteins whose ability to recognize and bind to target molecules with great specificity makes them ideally suited to serve as agents that selectively attack cancer cells. **Box 24B** describes a

technique for manufacturing pure (“monoclonal”) antibodies in large quantities and illustrates how such antibodies have been used for treating cancer.

Herceptin and Gleevec Attack Cancer Cells by Molecular Targeting

Until the early 1980s, the development of new cancer drugs focused largely on agents that disrupt DNA and interfere with cell division. While such drugs are useful in treating cancer, their effectiveness is often limited by toxic effects on normal dividing cells. In the past two decades, the identification of individual genes that are mutated or abnormally expressed in cancer cells has created a new possibility—**molecular targeting**—in which drugs are designed to specifically target those proteins that are critical to the cancer cell.

One approach for molecular targeting involves the use of monoclonal antibodies that bind to proteins involved in the signaling pathways that drive cancer cell proliferation. The first such antibody approved for use in cancer patients, called *Herceptin*, binds to and inactivates the growth factor receptor produced by the *ERBB2* gene (also known as *HER2*). As we saw earlier in the chapter, about 25% of all breast and ovarian cancers have amplified *ERBB2* genes that produce excessive amounts of this receptor. When individuals with such cancers are treated with Herceptin, the Herceptin antibody binds to the receptor and inhibits its ability to stimulate cell proliferation, thereby slowing or stopping tumor growth. Other monoclonal antibodies now used in cancer therapy include *Erbitux* (directed against the epidermal growth factor receptor) and *Avastin* (directed against the angiogenesis stimulating growth factor, VEGF).

An alternative way of targeting molecules for inactivation, called *rational drug design*, involves the laboratory synthesis of *small molecule inhibitors* that are designed to inactivate specific target proteins. One of the first anti-cancer drugs developed in this way was *Gleevec*. Gleevec binds to and inhibits an abnormal tyrosine kinase produced by the *BCR-ABL* oncogene, whose association with chronic myelogenous leukemia was described earlier in the chapter. The *BCR-ABL* oncogene arises from the fusion of two unrelated genes and produces a structurally abnormal tyrosine kinase that represents an ideal drug target because it is present only in cancer cells. The effectiveness of Gleevec as a treatment for early stage myelogenous leukemia is quite striking. More than half of the patients treated with Gleevec have no signs of the cancer six months after treatment, a response rate that is 10 times better than that observed with earlier treatments. Other small molecule inhibitors of protein kinases that have subsequently been found to be useful in cancer therapy include *Iressa*, *Tarceva*, *Sutent*, and *Nexavar*.

Growth factor receptors, growth factors, and protein kinases are not the only candidates for molecular targeting. The uncontrolled proliferation, survival, invasion,

and metastasis of cancer cells is caused by disruptions in a variety of signaling pathways, and any of the proteins involved in these pathways is a potential target for anti-cancer drugs.

Anti-angiogenic Therapies Act by Attacking a Tumor’s Blood Supply

Molecular targeting isn’t always aimed at cancer cells. Earlier we saw that sustained tumor growth depends on *angiogenesis* (growth of new blood vessels), so it is logical to expect that inhibitors that target blood vessel growth might be useful for treating cancer. Initial support for this concept of *anti-angiogenic therapy* came from the studies of Judah Folkman, who found that angiogenesis inhibitors make tumors shrink in mice.

The first anti-angiogenic drug to be approved for use in humans was *Avastin*, a monoclonal antibody that binds to and inactivates the angiogenesis-stimulating growth factor, VEGF. In tumors that depend on VEGF to stimulate angiogenesis, Avastin is expected to slow tumor growth by inhibiting angiogenesis. Avastin has been found to improve short-term survival rates for several types of cancer, but the benefits are usually temporary and tumor growth resumes. Dozens of other drugs that target angiogenesis are currently being evaluated to see if they might be more effective than Avastin, but it will be at least several years before the value of such anti-angiogenic agents becomes clear.

Cancer Treatments Can Be Tailored to Individual Patients

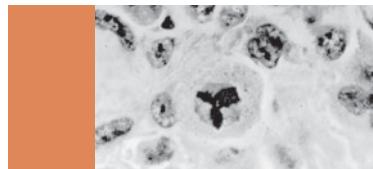

Tools are now becoming available to enhance the effectiveness of cancer therapies through a strategy called *personalized medicine*—an approach in which treatment choices are based on the individual characteristics of each patient. It has been known for many years that people with cancers that appear to be identical by traditional criteria often exhibit different outcomes after receiving the same treatment. *Transcriptome analysis*—the use of DNA microarrays to determine which genes are being transcribed into RNA (page 733)—has provided an explanation: Cancers involving the same cell type often exhibit differing patterns of gene expression that cause tumors to behave differently.

These differing patterns of gene expression allow predictions about tumor behavior to be made. In breast cancers, for example, the expression of 21 key genes turns out to be a good indicator of whether a given tumor is likely to metastasize. A test called *Oncotype DX* is now available that can measure the activity of these 21 genes and convert the data into a single number known as a *recurrence score*. Women whose breast tumors have a high recurrence score are more likely to have their cancers recur after surgery. In the absence of such information, doctors would usually recommend chemotherapy for most patients after surgery. The value of gene expression

testing is that it can help identify those patients who are most likely to benefit from chemotherapy.

Analyzing gene expression profiles and testing for the presence of specific mutations may also help guide the choice of which drug to use. A striking example involves *Iressa*, a drug that acts by inhibiting the tyrosine kinase activity of the epidermal growth factor (EGF) receptor. Iressa causes tumors to shrink in only 10% of lung cancer patients, but when the drug does work, it works extremely well. The reason Iressa is more effective in some individ-

uals than others has been traced to the presence of a mutant EGF receptor gene in the cancers of the patients who receive the most benefit from the drug. When grown in culture, lung cancer cells containing the mutant EGF receptor are found to be more sensitive to the growth-inhibiting effects of Iressa than are cancer cells containing the normal EGF receptor. This discovery opens the door to a personalized type of cancer therapy in which genetic testing of cancer cells is used to identify patients who are most likely to benefit from a particular type of treatment.

SUMMARY OF KEY POINTS

Uncontrolled Cell Proliferation and Survival

- Cancer cells proliferate in an uncontrolled way and are capable of spreading by invasion and metastasis.
- The balance between cell division and cell differentiation or death is disrupted in cancers, leading to a progressive increase in the number of dividing cells.
- Cancer cells are anchorage-independent, exhibit a decreased susceptibility to density-dependent inhibition of growth, and are able to replenish their telomeres.

How Cancers Spread

- Sustained tumor growth requires a network of blood vessels whose growth is triggered by an increased production of angiogenesis activators and a decreased production of angiogenesis inhibitors.
- Cancer cells invade surrounding tissues, enter the circulatory system, and metastasize to distant sites. Invasion is facilitated by decreased cell-cell adhesion, increased motility, and secretion of proteases that degrade the extracellular matrix and basal lamina. Only a tiny fraction of the cancer cells that enter the bloodstream establish successful metastases.
- Sites of metastasis are determined by the location of the first capillary bed as well as by organ-specific conditions that influence cancer cell growth.
- Cancers have various ways of evading destruction by the immune system. Interactions between tumor cells and components of the surrounding microenvironment influence tumor growth, invasion, and metastasis.

What Causes Cancer?

- Some cancers are caused by certain kinds of chemicals, including those found in tobacco smoke. Chemicals cause cancer through a multistep process involving initiation,

promotion, and tumor progression. Initiation is based on DNA mutation, whereas promotion involves a prolonged period of cell proliferation accompanied by selection of cells exhibiting enhanced growth properties. During tumor progression, additional mutations as well as epigenetic changes in gene expression produce cells with increasingly aberrant traits.

- Cancer can also be caused by ionizing or UV radiation, both of which trigger DNA mutations, as well as by certain viruses, bacteria, and parasites.
- Some cancer-causing viruses trigger cell proliferation directly, either through the action of viral genes or by altering the behavior of cellular genes. Other viruses and infectious agents create tissue destruction that indirectly stimulates cell proliferation under conditions in which DNA damage is likely.

Oncogenes and Tumor Suppressor Genes

- Oncogenes are genes whose presence can cause cancer. Although oncogenes are sometimes brought into cells by viruses, more often they arise from normal cellular genes (proto-oncogenes) by point mutation, gene amplification, chromosomal translocation, local DNA rearrangements, or insertional mutagenesis.
- Many of the proteins produced by oncogenes are signaling pathway components, such as growth factors, receptors, plasma membrane GTP-binding proteins, nonreceptor protein kinases, transcription factors, and cell cycle and apoptosis regulators. Oncogenes code for abnormal forms or excessive quantities of such proteins, thereby leading to excessive cell proliferation and survival.
- Tumor suppressor genes are genes whose loss or inactivation can lead to cancer. Susceptibility to cancer is increased in people who inherit defective tumor suppressor genes.
- Common tumor suppressor genes include the *RB* gene, which produces a protein that restrains passage from G1 into S phase; the *p53* gene, which produces a protein that prevents

proliferation and triggers apoptosis in cells with damaged DNA; and the *APC* gene, which produces a protein that inhibits the Wnt pathway.

- The genetic instability of cancer cells facilitates the acquisition of multiple mutations. Genetic instability arises from defects in DNA repair mechanisms, disruptions in pathways that trigger apoptosis, and failures in chromosome-sorting mechanisms.
- Cancers arise through a stepwise accumulation of mutations and epigenetic changes involving oncogenes and tumor suppressor genes. Most of the affected genes code for proteins, but some produce microRNAs.

Diagnosis, Screening, and Treatment

- Screening techniques, such as the Pap smear, can prevent cancer deaths by detecting cancer before it has spread.
- Cancer treatments usually involve surgery to remove the primary tumor, followed (if necessary) by radiation therapy and/or chemotherapy to kill or inhibit the growth of any remaining cancer cells.
- Newer treatment approaches include immunotherapies that exploit the ability of the immune system to attack cancer cells, molecular targeting drugs that bind to proteins that play critical roles in cancer cells, and anti-angiogenic agents that attack a tumor's blood supply.

MAKING CONNECTIONS

This final chapter on cancer cells has given us an opportunity to pull together many aspects of cell biology and show how investigating the properties of cancer cells has deepened our understanding of normal cells. For example, you learned how studying families with a hereditary form of a rare eye cancer, retinoblastoma, led to the discovery of the *RB* gene and its protein product, whose role in normal cell cycle regulation was described in Chapter 19. You also saw in this chapter that uncontrolled proliferation, one of the key

properties of cancer cells, arises from defects in cell signaling, cell cycle control, and apoptosis mechanisms that were described in Chapters 14 and 19. Another key property of cancer cells—the ability to invade and metastasize— involves changes in cell adhesion molecules (cadherins) described in Chapter 17. Finally, cancer is ultimately a genetic disease based on mutation and altered expression of DNA, whose role in storing and transmitting genetic information was covered in Chapters 18 through 23.

PROBLEM SET

More challenging problems are marked with a •.

24-1 Normal Cells and Cancer Cells. You are given two test tubes, one containing cells from a human cancer and the other containing normal cells. Before you begin your studies, the labels fall off the test tubes. Describe at least four experiments you could carry out to determine which sample contains the cancer cells.

24-2 Angiogenesis. Describe two pieces of evidence supporting the idea that angiogenesis is required for tumors to grow beyond a tiny clump of cells, and two pieces of evidence supporting the idea that cancer cells secrete molecules that stimulate angiogenesis.

24-3 How Cancers Spread. Describe the three main stages involved in metastasis, including a description of the relevant cellular properties.

• **24-4 Rats, Guinea Pigs, and Humans.** The chemical substance 2-acetylaminofluorene (AAF) causes bladder cancer when injected into rats but not guinea pigs. If normal bladder cells obtained from rats and guinea pigs are grown in culture and exposed to AAF, neither are converted into cancer cells. How can you explain these findings? Does your explanation suggest how to predict whether AAF is carcinogenic in humans without actually exposing humans to AAF?

24-5 Oncogenes and Tumor Suppressor Genes. Indicate whether each of the following descriptions applies to an oncogene (OG), a proto-oncogene (PO), or a tumor suppressor gene (TS). Some descriptions may apply to more than one of these gene types. Explain your answers.

- (a) A type of gene found in normal cells.
- (b) A gene that could code for a normal growth factor.
- (c) A type of gene found in cancer cells.
- (d) A type of gene found only in cancer cells.
- (e) A gene whose presence can cause cancer.
- (f) A gene whose absence can cause cancer.
- (g) A type of gene found in normal cells and cancer cells.

24-6 Children of the Moon. Children with xeroderma pigmentosum usually cannot carry out excision repair. Why does this make them so susceptible to developing cancer? Why was the word “usually” included in the first sentence?

• **24-7 Cancer Screening.** The annual incidence of colon cancer in the United States is about 55 cases per 100,000. Because colon cancer often causes bleeding, doctors sometimes use a screening procedure called the fecal occult blood test (FOBT) to look for tiny amounts of blood in the feces. One form of this test has a specificity of about 98%, which means that when it

indicates the presence of blood in the feces, the result is an error (i.e., cancer is not present) only 2% of the time. While this may seem like excellent specificity, a 2% “false positive” rate makes this test almost useless as a tool for colon cancer screening. Why?

- **24-8 Monoclonal Antibodies and Lymphoma.** Monoclonal antibodies directed against the CD20 antigen are used to treat certain forms of lymphoma. However, the CD20 antigen is present on both normal and malignant lymphocytes, and treatment with the antibody therefore kills normal cells as well as cancer cells. Why do you think this antibody still turns out to be an effective treatment for lymphoma?

APPENDIX VISUALIZING CELLS AND MOLECULES

Cell biologists often need to examine the structure of cells and their components, and they need to see specific structures or molecules amid a complicated mixture of cellular components. The microscope is an indispensable tool for this purpose because most cellular structures are too small to be seen by the unaided eye. In fact, the beginnings of cell biology can be traced to the invention of the **light microscope**, which made it possible for scientists to see enlarged images of cells for the first time. The first generally useful light microscope was developed in 1590 by Z. Janssen and his nephew, H. Janssen. Many important microscopic observations were reported during the next century, notably those of Robert Hooke, who observed the first cells, and Antonie van Leeuwenhoek, whose improved microscopes provided our first glimpses of internal cell structure. Since then, the light microscope has undergone numerous improvements and modifications, right up to the present time.

Just as the invention of the light microscope heralded a wave of scientific achievement by allowing us to see cells for the first time, the development of the **electron microscope** in the 1930s revolutionized our ability to explore cell structure and function. Because it is at least a hundred times better at visualizing objects than the light microscope is, the electron microscope ushered in a new era in cell biology, opening our eyes to an exquisite subcellular architecture never before seen and changing forever the way we think about cells.

Light microscopy has experienced a renaissance in recent years as the development of specialized new techniques allows researchers to explore aspects of cell structure and behavior that cannot be readily studied by electron microscopy. These advances have involved the merging of technologies from physics, engineering, chemistry, and molecular biology, and they have greatly expanded our ability to study cells using the light microscope.

In this appendix, we explore the fundamental principles of light and electron microscopy, emphasizing the various specialized techniques used to adapt these two types of microscopy for a variety of specialized purposes. We also examine other related technologies that extend the range of view beyond the microscope to visualization of single molecules at high resolution.

Optical Principles of Microscopy

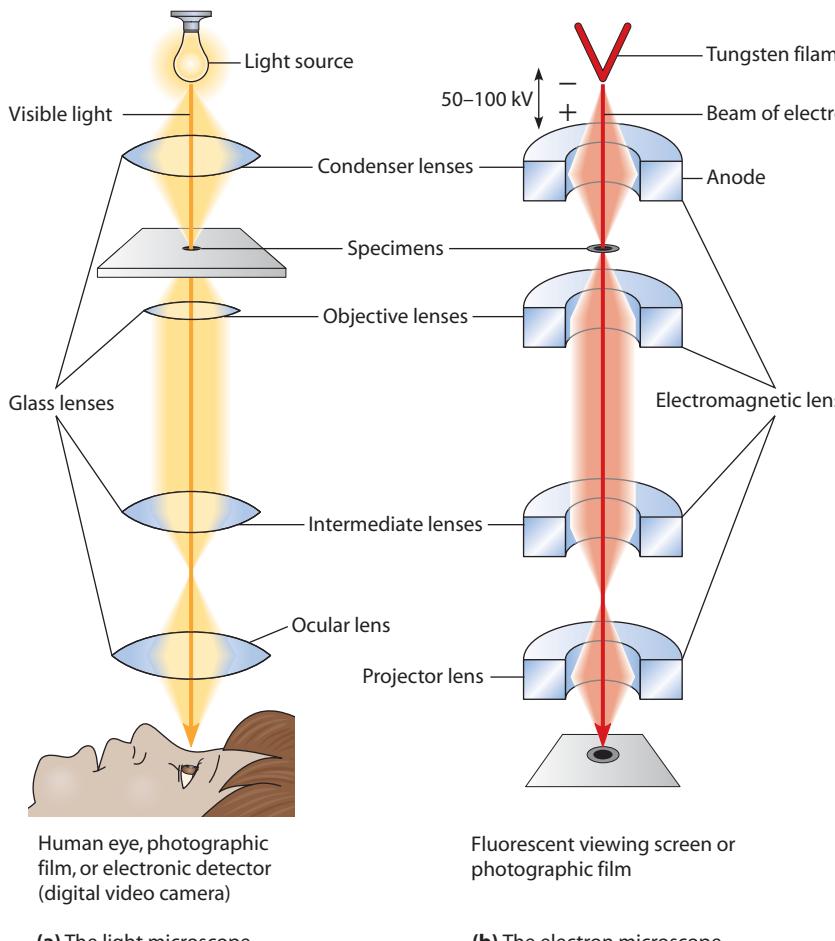

Although light and electron microscopes differ in many ways, they make use of similar optical principles to form images. Therefore, we begin our discussion of microscopy by examining these underlying common principles, placing special emphasis on the factors that determine how small an object can be seen with current technologies.

The Illuminating Wavelength Sets a Limit on How Small an Object Can Be Seen

Regardless of the type of microscope being used, three elements are always needed to form an image: a *source of illumination*, a *specimen* to be examined, and a system of lenses that focuses the illumination on the specimen and forms the image. **Figure A-1** illustrates these features for a light microscope and an electron microscope. In a light microscope, the source of illumination is *visible light* (wavelength approximately 400–700 nm), and the lens system consists of a series of glass lenses. The image can either be viewed directly through an eyepiece or focused on a detector, such as photographic film or an electronic camera. In an electron microscope, the illumination source is a *beam of electrons* emitted by a heated tungsten filament, and the lens system consists of a series of electromagnets. The electron beam is focused on either a fluorescent screen or photographic film, or it is digitally imaged using a detector.

Despite these differences in illumination source and instrument design, both types of microscopes depend on the same principles of optics and form images in a similar manner. When a specimen is placed in the path of a light or electron beam, physical characteristics of the beam are changed in a way that creates an image that can be interpreted by the human eye or recorded on a photographic detector. To understand this interaction between the illumination source and the specimen, we need to understand the concept of wavelength, which is illustrated in **Figure A-2** using the following simple analogy.

If two people hold onto opposite ends of a slack rope and wave the rope with a rhythmic up-and-down motion, they will generate a long, regular pattern of movement in the rope called a *waveform* (Figure A-2a). The distance from the crest of one wave to the crest of the next is called the **wavelength**. If someone standing to one side of the rope tosses a large object such as a beach ball toward the

(a) The light microscope

(b) The electron microscope

rope, the ball may interfere with, or perturb, the waveform of the rope's motion (Figure A-2b). However, if a small object, such as a softball, is tossed toward the rope, the movement of the rope will probably not be affected at all (Figure A-2c). If the rope holders move the rope faster, the motion of the rope will still have a waveform, but the wavelength will be shorter (Figure A-2d). In this case, a softball tossed toward the rope is quite likely to perturb the rope's movement (Figure A-2e).

This simple analogy illustrates an important principle: The ability of an object to perturb a wave's motion depends crucially on the size of the object in relation to the wavelength of the motion. This principle is of great importance in microscopy because it means that the wavelength of the illumination source sets a limit on how small an object can be seen. To understand this relationship, we need to recognize that the moving rope of Figure A-2 is analogous to the beam of light (photons) or the electrons used as an illumination source in a light or electron microscope, respectively. In other words, both light and electrons behave as waves. When a beam of light (or electrons) encounters a specimen, the specimen alters the physical characteristics of the illuminating beam, just as the beach ball or softball alters the motion of the rope. And because an object can be detected only by its effect on the wave, the wavelength must be comparable in size to the object that is to be detected.

FIGURE A-1 Optical Systems of the Light Microscope and the Electron Microscope. (a) The light microscope uses visible light (wavelength approximately 400–700 nm) and glass lenses to form an image of the specimen that can be seen by the eye, focused on photographic film, or received by an electronic detector such as a digital camera. (b) The electron microscope uses a beam of electrons emitted by a tungsten filament and focused by electromagnetic lenses to form an image of the specimen on a fluorescent screen, a digital detector, or photographic film. (These diagrams have been drawn to emphasize the similarities in overall design between the two types of microscope. In reality, a light microscope is designed with the light source at the bottom and the ocular lens at the top, as shown in Figure A-5b.)

Once we understand this relationship between wavelength and object size, we can readily appreciate why very small objects can be seen only by electron microscopy: The wavelengths of electrons are very much shorter than those of photons. Thus, objects such as viruses and ribosomes are too small to perturb the waveform of photons, but they can readily interact with electrons. As we discuss different types of microscopes and specimen preparation techniques, you might find it helpful to ask yourself how the source and specimen are interacting and how the characteristics of both are modified to produce an image.

Resolution Refers to the Ability to Distinguish Adjacent Objects as Separate from One Another

When waves of light or electrons pass through a lens and are focused, the image that is formed results from a property of waves called **interference**—the process by which two or more waves combine to reinforce or cancel one another, producing a wave equal to the sum of the two combining waves. Thus, the image that you see when you look at a specimen through a series of lenses is really just a pattern of either additive or canceling interference of the waves that went through the lenses, a phenomenon known as **diffraction**.

In a light microscope, glass lenses are used to direct photons, whereas an electron microscope uses electro-

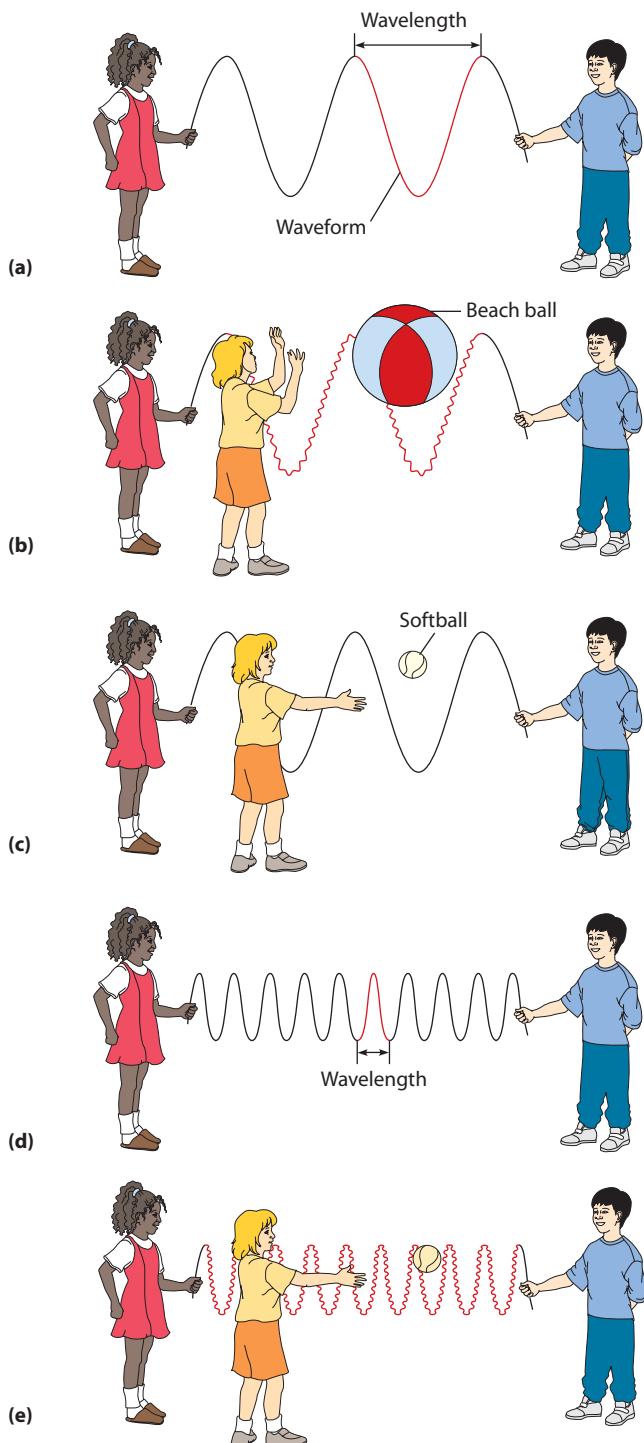

FIGURE A-2 Wave Motion, Wavelength, and Perturbations.

The wave motion of a rope held between two people is analogous to the waveform of both photons and electrons, and it can be used to illustrate the effect of the size of an object on its ability to perturb wave motion. (a) Moving a slack rope up and down rhythmically will generate a waveform with a characteristic wavelength. (b) When thrown against a rope, an object with a diameter comparable to the wavelength of the rope (e.g., a beach ball) will perturb the motion of the rope. (c) An object with a diameter significantly less than the wavelength of the rope (e.g., a softball) will probably cause little or no perturbation of the rope because, with its smaller diameter, it is not likely to strike the rope when tossed toward it. (d) If the rope is moved more rapidly, the wavelength will be reduced substantially. (e) A softball can now perturb the motion of the rope because its diameter is comparable to the wavelength of the rope.

lens of the microscope from the specimen (**Figure A-4**). Angular aperture is therefore a measure of how much of the illumination that leaves the specimen actually passes through the lens. This in turn determines the sharpness of the interference pattern and therefore the ability of the lens to convey information about the specimen. In the best light microscopes, the angular aperture is about 70° .

The angular aperture of a lens is one of the factors influencing a microscope's **resolution**, which is defined as the minimum distance that can separate two points that still remain identifiable as separate points when viewed through the microscope.

Resolution is governed by three factors: the wavelength of the light used to illuminate the specimen, the angular aperture, and the refractive index of the medium surrounding the specimen. (**Refractive index** is a measure of the change in the velocity of light as it passes from one medium to another.) The effect of these three variables on resolution is described quantitatively by an equation known as the *Abbe equation*:

$$r = \frac{0.61 \lambda}{n \sin \alpha} \quad (\text{A-1})$$

where r is the resolution, λ is the wavelength of the light used for illumination, n is the refractive index of the

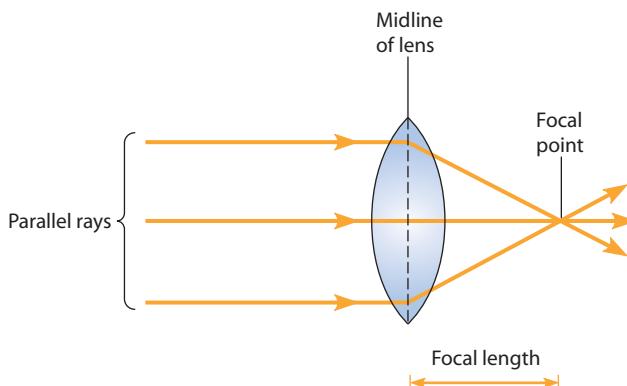

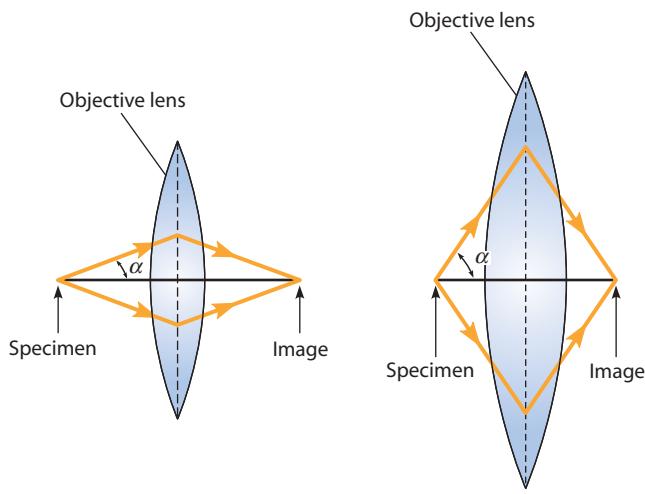

FIGURE A-3 The Focal Length of a Lens. Focal length is the distance from the midline of a lens to the point where parallel rays passing through the lens converge to a focus.

magnets as lenses to direct electrons. Yet both kinds of lenses have two fundamental properties in common: focal length and angular aperture. The **focal length** is the distance between the midline of the lens and the point at which rays passing through the lens converge to a focus (**Figure A-3**). The focal length is determined by the index of refraction of the lens itself, the medium in which it is immersed, and the geometry of the lens. The lens magnifying strength, measured in diopters, is the inverse of the focal length, measured in meters. The **angular aperture** is the half-angle α of the cone of light entering the objective

(a) Low-aperture lens

(b) High-aperture lens

FIGURE A-4 The Angular Aperture of a Lens. The angular aperture is the half-angle α of the cone of light entering the objective lens of the microscope from the specimen. (a) A low-aperture lens (α is small). (b) A high-aperture lens (α is large). The larger the angular aperture, the more information the lens can transmit. The best glass lenses have an angular aperture of about 70° .

medium between the specimen and the objective lens of the microscope, and α is the angular aperture as previously defined. The constant 0.61 represents the degree to which image points can overlap and still be recognized as separate points by an observer.

In the preceding equation, the quantity $n \sin \alpha$ is called the **numerical aperture** of the objective lens, abbreviated **NA**. An alternative expression for resolution is therefore

$$r = \frac{0.61\lambda}{NA} \quad (\text{A-2})$$

The Practical Limit of Resolution Is Roughly 200 nm for Light Microscopy and 2 nm for Electron Microscopy

Maximizing resolution is an important goal in both light and electron microscopy. Because r is a measure of how close two points can be and still be distinguished from each other, resolution improves as r becomes smaller. Thus, for the best resolution, the numerator of equation A-2 should be as small as possible and the denominator should be as large as possible.

Consider a glass lens that uses visible light as an illumination source. First, we need to make the numerator as small as possible. The wavelength for visible light falls in the range of 400–700 nm, so the minimum value for λ is set by the shortest wavelength in this range that is practical to use for illumination, which turns out to be blue light of approximately 450 nm. To maximize the denominator of Equation A-2, recall that the numerical aperture is the product of the refractive index and the sine of the

angular aperture. Both of these values must therefore be maximized to achieve optimal resolution. Since the angular aperture for the best objective lenses is approximately 70° , the maximum value for $\sin \alpha$ is about 0.94. The refractive index of air is approximately 1.0, so for a lens designed for use in air, the maximum numerical aperture is approximately 0.94. Putting all of these numbers together, the resolution in air for a sample illuminated with blue light of 450 nm can be calculated as follows:

$$\begin{aligned} r &= \frac{0.61\lambda}{NA} \\ &= \frac{(0.61)(450)}{0.94} = 292 \text{ nm} \end{aligned} \quad (\text{A-3})$$

As a rule of thumb, then, the limit of resolution for a glass lens in air is roughly 300 nm.

As a means of increasing the numerical aperture, some microscope lenses are designed to be used with a layer of *immersion oil* between the lens and the specimen. Immersion oil has a higher refractive index than air and therefore allows the lens to receive more of the light transmitted through the specimen. Since the refractive index of immersion oil is about 1.5, the maximum numerical aperture for an oil immersion lens is about $1.5 \times 0.94 = 1.4$. If we perform the same calculations as before, we find that the resolution of an oil immersion lens is approximately 200 nm. Thus, the **limit of resolution** (best possible resolution) for a microscope that uses visible light is roughly 300 nm in air and 200 nm with an oil immersion lens. In actual practice, such limits can rarely be reached because of aberrations (technical flaws) in the lenses. By using ultraviolet light as an illumination source, the resolution can be enhanced to approximately 100 nm because of the shorter wavelength (200–300 nm) of this type of light. However, special cameras must be used because ultraviolet light is invisible to the human eye. Moreover, ordinary glass is opaque to ultraviolet light, so expensive quartz lenses must be used.

Because the limit of resolution measures the ability of a lens to distinguish between two objects that are close together, it sets an upper boundary on the **useful magnification** that is possible with any given lens. In practice, the greatest useful magnification that can be achieved with a light microscope is approximately 1000 times the numerical aperture of the lens being used. Since numerical aperture ranges from approximately 1.0 to 1.4, this means that the useful magnification of a light microscope is limited to roughly $1000\times$ in air and $1400\times$ with immersion oil. Magnification greater than these limits is referred to as “empty magnification” because it provides no additional information about the object being studied.

The most effective way to achieve better magnification is to switch from visible light to electrons as the illumination source. Because the wavelength of an electron is approximately 100,000 times shorter than that of a photon of visible light, the theoretical limit of resolution

of the electron microscope (0.002 nm) is orders of magnitude better than that of the light microscope (200 nm). However, practical problems in the design of the electromagnetic lenses used to focus the electron beam prevent the electron microscope from achieving this theoretical potential. The main problem is that electromagnets produce considerable distortion when the angular aperture is more than a few tenths of a degree. This tiny angle is several orders of magnitude less than that of a good glass lens (about 70°), giving the electron microscope a numerical aperture considerably smaller than that of the light microscope. The limit of resolution for the best electron microscope is therefore only approximately 0.2 nm, far from the theoretical limit of 0.002 nm. Moreover, when viewing biological samples, problems with specimen preparation and contrast are such that the practical limit of resolution is often closer to 2 nm. Practically speaking, therefore, resolution in an electron microscope is generally about 100 times better than that of the light microscope. As a result, the useful magnification of an electron microscope is approximately 100 times that of a light microscope, or approximately 100,000 \times .

The Light Microscope

It was the light microscope that first opened our eyes to the existence of cells. A pioneering name in the history of light microscopy is that of Antonie van Leeuwenhoek, the Dutch

shopkeeper who is generally regarded as the father of light microscopy. Leeuwenhoek's lenses, which he manufactured himself during the late 1600s, were of surprisingly high quality for his time. They were capable of 300-fold magnification—a tenfold improvement over previous instruments. This improved magnification made the interior of cells visible for the first time, and Leeuwenhoek's observations over a period of more than 25 years led to the discovery of cells in various types of biological specimens and set the stage for the formulation of the cell theory.

Compound Microscopes Use Several Lenses in Combination

In the 300 years since Leeuwenhoek's pioneering work, considerable advances in the construction and application of light microscopes have been made. Today, the instrument of choice for light microscopy uses several lenses in combination and is therefore called a **compound microscope** (Figure A-5). The optical path through a compound microscope, illustrated in Figure A-5b, begins with a source of illumination, often a light source located in the base of the instrument. The light from the source first passes through **condenser lenses**, which direct the light toward a specimen mounted on a glass slide and positioned on the **stage** of the microscope. The **objective lens**, located immediately above the specimen, is responsible for forming the *primary image*. Most compound microscopes have several objective lenses of differing magnifications mounted on a rotatable turret.

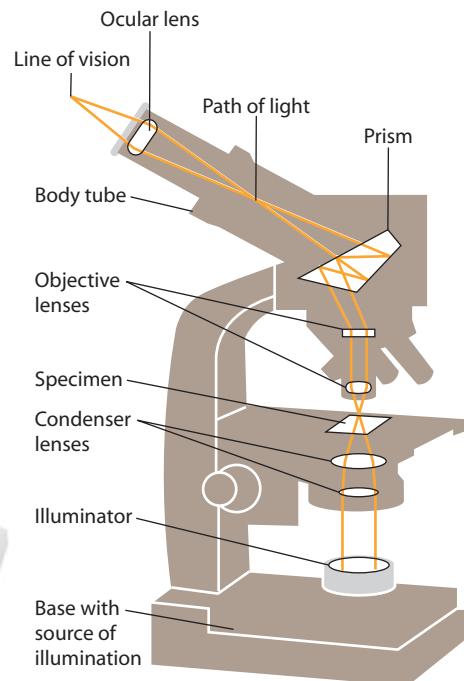

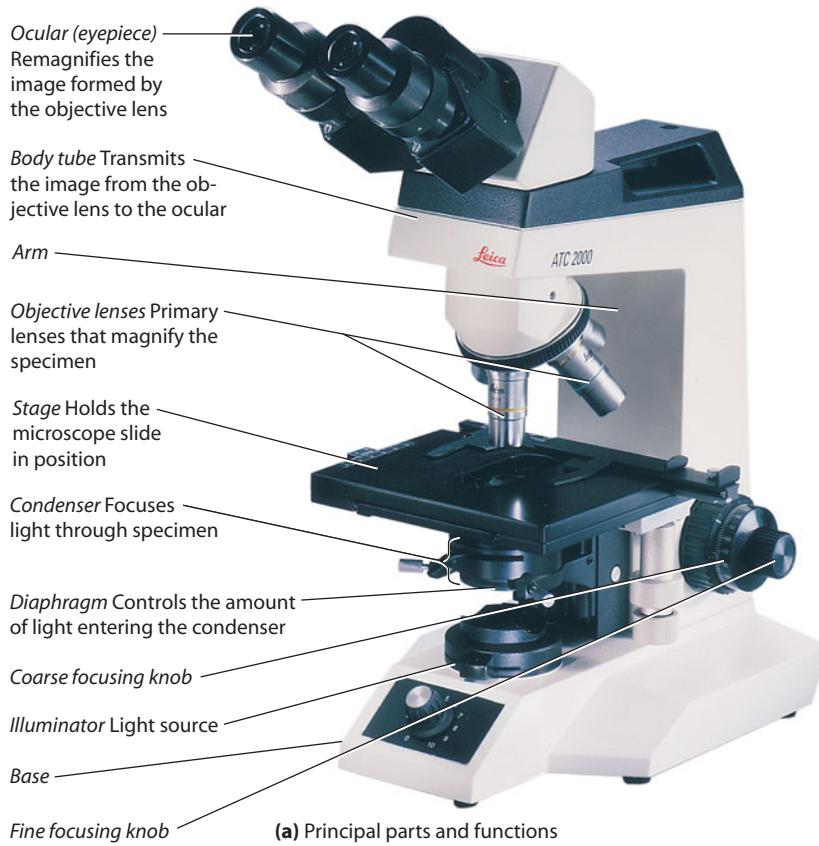

FIGURE A-5 The Compound Light Microscope. (a) A compound light microscope. (b) The path of light through the compound microscope.

The primary image is further enlarged by the **ocular lens**, or *eyepiece*. In some microscopes, an **intermediate lens** is positioned between the objective and ocular lenses to accomplish still further enlargement. Overall magnification of the image can be calculated by multiplying the enlarging powers of the objective lens, the ocular lens, and the intermediate lens (if present). Thus, a microscope with a $10\times$ objective lens, a $2.5\times$ intermediate lens, and a $10\times$ ocular lens will magnify a specimen 250-fold.

The elements of the microscope described so far create a basic form of light microscopy called **brightfield microscopy**. Compared with other microscopes, the bright-field microscope is inexpensive and simple to align and use. However, the only specimens that can be seen directly by brightfield microscopy are those possessing color or some other property that affects the amount of light that passes through. Many biological specimens lack these characteristics and must therefore be stained with dyes or examined with specialized types of light microscopes. These special microscopes have various advantages that make them especially well suited for visualizing specific types of specimens. These include phase-contrast, differential interference contrast, fluorescence, and confocal microscopes. We will look at these and several other important techniques in the following sections.

Phase-Contrast Microscopy Detects Differences in Refractive Index and Thickness

As we will describe in more detail later, cells are often killed, sliced into thin sections, and stained before being examined by brightfield microscopy. While such procedures are useful for visualizing the details of a cell's internal architecture, little can be learned about the dynamic aspects of cell behavior by examining cells that have been killed, sliced, and stained. Therefore, various techniques have been developed to observe cells that are intact and, in many cases, still living. One such technique, **phase-contrast microscopy**, improves contrast without sectioning and staining by exploiting differences in the thickness and refractive index of various regions of the cells being examined.

To understand the basis of phase-contrast microscopy, we must first recognize that a beam of light is made up of many individual rays of light. As the rays pass from the light source through the specimen, their velocity may be affected by the physical properties of the specimen. Usually, the velocity of the rays is slowed down to varying extents by different regions of the specimen, resulting in a change in phase relative to light waves that have not passed through the specimen. (Light waves are said to be traveling *in phase* when the crests and troughs of the waves match each other.)

Although the human eye cannot detect such phase changes directly, the phase-contrast microscope overcomes this problem by converting phase differences into alterations in brightness. This conversion is accomplished using a **phase plate** (Figure A-6), which is an optical material inserted into the light path above the objective lens. On

average, light passing through transparent specimens is retarded by approximately $\frac{1}{4}$ wavelength. The direct, undiffracted light passes through a portion of the phase plate that speeds it up by approximately $\frac{1}{4}$ wavelength. Now the two types of light interfere with one another, producing an image with highly contrasting bright and dark areas against an evenly illuminated background (Figure A-7). As a result, internal structures of cells are often better visualized by phase-contrast microscopy than with brightfield optics.

This approach to light microscopy is particularly useful for examining living, unstained specimens because biological materials almost inevitably diffract light. Phase-contrast microscopy is widely used in microbiology and tissue culture research to detect bacteria, cellular organelles, and other small entities in living specimens.

Differential Interference Contrast (DIC) Microscopy Utilizes a Split Light Beam to Detect Phase Differences

Differential interference contrast (DIC) microscopy, or *Nomarski* microscopy (named for its inventor), resembles phase-contrast microscopy in principle but is more sensitive because it employs a special prism to split the

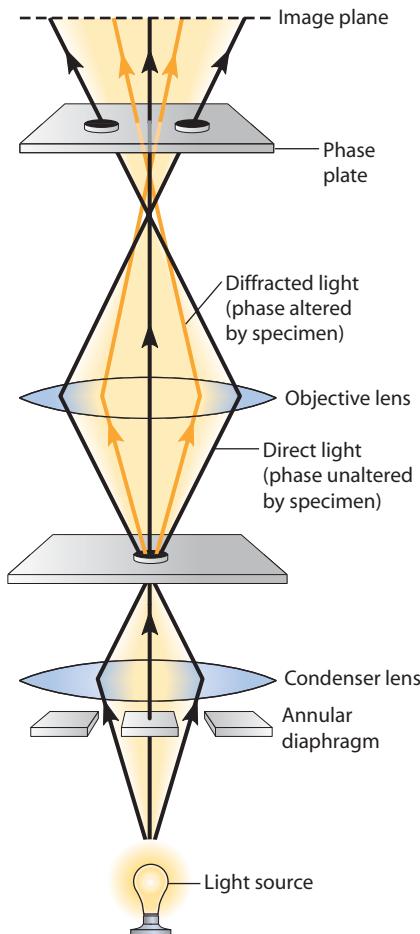

FIGURE A-6 Optics of the Phase-Contrast Microscope.

Configuration of the optical elements and the paths of light rays through the phase-contrast microscope. Orange lines represent light diffracted by the specimen, and black lines represent direct light.

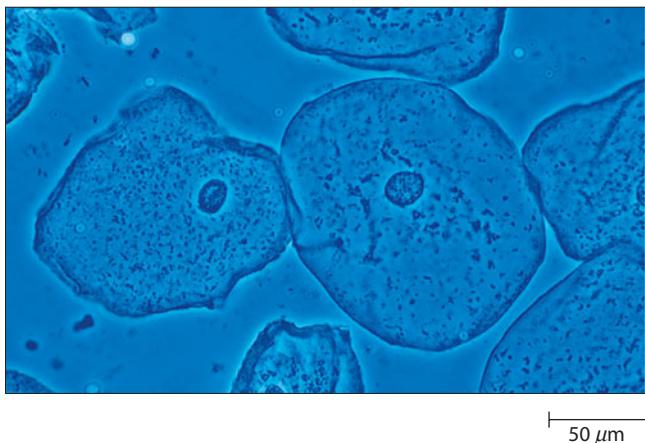

FIGURE A-7 Phase-Contrast Microscopy. A phase-contrast micrograph of epithelial cells. The cells were observed in an unprocessed and unstained state, which is a major advantage of phase-contrast microscopy.

illuminating light beam into two separate rays (**Figure A-8**). When the two beams are recombined, any changes that occurred in the phase of one beam as it passed through the specimen cause it to interfere with the second beam. Because the largest phase changes usually occur at cell edges (the refractive index is more constant within the cell), the outline of the cell typically gives a strong signal. The image appears three-dimensional due to a shadow-casting illusion that arises because differences in phase are positive on one side of the cell but negative on the opposite side of the cell (**Figure A-9**).

The optical components required for DIC microscopy consist of a *polarizer*, an *analyzer*, and a pair of *Wollaston prisms* (see Figure A-8). The polarizer and the first Wollaston prism split a beam of light, creating two beams that are separated by a small distance along one direction. After traveling through the specimen, the beams are recombined by the second Wollaston prism. If no specimen is present, the beams recombine to form one beam that is identical to the one that initially entered the polarizer and first Wollaston prism. In the presence of a specimen, the two beams do not recombine in the same way (i.e., they interfere with each other), and the resulting beam's polarization becomes rotated slightly compared with the original. The net effect is a remarkable enhancement in resolution that makes this technique especially useful for studying living, unstained specimens. As we will soon see, combining this technique with digital microscopy is an especially effective approach for studying dynamic events within cells as they take place.

Other contrast enhancement methods are also used by cell biologists. *Hoffman modulation contrast*, developed by Robert Hoffman, increases contrast by detecting optical gradients across a transparent specimen using special filters and a rotating polarizer. Hoffman modulation contrast results in a shadow-casting effect similar to that in DIC microscopy.

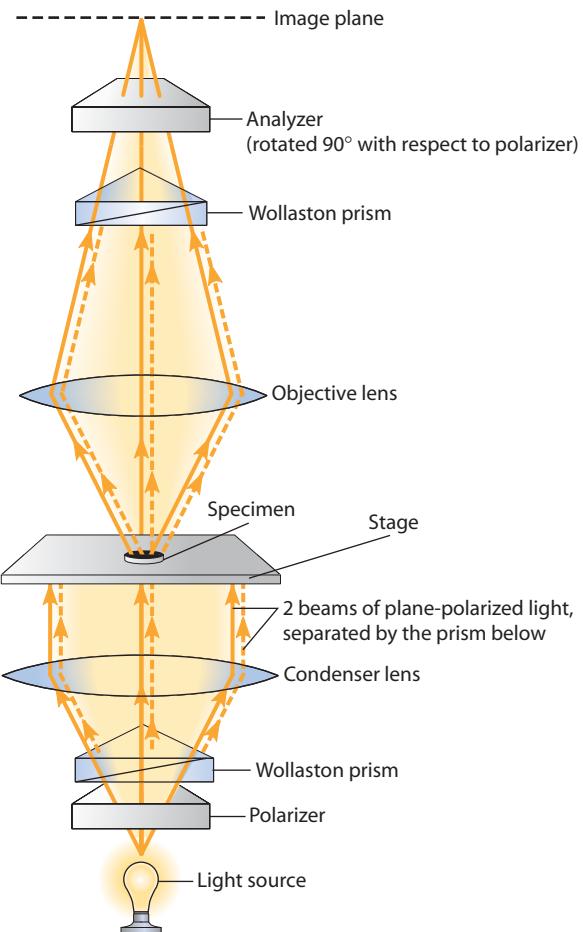

FIGURE A-8 Optics of the Differential Interference Contrast (DIC) Microscope. Configuration of the optical elements and the paths of light rays through the DIC microscope.

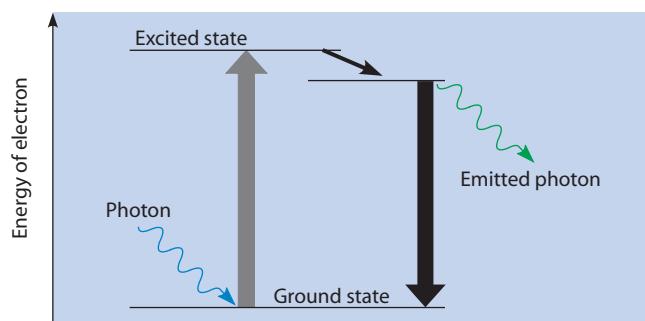

FIGURE A-9 DIC Microscopy. A DIC micrograph of a four-cell sea urchin embryo. Notice the shadow-casting effect that makes these cells appear dark at the bottom and light at the top.

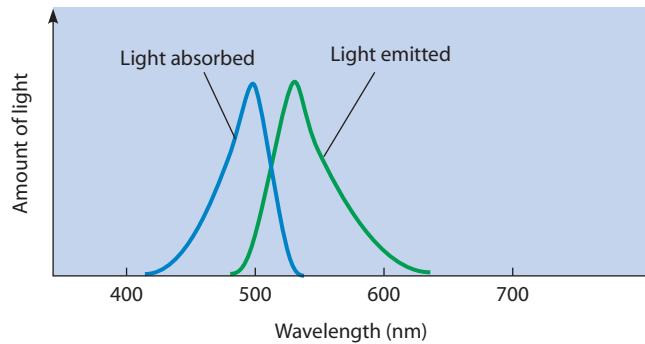

Fluorescence Microscopy Can Detect the Presence of Specific Molecules or Ions Within Cells

Although the microscopic techniques described so far are quite effective for visualizing cell structures, they provide relatively little information concerning the location of specific molecules. One way of obtaining such information is through the use of **fluorescence microscopy**. To understand how fluorescence microscopy works, it is first necessary to understand the phenomenon of fluorescence.

The Nature of Fluorescence. The term **fluorescence** refers to a process that begins with the absorption of light by a molecule and ends with emission of light with a longer wavelength. This phenomenon is best approached by considering the quantum behavior of light, as opposed to its wavelike behavior. **Figure A-10a** is a diagram of the various energy levels of a simple atom. When an atom absorbs a photon (or *quantum*) of light of the proper energy, one of its electrons jumps from its ground state to a higher-energy, or *excited*, state. Eventually, this electron often loses some of its energy and drops back down to the

(a) Energy diagram

(b) Absorption and emission spectra

FIGURE A-10 Principles of Fluorescence. (a) An energy diagram of fluorescence from a simple atom. Light of a certain energy is absorbed (e.g., the blue light shown here). The electron jumps from its ground state to an excited state. It returns to the ground state by emitting a photon of lower energy and hence longer wavelength (e.g., green light). (b) The absorption and emission spectra of a typical fluorescent molecule. The blue curve represents the amount of light absorbed as a function of wavelength, and the green curve shows the amount of emitted light as a function of wavelength.

original ground state, emitting another photon as it does so. The emitted photon is always of less energy (longer wavelength) than the original photon that was absorbed. Thus, for example, shining blue light on the atom may result in green light being emitted. (The energy of a photon is inversely proportional to its wavelength; therefore, green light, being longer in wavelength than blue light, is lower in energy.)

Real fluorescent molecules have energy diagrams that are more complicated than that depicted in Figure A-10a. The number of possible energy levels in real molecules is much greater, so the different energies that can be absorbed, and emitted, are correspondingly greater. The absorption and emission spectra of a typical fluorescent molecule are shown in Figure A-10b. Every fluorescent molecule has its own characteristic absorption and emission spectra.

The Fluorescence Microscope. Fluorescence microscopy is a specialized type of light microscopy that employs light to excite fluorescence in the specimen. A standard fluorescence microscope has an *excitation filter* between the light source and the rest of the light path that transmits only light of a particular wavelength (**Figure A-11**). A *dichroic mirror*, which reflects light below a certain wavelength and transmits light above a certain wavelength, deflects the incoming light toward the objective lens, which focuses the light onto the specimen (because

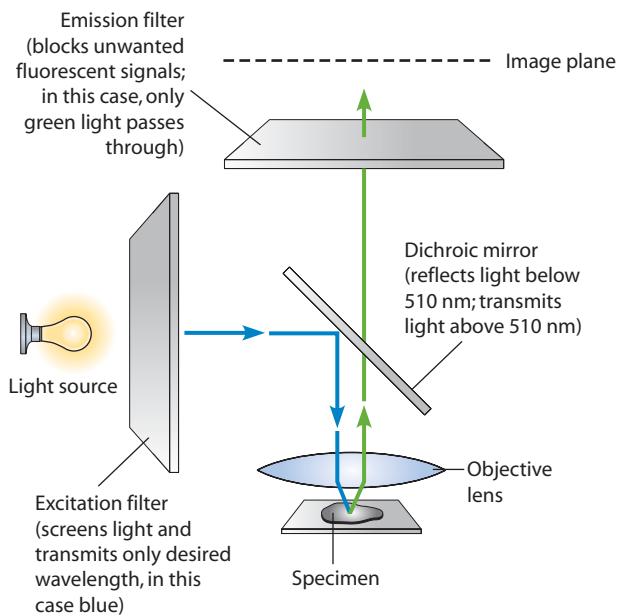

FIGURE A-11 Optics of the Fluorescence Microscope.

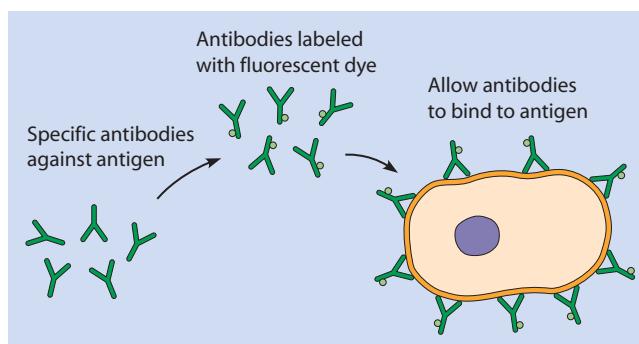

Configuration of the optical elements and the paths of light rays through the fluorescence microscope. Light from the source passes through an excitation filter that transmits only excitation light (solid blue lines). Illumination of the specimen with this light induces fluorescent molecules in the specimen to emit longer-wavelength light (green lines). The emission filter subsequently removes the excitation light, while allowing passage of the emitted light. The image is therefore formed exclusively by light emitted by fluorescent molecules in the specimen.

the light is routed through the objective lens onto the specimen in this way, this technique is often called *epifluorescence microscopy*, from the Greek *epi*, “upon”). The incoming light causes fluorescent compounds in the specimen to emit light of longer wavelength, which passes back through the objective lens. The longer wavelength light, instead of being reflected, passes through the dichroic mirror and encounters an *emission filter* that specifically prevents light that does not match the emission wavelength of the fluorescent molecules of interest from exiting the microscope. This leaves only the emission wavelengths to form the final fluorescent image, which therefore appears bright against a dark background.

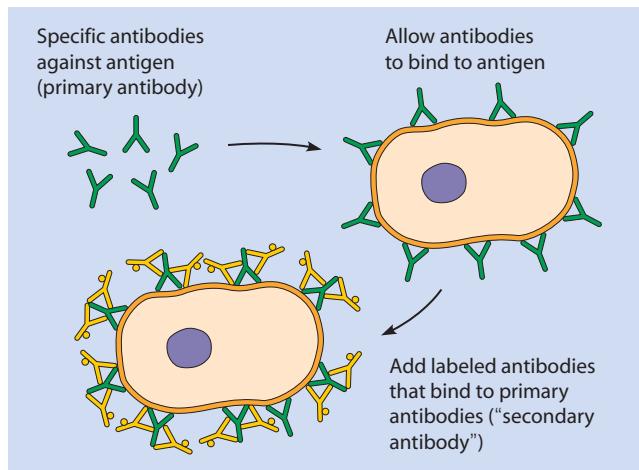

Fluorescent Antibodies. To use fluorescence microscopy for locating specific molecules or ions within cells, researchers must employ special indicator molecules called *fluorescent probes*. A fluorescent probe is a molecule capable of emitting fluorescent light that can be used to indicate the presence of a specific molecule or ion.

One of the most common applications of fluorescent probes is in **immunostaining**, a technique based on the ability of antibodies to recognize and bind to specific molecules. (The molecules that antibodies bind to are called *antigens*.) Antibodies can be generated in the laboratory by injecting a foreign protein or other macromolecule into an animal such as a rabbit or mouse. In this way, it is possible to produce antibodies that will bind selectively to virtually any protein that a scientist wishes to study. Antibodies are not directly visible using light microscopy, however, so they are linked to a fluorescent dye such as *fluorescein*, which emits green light, or to *rhodamine*, which emits red light. More recently, antibodies have been linked to *quantum dots*—tiny, light-emitting crystals that are chemically more stable than traditional dyes, can be tuned to very specific wavelengths, and have other useful properties. To identify the subcellular location of a specific protein, cells are simply stained with a fluorescent antibody directed against that protein. The location of the fluorescence is then detected by viewing the cells with light of the appropriate wavelength.

Immunofluorescence microscopy can be performed using antibodies that are directly labeled with a fluorescent dye (**Figure A-12a**). However, immunofluorescence microscopy is more commonly performed using **indirect immunofluorescence** (Figure A-12b). In indirect immunofluorescence, a tissue or cell is treated with an antibody that is not labeled with dye. This antibody, called the *primary antibody*, attaches to specific antigenic sites within the tissue or cell. A second type of antibody, called the *secondary antibody*, is then added. The secondary antibody is labeled with a fluorescent dye, and it attaches to the primary antibody. Because more than one primary antibody molecule can attach to an antigen and more than one secondary antibody molecule can attach to each primary antibody, more fluorescent molecules are concentrated near each molecule that we seek to detect. As

(a) Immunofluorescence

(b) Indirect immunofluorescence

FIGURE A-12 Immunostaining Using Fluorescent Antibodies. Immunofluorescence microscopy relies on the use of fluorescently labeled antibodies to detect specific molecular components (antigens) within a tissue sample. (a) In direct immunofluorescence, an antibody that binds to a molecular component in a tissue sample is labeled with a fluorescent dye. The labeled antibody is then added to the tissue sample, and it binds to the tissue in specific locations. The pattern of fluorescence that results is visualized using fluorescence or confocal microscopy. (b) In indirect immunofluorescence, a primary antibody is added to the tissue. Then a secondary antibody that carries a fluorescent label is added. The secondary antibody binds to the primary antibody. Because more than one fluorescent secondary antibody can bind to each primary antibody, indirect immunofluorescence effectively amplifies the fluorescent signal, making it more sensitive than direct immunofluorescence.

a result, indirect immunofluorescence results in signal amplification, and it is much more sensitive than the use of a primary antibody alone. The method is “indirect” because it does not examine where antibodies are bound to antigens; technically, the fluorescence reflects where the secondary antibody is located. This, of course, provides an indirect measure of where the original molecule of interest is located.

By using different combinations of antibodies or other fluorescent probes, more than one molecule in a cell can be labeled at the same time. Different probes can be imaged using different combinations of fluorescent filters, and the different images can be combined to generate

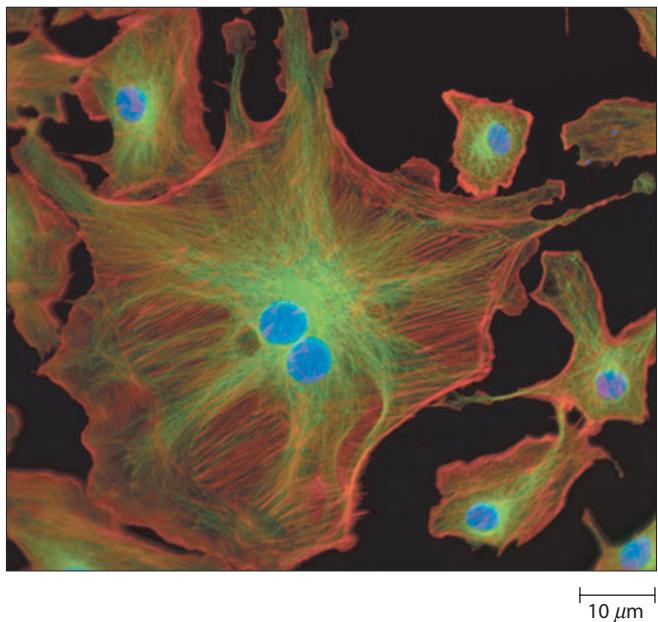

FIGURE A-13 Fluorescence Microscopy. Bovine pulmonary artery endothelial cells stained with an anti- β -tubulin mouse monoclonal antibody and a BODIPY FL secondary antibody (green) to label microtubules, Texas Red phalloidin (red) for labeling F-actin, and DAPI (blue) for labeling DNA in nuclei.

striking pictures of cellular structures. **Figure A-13** shows one example of this approach, in which endothelial cells are labeled with antibodies against β -tubulin (green), actin (red), and DNA (blue).

Other Fluorescent Probes. Naturally occurring proteins that selectively bind to specific cell components are also used in fluorescence microscopy. For example, the red structures in Figure A-13 are stained with a Texas Red-tagged mushroom toxin, *phalloidin*, which binds specifically to actin microfilaments. Another powerful fluorescence technique utilizes the **green fluorescent protein (GFP)**, a naturally fluorescent protein made by the jellyfish *Aequoria victoria*. Using recombinant DNA techniques, scientists can fuse DNA encoding GFP to a

gene coding for a particular cellular protein. The resulting recombinant DNA can then be introduced into cells, where it is expressed to produce a fluorescently tagged version of the normal cellular protein. In many cases, the fusion of GFP to the end of a protein does not interfere with its function, allowing the use of fluorescence microscopy to view the GFP-fusion protein as it functions in a living cell (**Figure A-14**). Molecular biologists have produced mutated forms of GFP that absorb and emit light at a variety of wavelengths. Other naturally fluorescent proteins have also been identified, such as a red fluorescent protein from coral. These tools have expanded the repertoire of fluorescent molecules at the disposal of cell biologists.

Besides detecting macromolecules such as proteins, fluorescence microscopy can be used to monitor the sub-cellular distribution of various ions. To accomplish this task, chemists have synthesized molecules whose fluorescent properties are sensitive to the concentrations of ions such as Ca^{2+} , H^+ , Na^+ , Zn^{2+} , and Mg^{2+} , as well as to the electrical potential across the plasma membrane or the membranes of organelles. For example, a fluorescent probe called *fura-2* is commonly used to track the Ca^{2+} concentration inside living cells, because *fura-2* emits a yellow fluorescence in the presence of low concentrations of Ca^{2+} and a green and then blue fluorescence in the presence of progressively higher concentrations of this ion. Therefore, monitoring the color of the fluorescence in living cells stained with this probe allows scientists to observe changes in the intracellular Ca^{2+} concentration as they occur.

Confocal Microscopy Minimizes Blurring by Excluding Out-of-Focus Light from an Image

When biologists use fluorescence microscopy to view intact cells, the resolution is limited. This occurs because, although fluorescence is emitted throughout the entire depth of the specimen, the viewer can focus the objective lens on only a single plane at any given time. As a result, light emitted from regions of the specimen above and below the focal plane causes a blurring of the image

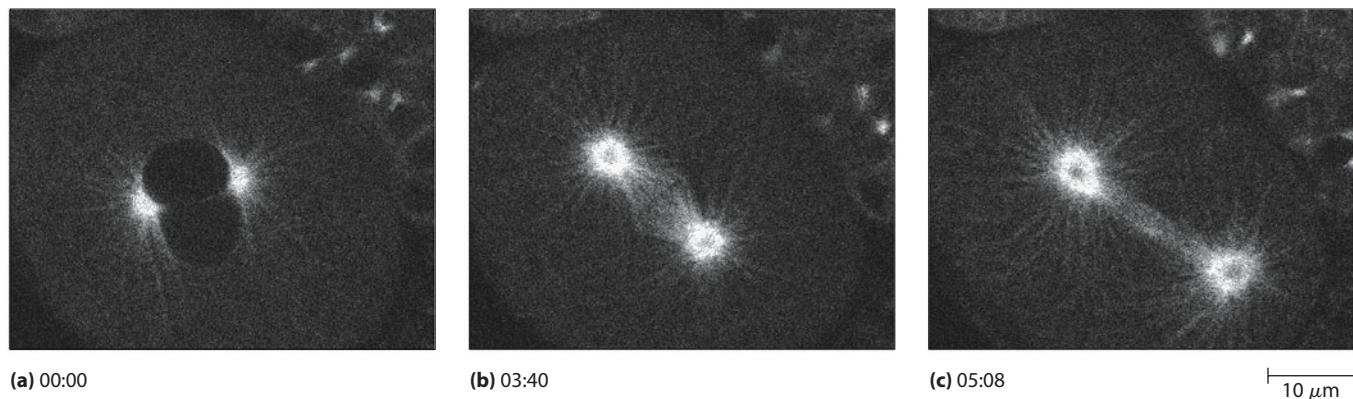

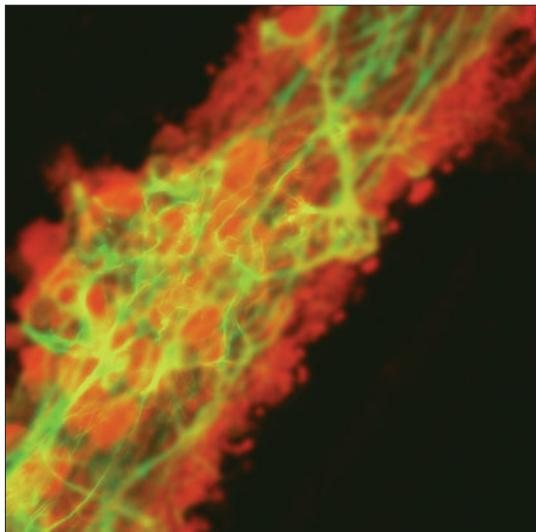

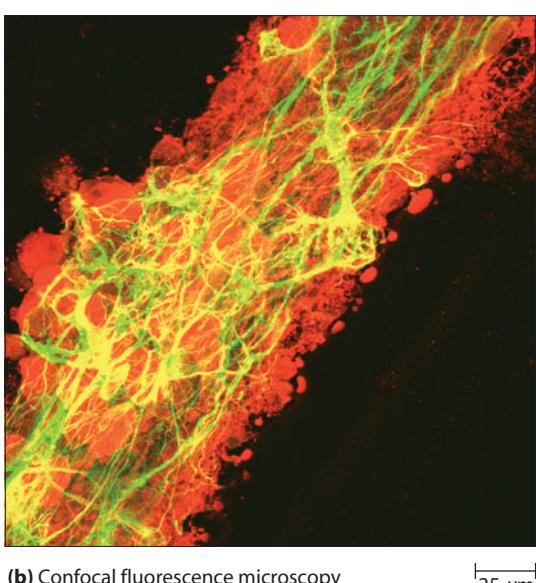

FIGURE A-14 Using Green Fluorescent Protein to Visualize Proteins. An image series of a living, one-cell nematode worm embryo undergoing mitosis. The embryo is expressing β -tubulin that is tagged with green fluorescent protein (GFP). Elapsed time from the first frame is shown in minutes:seconds.

(a) Traditional fluorescence microscopy

(b) Confocal fluorescence microscopy

$25 \mu\text{m}$

FIGURE A-15 Comparison of Confocal Fluorescence Microscopy with Traditional Fluorescence Microscopy. These fluorescence micrographs show fluorescently labeled glial cells (red) and nerve cells (green) stained with two different fluorescent markers. (a) In traditional fluorescence microscopy, the entire specimen is illuminated, so fluorescent material above and below the plane of focus tends to blur the image. (b) In confocal fluorescence microscopy, incoming light is focused on a single plane, and out-of-focus fluorescence from the specimen is excluded. The resulting image is therefore much sharper.

(**Figure A-15a**). To overcome this problem, cell biologists often turn to the **confocal microscope**—a specialized type of light microscope that employs a laser beam to produce an image of a single plane of the specimen at a time (Figure A-15b). This approach improves the resolution along the optical axis of the microscope—that is, structures in the middle of a cell may be distinguished from those on the top or bottom. Likewise, a cell in the middle of a piece of tissue can be distinguished from cells above or below it.

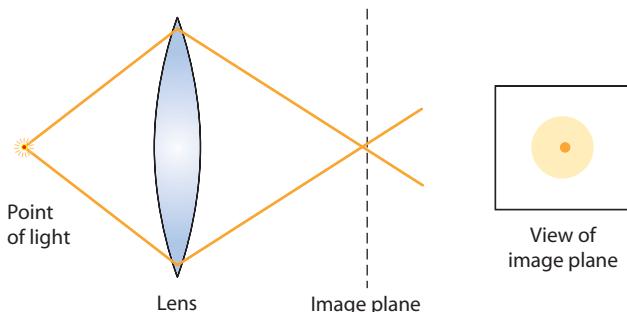

To understand this type of microscopy, it is first necessary to consider the paths of light taken through a simple lens. **Figure A-16** illustrates how a simple lens forms an image of a point source of light. To understand what your eye would see, imagine placing a piece of photographic film in the plane of focus (image plane). Now ask how the images of other points of light placed further away or closer to the lens contribute to the original image (Figure A-16b). As you might guess, there is a precise relationship between the distance of the object from the lens (o), the distance from the lens to the image of that object brought into focus (i), and the focal length of the lens (f). This relationship is given by the equation

$$\frac{1}{f} = \frac{1}{o} + \frac{1}{i} \quad (\text{A-4})$$

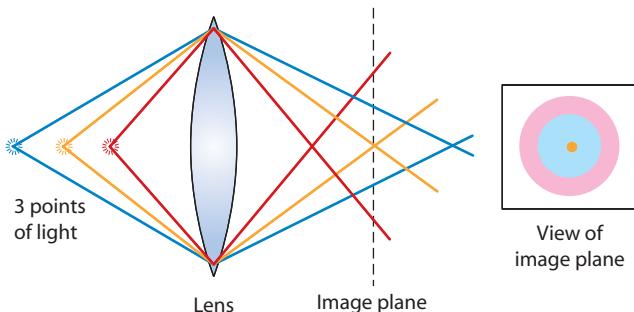

As Figure A-16b shows, light arising from the points that are not in focus covers a greater surface area on the film because the rays are still either converging or diverging. Thus, the image on the film now has the original point source that is in focus, with a superimposed halo of light from the out-of-focus objects.

If we were interested only in seeing the original point source, we could mask out the extraneous light by placing an aperture, or *pinhole*, in the same plane as the film. This principle is used in a confocal microscope to discriminate against out-of-focus rays. In a real specimen, of course, we have more than one extraneous source of light on each side of the object we wish to see; in fact, we have a continuum of points. To understand how this affects our image, imagine that instead of three points of light, our specimen consists of a long, thin tube of light, as in Figure A-16c. Now consider obtaining an image of some arbitrary small section, dx . If the tube sends out the same amount of light per unit length, then even with a pinhole, the image of interest will be obscured by the halos arising from other parts of the tube. This occurs because there is a small contribution from each out-of-focus section, and the sheer number of small sections will create a large background over the section of interest.

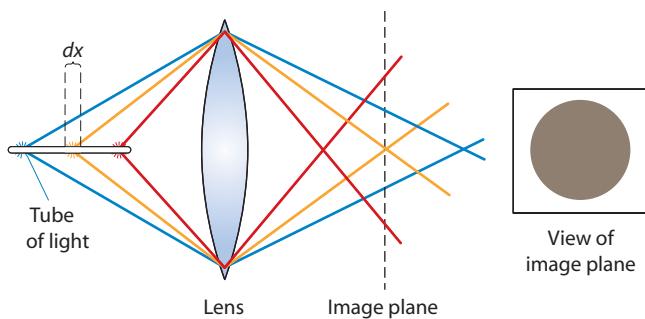

This situation is very close to the one we face when dealing with real biological samples that have been stained with a fluorescent probe. In general, the distribution of the probe is three-dimensional, and the image is often marred by the halo of background light that arises mostly from probes above and below the plane of interest. To circumvent this, we can preferentially illuminate the plane of interest, thereby biasing the contributions in the image plane so that they arise mostly from a single plane (Figure A-16d). Thus, the essence of confocal microscopy is to bring the illumination beam that excites the fluorescence into focus in a single plane, and to use a pinhole to ensure that the light we collect in the image plane arises mainly from that plane of focus.

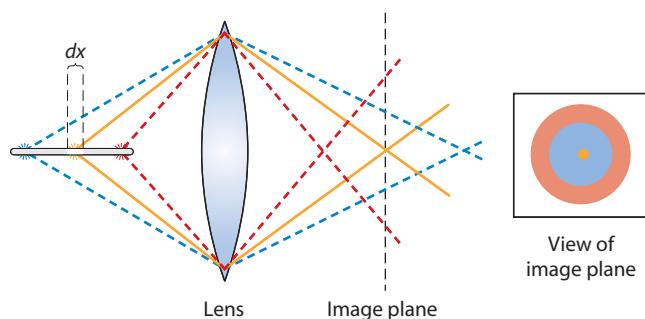

(a) Formation of an image of a single point of light by a lens

(b) Formation of an image of a point of light in the presence of two other points

(c) Formation of an image of a section of an equally bright tube of light

(d) Formation of an image of a brightened section of a tube of light

Figure A-17 illustrates how these principles are put to work in a laser scanning confocal microscope, which illuminates specimens using a laser beam focused by an objective lens down to a diffraction-limited spot. The position of the spot is controlled by scanning mirrors, which allow the beam to be swept over the specimen in a precise pattern. As the beam is scanned over the spec-

FIGURE A-16 Paths of Light Through a Single Lens. (a) The image of a single point of light formed by a lens. (b) The paths of light from three points of light at different distances from the lens. In the image plane, the in-focus image of the central point is superimposed on the out-of-focus rays of the other points. A pinhole or aperture around the central point can be used to discriminate against out-of-focus rays and maximize the contributions from the central point. (c) The paths of light originating from a continuum of points, represented as a tube of light. This is similar to a uniformly illuminated sample. In the image plane, the contributions from an arbitrarily small in-focus section, dx , are completely obscured by the other out-of-focus rays; here a pinhole does not help. (d) By illuminating only a single section of the tube strongly and the rest weakly, we can recover information in the image plane about the section dx . Now a pinhole placed around the spot will reject out-of-focus rays. Because the rays in the middle are almost all from dx , we have a means of discriminating against the dimmer, out-of-focus points.

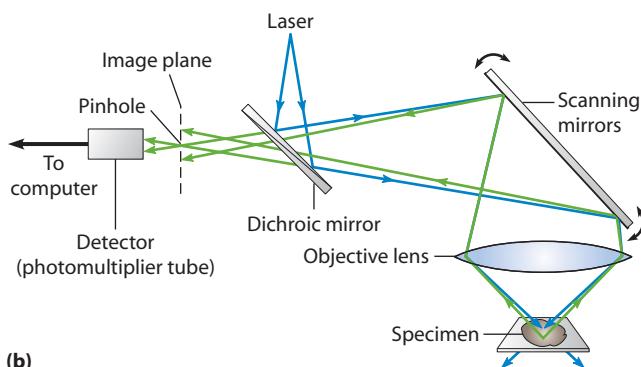

imen, an image of the specimen is formed in the following way. First, the fluorescent light emitted by the specimen is collected by the objective lens and returned along the same path as the original incoming light. The path of the fluorescent light is then separated from the laser light using a dichroic mirror, which reflects one color but transmits another. Because the fluorescent light has a longer wavelength than the excitation beam, the fluorescence color is shifted (for example, from blue to green). The fluorescent light passes through a pinhole placed at an image plane in front of a photomultiplier tube, which acts as a detector. The signal from the photomultiplier tube is then digitized and displayed by a computer. To see the enhanced resolution that results from confocal microscopy, look back to Figure A-15, which shows images of the same cell visualized by conventional fluorescence microscopy and by laser scanning confocal microscopy.

As an alternative to laser scanning confocal microscopy, a *spinning disc confocal microscope* uses rapidly spinning discs containing a series of small lenses and a corresponding series of pinholes. Although it cannot produce optical sections as thin as those produced by laser scanning microscopes, it can generate confocal images that can be acquired rapidly using sensitive digital cameras. Such speed is useful for visualizing very rapid events within living cells.

In confocal microscopy, a pinhole is used to exclude out-of-focus light. The result is a sharp image, but molecules above and below the focal plane of the objective lens are still being excited by the incoming light. This can result in rapid bleaching of the fluorescent molecules. In some cases, especially when viewing living cells that contain fluorescent molecules, such bleaching releases toxic radicals that can cause the cells to die. To reduce such “photodamage,” it would be desirable if only the fluorescent molecules very close to the focal plane being examined were excited. This is possible using **multiphoton excitation microscopy**, in which a laser that rapidly emits pulses of high-amplitude light is used to irradiate the specimen. When two (or in some cases, three or more) photons arrive at the specimen almost simultaneously,

(a)

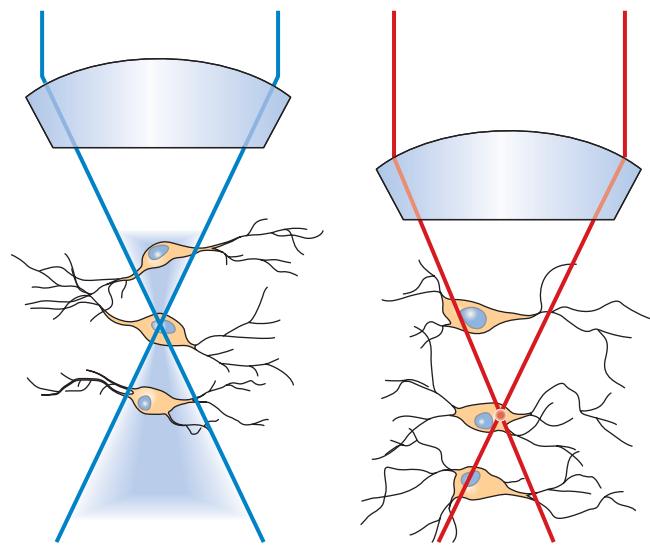

(b)

FIGURE A-17 A Laser Scanning Confocal Microscope.

(a) A photograph and (b) a schematic of a laser scanning confocal microscope (LSCM). A laser is used to illuminate one spot at a time in the specimen (blue lines). Scanning mirrors move the spot in a given plane of focus through a precise pattern. The fluorescent light being emitted from the specimen (green lines) bounces off the same scanning mirrors and returns along the original path of the illumination beam. The emitted light does not return to the laser, but instead is transmitted through the dichroic mirror (which in this example reflects blue light but transmits green light). A pinhole in the image plane blocks the extraneous rays that are out of focus. The light is detected by a photomultiplier tube, whose signal is digitized and stored by a computer.

The physics of light indicates that these photons can combine to effectively approximate a photon of shorter wavelength. When this approximate wavelength is near the absorption wavelength for a fluorescent molecule, the fluorescent molecule absorbs the light and fluoresces (**Figure A-18**). The likelihood of this happening is very low, except near the focal plane of the objective lens. As a result, only the fluorescent molecules that are in focus fluoresce. The result is very similar in sharpness to confocal

(a) Confocal microscopy

(b) Multiphoton microscopy

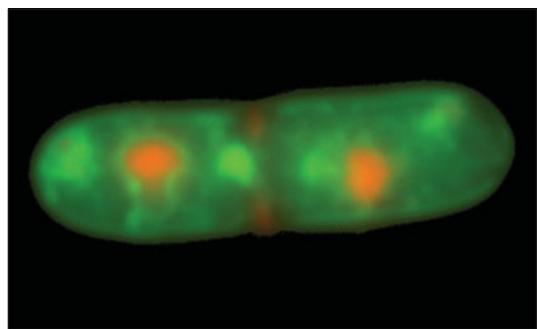

FIGURE A-18 Multiphoton Excitation Microscopy. (a) In a standard LSCM, the laser results in fluorescence in an hourglass-shaped path throughout the specimen. Because a large area fluoresces, photodamage is much more likely to occur than in multiphoton excitation microscopy. (b) In a multiphoton excitation microscope, fluorescence is limited to a spot at the focus of the pulsed infrared laser beam, resulting in much less damage. The infrared illumination also penetrates more deeply into the specimen than visible light does.

microscopy, but no pinhole is needed since there is no out-of-focus light that needs to be excluded. Photodamage is also dramatically reduced. As an example, multiphoton excitation microscopy was used to image the living embryo shown in Figure A-14.

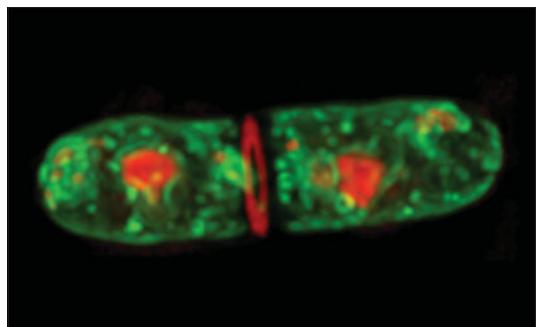

A third technique, **digital deconvolution microscopy**, can be used to provide very sharp images. Digital deconvolution relies on a completely different principle. In this case, normal fluorescence microscopy is used to acquire a series of images throughout the thickness of a specimen. Then a computer is used to digitally process, or *deconvolve*, each focal plane to mathematically remove the contribution due to the out-of-focus light. In many cases, digital deconvolution can produce images comparable to those obtained by confocal microscopy (**Figure A-19**). One advantage of deconvolution is that the microscope is not restricted to the specific wavelengths of light used in the lasers commonly found in confocal microscopes.

Digital Microscopy Can Record Enhanced Time-Lapse Images

The advent of solid-state light detectors has, in many circumstances, made it possible to replace photographic film with an electronic equivalent—that is, with a video camera or digital imaging camera. These developments have given rise to the technique of **digital microscopy**, in which microscopic images are recorded and stored electronically by placing a video or digital camera in the image plane produced by the ocular lens. The resulting digital

(a)

(b)

4 μ m

FIGURE A-19 Digital Deconvolution Microscopy. A fission yeast cell stained with a dye specific for DNA (red) and a membrane-specific dye (green). The image in (a) is an unprocessed optical section through the center of the cell, while the image in (b) is a projection of all the sections following three-dimensional image processing. The ring of the developing medial septum (red) is forming between the two nuclei (red) that arose by nuclear division during the previous mitosis.

images can then be *enhanced* by a computer to increase contrast and remove background features that obscure the image of interest (**Figure A-20**).

The resulting enhancement allows the visualization of structures that are an order of magnitude smaller than those

that can be seen with a conventional light microscope. Digital techniques can be applied to conventional brightfield light microscopy, as well as to DIC and fluorescence microscopy, thereby creating a powerful set of approaches for improving the effectiveness of light microscopy.

An additional advantage of digital microscopy is that the specimen does not need to be killed by fixation, as is required with electron microscopy, so dynamic events can be monitored as they take place. Moreover, special, sensitive cameras have been developed that can detect extremely dim images, thereby facilitating the ability to record a rapid series of time-lapse pictures of cellular events as they proceed. This technique has allowed scientists to obtain information on the changes in concentration and subcellular distribution of such cytosolic components as second messengers during cellular signaling and to study the role of cytoskeletal structures in intracellular movements.

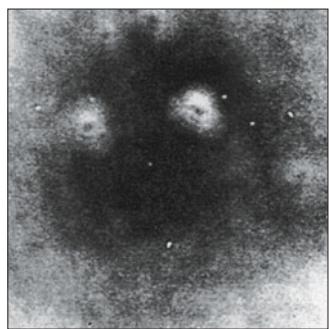

Digital microscopy is not only useful for examining events in one focal plane. In a variation of this technique, a computer is used to control a focus motor attached to a microscope. Images are then collected throughout the thickness of a specimen. When such a series of images is collected at specific time intervals, such microscopy is called *four-dimensional microscopy* (this phrase is borrowed from physics; the four dimensions are the three dimensions of space plus the additional dimension of time). Analyzing four-dimensional data requires special computer software that can navigate between focal planes over time to display specific images.

Optical Methods Can Be Used to Measure the Movements and Properties of Proteins and Other Macromolecules

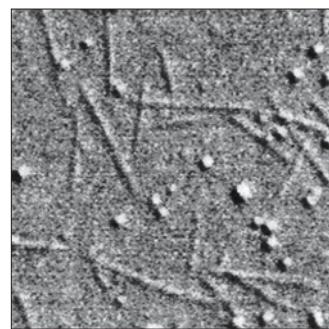

Optical microscopy can be used to help us visualize where molecules reside within cells and to study the dynamic movements and properties of biological molecules. We briefly consider these modern techniques in this section.

(a)

(b)

(c)

(d)

2.5 μ m

FIGURE A-20 Computer-Enhanced Digital Microscopy. This series of micrographs shows how computers can be used to enhance images obtained with light microscopy. In this example, an image of several microtubules—too small to be seen with unenhanced light microscopy—are processed to make them visible in detail. (a) The image resulting from electronic contrast enhancement of the original image (which appeared to be empty). (b) The background of the enhanced image in (a), which is then (c) subtracted from image (a), leaving only the microtubules. (d) The final, detailed image resulting from electronic averaging of the separate images processed as shown in parts a–c.

Photobleaching, Photoactivation, and Photoconversion. When fluorescent molecules are irradiated with light at the appropriate excitation wavelength for long periods of time, they undergo **photobleaching** (i.e., the irradiation induces the molecules to cease fluorescing). If a cell is exposed to intense light in only a small region, such bleaching results in a characteristic decrease in fluorescence (**Figure A-21a**). As unbleached molecules move into the bleach zone, the fluorescence gradually returns to normal levels. Such *fluorescence recovery after photobleaching (FRAP)* is therefore one useful measure of

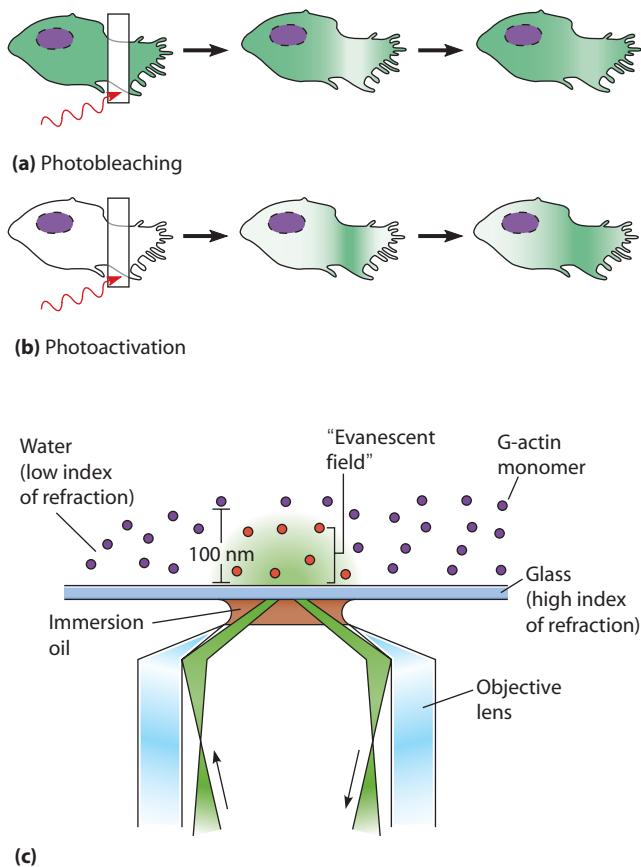

FIGURE A-21 Techniques for Studying Dynamic Movements of Molecules Within Cells. (a) Photobleaching of fluorescent molecules. A well-defined area of a cell is irradiated, causing bleaching of fluorescent molecules. Gradually, new, unbleached molecules invade the bleached zone. (b) Photoactivation of fluorescent proteins. Photoactivation of a selected region (indicated by the box) results in an increase in fluorescence. Subsequent movements of the fluorescent molecules can then be monitored. (c) Total internal reflection fluorescence (TIRF) microscopy. This procedure is often performed using an inverted microscope, which places the objective lens under the specimen. The example shown here involves fluorescent G-actin monomers (see Chapter 15). When a parallel beam of light in a medium of high refractive index (such as glass) strikes an interface with a medium of lower refractive index (such as a cell or water) at an angle that exceeds the critical angle, it undergoes total internal reflection. Total internal reflection results in an “evanescent field” in the medium of lower refractive index, which falls off quickly with distance. This allows only a very small number of fluorescent molecules to be seen.

how fast molecules diffuse or undergo directed transport (see Figure 7-11 for a classic example of the use of FRAP).

In other cases, fluorescent molecules are chemically modified so that they do not fluoresce until they are irradiated with a specific wavelength of light, usually ultraviolet light. The UV light induces the release of the chemical modifier, allowing the molecule of interest to fluoresce. Both chemically modified dyes and forms of GFP have been produced that behave in this way. Such compounds are often called *caged compounds* because they are “freed” only by this light-induced cleavage. Uncaging, or **photoactivation**, produces the converse situation to photobleaching: Local uncaging of a fluorescent molecule produces a bright spot of fluorescence that can be followed as the molecules diffuse throughout the cell (Figure A-21b). Uncaging via photoactivation can also be used to convert other kinds of inert molecules to their active state. For example, “caged calcium” is actually a calcium chelator that is bound to calcium ions. When the caged compound is irradiated, it gives up its calcium, causing a local elevation of calcium within the cell. A third technique causes a fluorescent molecule to permanently change its fluorescence properties after it is exposed to ultraviolet or other short wavelengths of light. Such **photoconversion** can, for example, cause a green fluorescent protein to become a red fluorescent protein and has uses that are similar to photoactivation. Other fluorescent molecules can be temporarily switched “off” so that they do not fluoresce and then back “on” again, a process called “**photoswitching**.”

Total Internal Reflection Fluorescence Microscopy.

An even more spatially precise method for observing fluorescent molecules involves **total internal reflection fluorescence (TIRF) microscopy**. TIRF relies on a useful property of light: When light moves from a medium with a high refractive index (such as glass) to a medium with a lower refractive index (such as water or a cell), if the angle of incidence of the light exceeds a certain angle (called the *critical angle*), the light is reflected. You may be familiar with fiber-optic cables, which rely on the same physical principle. The curvature of the fiber causes almost all of the light that passes into the cable to be internally reflected, allowing such fibers to serve as “light pipes.” Microscopists can use special lenses to exploit total internal reflection as well. When fluorescent light shines on a cell such that all of the light exceeds the critical angle, it will undergo total internal reflection. If all of the light is reflected, why is TIRF useful? It turns out that a very small layer of light, called the “evanescent field,” extends into the water or cell (Figure A-21c). This layer is very thin, about 100 nm, making TIRF up to ten times better than a confocal microscope for resolving small objects very close to the surface of a coverslip. This makes TIRF extremely useful for studying the release of secretory vesicles or for observing the polymerization of actin.

Fluorescence Resonance Energy Transfer. Fluorescence microscopy is useful not only for observing the movements of proteins but also for measuring their physical interactions with one another. When two fluorescent molecules whose fluorescence properties are matched are brought very close to one another, it is possible for them to experience **fluorescence resonance energy transfer (FRET)**. In FRET, illuminating a cell at the excitation wavelength of the first, or *donor*, fluorophore results in energy transfer to the second, or *acceptor*, fluorophore. This energy transfer does not itself involve a photon of light; however, once it occurs, it causes the acceptor to emit light at its characteristic wavelength. A commonly used pair of fluorescent molecules used in FRET is derived from GFP: One glows with bluish (cyan) fluorescence (so it is called *cyan fluorescent protein*, or CFP); the other is excited by bluish light and glows with a yellowish color (so it is called *yellow fluorescent protein*, or YFP). FRET can be measured between two separate proteins (*intermolecular* FRET; **Figure A-22a**), or between fluorescent side chains on the same protein (*intramolecular* FRET; Figure A-22b). FRET acts only at a very short range (100 Ångstroms or less); as a result, intermolecular FRET provides a readout regarding where within a cell the two fluorescent proteins are essentially touching one another.

Intramolecular FRET is used in several kinds of “molecular biosensors.” We saw one example of such a biosensor in Chapter 14, when we considered “cameleons” (the spelling is correct; the name comes from the abbreviation for the protein calmodulin, CaM, part of which is used to make these types of sensors). These engineered proteins change shape to bring blue and yellow fluorescent protein subunits into contact only when calcium levels rise. The resulting FRET can be used to measure local calcium levels. Similar biosensors are being used to measure the local activation of small G proteins, such as Ras (Figure A-22c).

“Optical Tweezers.” The final application of light microscopy we will discuss relies on well-established ways in which light interacts with small objects. When photons strike small objects, they exert “light pressure” on them. When a small object is highly curved, such as a small plastic bead, the differential forces exerted by a tightly focused laser beam channeled through a microscope tend to cause the bead to remain in the center of the beam, trapping it via light pressure. Such **optical tweezers** can be used to move objects, or they can be used to exert exceedingly small forces on beads that are attached to proteins or other molecules. By measuring the forces exerted on beads coupled to myosin, for example, scientists have been able to measure the forces produced by the power stroke of a single myosin protein (**Figure A-23**).

Superresolution Microscopy Has Broken the Diffraction Limit

The wavelength of visible light seems to place a limit on what can be resolved in the light microscope. We described this limit, due to diffraction, using the Abbé

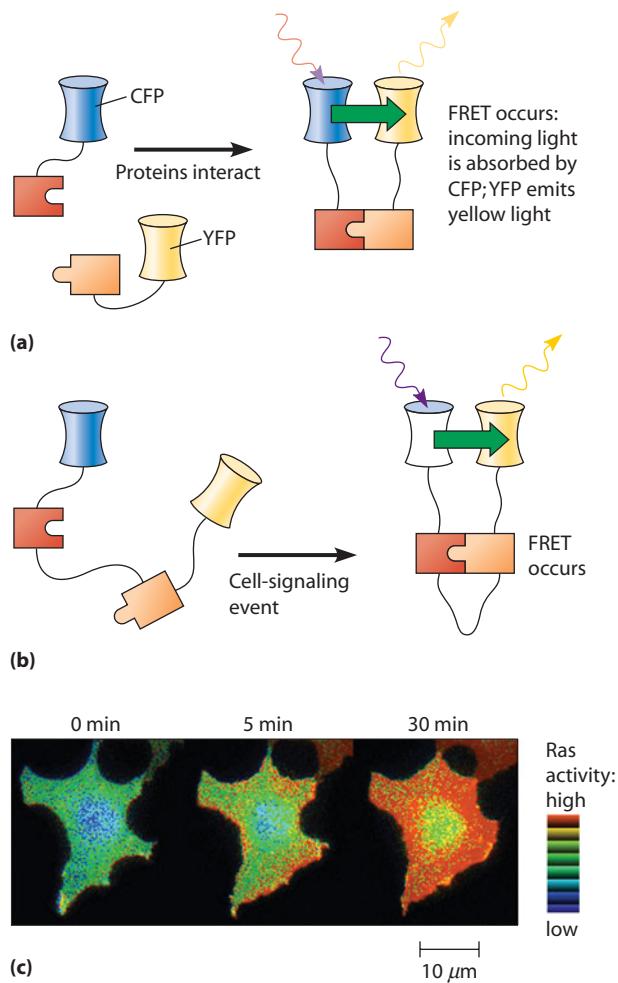

FIGURE A-22 Fluorescence Resonance Energy Transfer (FRET). (a) Intermolecular FRET. When two proteins attached to two different fluorescent side chains (such as cyan fluorescent protein, or CFP, and yellow fluorescent protein, or YFP) are in close proximity, the CFP can transfer energy directly to the YFP when the CFP is excited. The YFP then fluoresces. (b) Intramolecular FRET. In this case, CFP and YFP are attached to the same molecule, but they can interact only when the protein undergoes a conformational change. Such engineered proteins can be used as cellular “biosensors.” (c) Detecting Ras activation in a living cell. A COS-1 cell expressing a protein that undergoes intramolecular FRET in regions where Ras is active shows an increase in FRET after the cell is exposed to epidermal growth factor (EGF), which activates Ras.

equation. Recent ingenious techniques, collectively called **superresolution microscopy**, have broken this “diffraction barrier.” One of these techniques is called *stimulated emission depletion (STED) microscopy*. Like confocal microscopy, STED uses very short pulses of laser light to cause molecules in a specimen to fluoresce. The first pulse is immediately followed by a ring-shaped “depletion” pulse, which causes stimulated emission, moving electrons from the excited state (which causes fluorescence to occur) to a lower energy state before they can fluoresce. The interaction of the two pulses effectively results in a smaller spot size than could be achieved with a conventional microscope (**Figure A-24a**). Two other

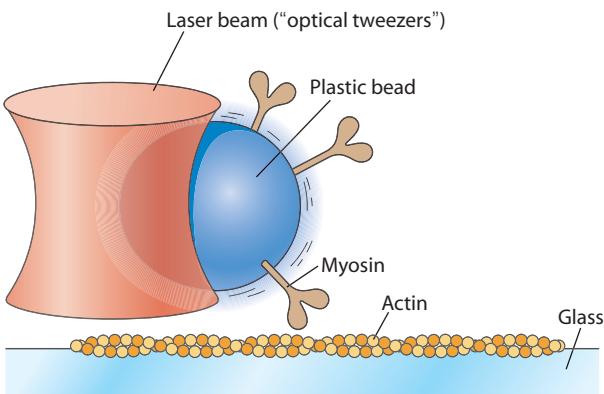

FIGURE A-23 “Optical Tweezers.” A small plastic bead can be held in place by a laser beam focused through the objective lens of a microscope. When the bead is attached to a molecule such as myosin, the force produced by the myosin as it pulls on an actin filament attached to a microscope slide can be precisely measured.

techniques take a different approach. These techniques, called *photoactivated localization microscopy (PALM)* and *stochastic optical reconstruction microscopy (STORM)*, use photoactivatable or photoswitchable probes, respectively. A specimen containing these probes is scanned many times but in a way that the fluorescence of individual molecules against a dark background can be pinpointed with improved precision using computers. These calculations are then combined to generate an image (Figure A-24b). As technology continues to improve, STED, PALM, STORM, and other superresolution techniques will continue to push the limits of resolution of the light microscope.

Sample Preparation Techniques for Light Microscopy

One attractive feature of using light microscopy is how easily most specimens can be prepared for examination. In some cases, preparing a sample involves nothing more than mounting a small piece of the specimen in a suitable liquid on a glass slide and covering it with a glass coverslip. The slide is then positioned on the specimen stage of the microscope and examined through the ocular lens, or with a camera. However, to take maximum advantage of the resolving power of the light microscope, samples are usually prepared in a way designed to enhance *contrast*—that is, differences in the darkness or color of the structures being examined. A common means for enhancing contrast is to apply specific dyes that color or otherwise alter the light-transmitting properties of cell constituents.

Specimen Preparation Often Involves Fixation, Sectioning, and Staining

To prepare cells for staining, tissues are often first treated with **fixatives** that kill the cells while preserving their structural appearance. The most widely employed fixatives are acids and aldehydes such as acetic acid, picric acid, formaldehyde, and glutaraldehyde. One way of fixing

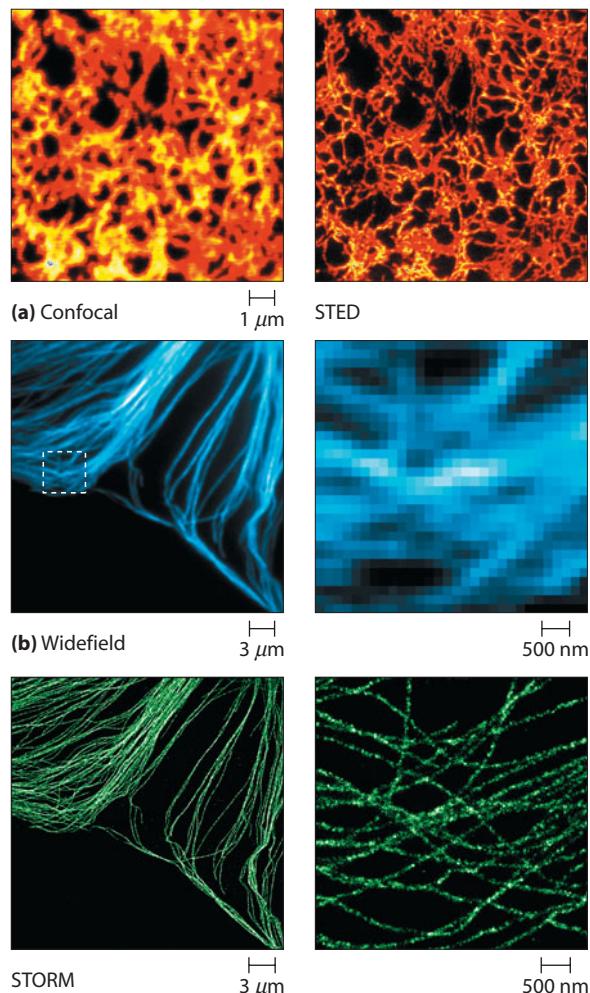

FIGURE A-24 Superresolution Microscopy Breaks the Diffraction Barrier. (a) A yellow fluorescent protein fused to a sequence that targets it to the endoplasmic reticulum was used to image the same specimen using confocal microscopy (left) and STED (right). (b) Comparison of immunostaining of microtubules using widefield (i.e., standard, non-confocal) fluorescence microscopy (top) and STORM (bottom). The right-hand panels zoom in on the boxed region. The zoomed confocal image, but not the STORM image, is blurry, because STORM imaging can identify fluorescent molecules with much higher spatial resolution.

tissues is simply to immerse them in the fixative solution. An alternative approach for animal tissues is to inject the fixative into the bloodstream of the animal before removing the organs—a technique known as *perfusion*.

In most cases, the next step is to slice the specimen into sections that are thin enough to transmit light. To prepare such *thin sections*, the specimen is embedded in a medium (such as plastic or paraffin wax) that can hold it rigidly in position while sections are cut. Since paraffin is insoluble in water, any water in the specimen must first be removed (by dehydration in alcohol, usually) and replaced by an organic solvent, such as xylene, in which paraffin is soluble. The processed tissue is then placed in warm, liquefied paraffin and allowed to harden. Dehydration is less critical if the specimen is embedded in a water-soluble medium instead of paraffin. Specimens may also be

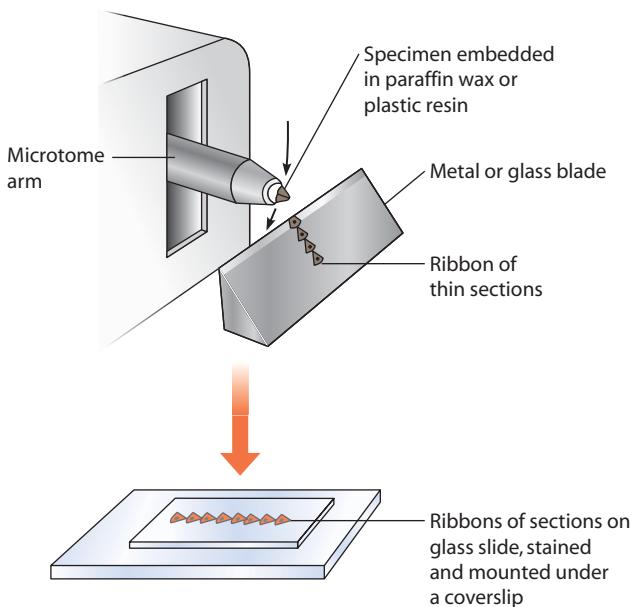

FIGURE A-25 Sectioning with a Microtome. The fixed specimen is embedded in paraffin wax or plastic resin and mounted on the arm of the microtome. As the arm moves up and down through a circular arc, the blade cuts successive sections. The sections adhere to each other, forming a ribbon of thin sections that can be mounted on a glass slide, stained, and protected with a coverslip.

embedded in epoxy plastic resin, or, as an alternative way of providing support, the tissue can simply be quick-frozen.

After embedding or quick-freezing, the specimen is sliced into thin sections a few micrometers thick by using a **microtome**, an instrument that operates somewhat like a meat slicer (Figure A-25). The specimen is simply mounted on the arm of the microtome, which advances the specimen by small increments toward a metal or glass blade that slices the tissue into thin sections. The sections are then mounted on a glass slide and subjected to **staining** with any of various dyes or antibodies that have been adapted for this purpose. Often a series of treatments are applied, each with an affinity for a different kind of cellular component. Once stained, the specimen is covered with a glass coverslip for protection.

A historically important approach for localizing specific components within cells is *microscopic autoradiography*, a technique that uses photographic emulsion to determine where a specific radioactive compound is located within a cell at the time the cell is fixed and sectioned for microscopy. When the emulsion is later developed and the specimen is examined under the microscope, *silver grains* appear directly above the specimen wherever radiation had bombarded the emulsion.

The Electron Microscope

The impact of electron microscopy on our understanding of cells can only be described as revolutionary. Yet, like light microscopy, electron microscopy has both strengths and weaknesses. In electron microscopy, resolution is

much better; but specimen preparation and instrument operation are often more difficult. Electron microscopes are of two basic designs: the *transmission electron microscope* and the *scanning electron microscope*. Scanning and transmission electron microscopes are similar in that each employs a beam of electrons to produce an image. However, the instruments use quite different mechanisms to form the final image, as we see next.

Transmission Electron Microscopy Forms an Image from Electrons That Pass Through the Specimen

The **transmission electron microscope (TEM)** is so named because it forms an image from electrons that are *transmitted* through the specimen being examined. As shown in Figure A-26, most of the parts of the TEM are similar in name and function to their counterparts in the light microscope, although their physical orientation is reversed. We will look briefly at each of the major features.

The Vacuum System and Electron Gun. Because electrons cannot travel very far in air, a strong vacuum must be maintained along the entire path of the electron beam. Two types of vacuum pumps work together to create this vacuum. On some TEMs, a device called a *cold trap* is incorporated into the vacuum system to help establish a high vacuum. The cold trap is a metal insert in the column of the microscope that is cooled by liquid nitrogen. The cold trap attracts gases and random contaminating molecules, which then solidify on the cold metal surface.

The electron beam in a TEM is generated by an **electron gun**, an assembly of several components. The *cathode*, a tungsten filament similar to a light bulb filament, emits electrons from its surface when it is heated. The cathode tip is near a circular opening in a metal cylinder. A negative voltage on the cylinder helps control electron emission and shape the beam. At the other end of the cylinder is the *anode*. The anode is kept at 0 V, while the cathode is usually maintained at 50–100 kV. This difference in voltage causes the electrons to accelerate as they pass through the cylinder and hence is called the **accelerating voltage**.

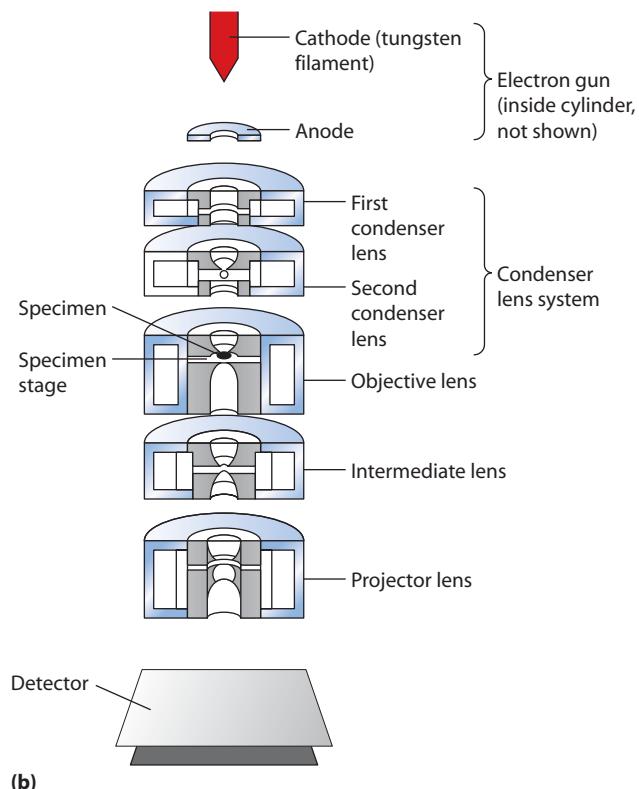

Electromagnetic Lenses and Image Formation. The formation of an image using electron microscopy depends on both the wavelike and the particle-like properties of electrons. Because electrons are negatively charged particles, their movement can be altered by magnetic forces. This means that the trajectory of an electron beam can be controlled using electromagnets, just as a glass lens can bend rays of light that pass through it.

As the electron beam leaves the electron gun, it enters a series of electromagnetic lenses (Figure A-26b). Each lens is simply a space influenced by an electromagnetic field. The focal length of each lens can be increased or decreased by varying the amount of electric current

(a)

FIGURE A-26 A Transmission Electron Microscope. (a) A photograph and (b) a schematic diagram of a TEM.

(b)

applied to its energizing coils. Thus, when several lenses are arranged together, they can control illumination, focus, and magnification.

The **condenser lens** is the first lens to affect the electron beam. It functions in the same fashion as its counterpart in the light microscope to focus the beam on the specimen. Most electron microscopes actually use a condenser lens system with two lenses to achieve better focus of the electron beam. The next component, the **objective lens**, is the most important part of the electron microscope's sophisticated lens system. The specimen is positioned on the specimen stage within the objective lens. The objective lens, in concert with the **intermediate lens** and the **projector lens**, produces a final image on a *viewing screen* that fluoresces when struck by electrons or that is produced directly by a detector.

How is an image formed from the action of these electromagnetic lenses on an electron beam? When the beam strikes the specimen, some electrons are scattered by the sample, whereas others continue in their paths relatively unimpeded. This scattering of electrons is the result of properties created in the specimen by preparation procedures we will describe shortly. Specimen preparation, in other words, imparts selective *electron density* to the specimen. That is, some areas become more opaque to electrons than others do. Electron-dense areas of the specimen will appear dark because few electrons pass through, whereas other areas will appear lighter because they permit the passage of more electrons.

The contrasting light, dark, and intermediate areas of the specimen create the final image. The image is formed by differing extents of electron transmission through the specimen, thus the name *transmission electron microscope*.

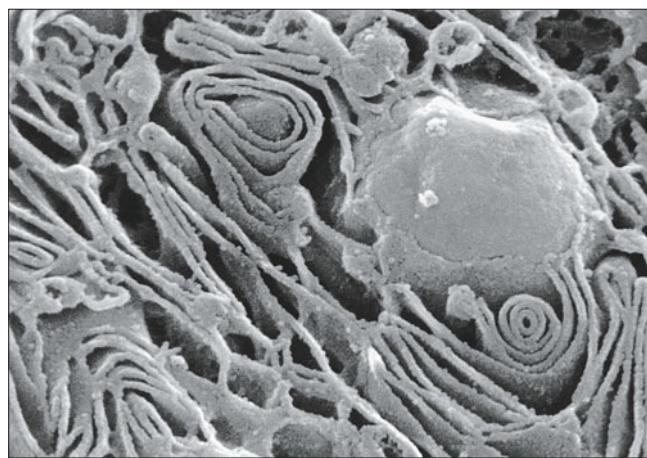

The Image Capture System. Since electrons are not visible to the human eye, the final image is detected in the transmission electron microscope by allowing the transmitted electrons to strike a fluorescent screen or photographic film. The use of film allows one to create a photographic print called an **electron micrograph**, which then becomes a permanent photographic record of the specimen (**Figure A-27a**). In many modern microscopes, a digital camera records the screen or a digital detector directly detects incoming electrons.

Voltage. An electron beam is too weak to penetrate very far into biological samples, so specimens examined by conventional transmission electron microscopy must be extremely thin (usually no more than 100 nm). Otherwise, the electrons will not be able to pass through the specimen, and the image will be entirely opaque. Examination of thicker sections requires a special **high-voltage electron microscope (HVEM)**, which is similar to a transmission electron microscope but utilizes an accelerating voltage that is much higher—about 200–1000 kV compared with the 50–100 kV of a TEM. Because the penetrating power of the resulting electron beam is roughly ten times as great as that of conventional electron microscopes, relatively

(a) Transmission electron micrograph

1 μm

FIGURE A-27 Comparison of Transmission and Scanning Electron Micrographs. (a) The transmission electron micrograph shows membranes of rough endoplasmic reticulum in the cytoplasm of a rat pancreas cell. The “rough” appearance of the membranes in this specimen is caused by the presence of numerous membrane-bound ribosomes. (b) A similar specimen viewed by scanning electron microscopy reveals the three-dimensional appearance of the rough endoplasmic reticulum, although individual ribosomes cannot be resolved.

thick specimens can be examined with good resolution. As a result, cellular structure can be studied in sections as thick as 1 μm , or about ten times the thickness possible with an ordinary TEM.

Scanning Electron Microscopy Reveals the Surface Architecture of Cells and Organelles

Scanning electron microscopy is a fundamentally different type of electron microscopy that produces images from electrons deflected from a specimen’s outer surface (rather than electrons transmitted through the specimen). It is an especially spectacular technique because of the sense of depth it gives to biological structures, thereby allowing surface topography to be studied (Figure A-27b). As the name implies, a **scanning electron microscope (SEM)** generates such an image by scanning the specimen’s surface with a beam of electrons.

An SEM and its optical system are shown in **Figure A-28**. The vacuum system and electron source are similar to those found in the TEM, although the accelerating voltage is lower (about 5–30 kV). The main difference between the two kinds of instruments lies in the way the image is formed. In an SEM, the electromagnetic lens system focuses the beam of electrons into an intense spot that is moved back and forth over the specimen’s surface by charged plates called *beam deflectors*, which are located between the condenser lens and the specimen. The beam deflectors attract or repel the beam according to the signals sent to them by the deflector circuitry (Figure A-28b).

As the electron beams sweep rapidly over the specimen, molecules in the specimen are excited to high energy levels and emit *secondary electrons*. These emitted electrons are captured by a detector located immediately above and to one side of the specimen, thereby generating an image of the specimen’s surface. The essential component of the detector

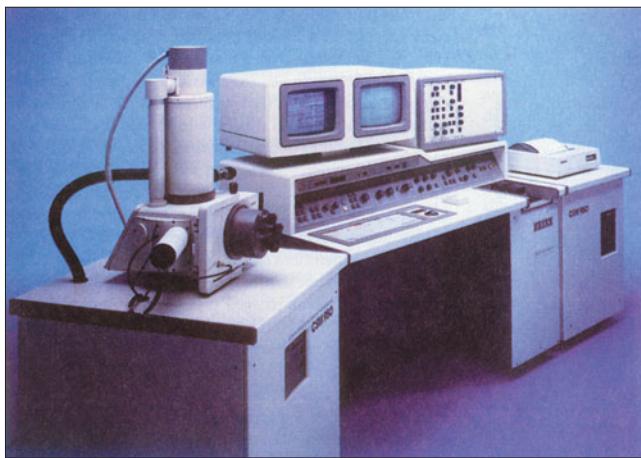

is a *scintillator*, which emits photons of light when excited by electrons that impinge upon it. The photons are used to generate an electronic signal to a video screen. The image then develops point by point, line by line on the screen as the primary electron beam sweeps over the specimen.

Sample Preparation Techniques for Electron Microscopy

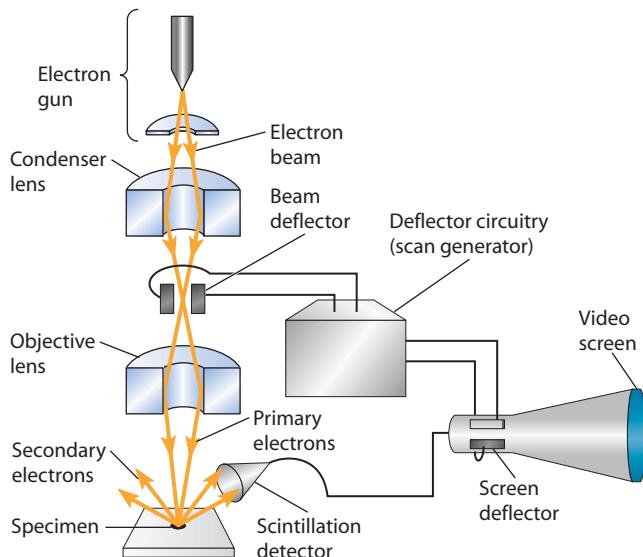

Specimens to be examined by electron microscopy can be prepared in several different ways, depending on the type of microscope and the kind of information the microscopist wants to obtain. In each case, however, the method is complicated, time-consuming, and costly compared with methods used for light microscopy. Moreover, living cells cannot be examined because the electron microscope requires specimens to be subjected to a vacuum.

Ultrathin Sectioning and Staining Are Common Preparation Techniques for Transmission Electron Microscopy

The most common way of preparing specimens for transmission electron microscopy involves slicing tissues and cells into ultrathin sections no more than 50–100 nm in thickness (less than one-tenth the thickness of the typical sections used for light microscopy). Specimens must first be chemically fixed and stabilized. The fixation step kills the cells but keeps the cellular components much as they were in the living cell. The fixatives employed are usually buffered solutions of aldehydes, most commonly glutaraldehyde. Following fixation, the specimen is often stained with a 1–2% solution of buffered osmium tetroxide (OsO_4), which binds to various components of the cell, making them more electron dense.

(a)

(b)

FIGURE A-28 A Scanning Electron Microscope. (a) A photograph and (b) a schematic diagram of an SEM. The image is generated by secondary electrons (short orange lines) emitted by the specimen as a focused beam of primary electrons (long orange lines) sweeps rapidly over it. The signal to the video screen is synchronized to the movement of the primary electron beam over the specimen by the deflector circuitry of the scan generator.

Chemical fixatives are very good at stabilizing many structures within cells, but they suffer from two drawbacks. First, they are slow; it takes a minimum amount of time for the fixative to diffuse into the sample to fix its structures. Second, chemical fixatives often extract cellular components (i.e., fine structures within the cell are often lost during fixation). **Cryofixation**, which typically involves extremely rapid freezing (within 20 msec) of a specimen under very high pressure, avoids these problems. Such *high-pressure freezing* is necessary; without it, water ice crystals form within the specimen, causing extensive damage to its fine structures. In most applications, high-pressure freezing is followed by *freeze substitution*. During freeze substitution, the water in the

sample is slowly replaced by an organic solvent, such as acetone, over a period of days. The resulting specimen can be processed for embedding and sectioning in the same way as chemically fixed specimens are processed.

The tissue is next passed through a series of alcohol solutions to dehydrate it, and then it is placed in a solvent such as acetone or propylene oxide to prepare it for embedding in liquefied plastic epoxy resin. After the plastic has infiltrated the specimen, it is put into a mold and heated in an oven to harden the plastic. The embedded specimen is then sliced into ultrathin sections by an instrument called an **ultramicrotome** (Figure A-29a). The specimen is mounted firmly on the arm of the ultramicrotome, which

(a) Ultramicrotome

(b) Micromtome arm of ultramicrotome

FIGURE A-29 An Ultramicrotome. (a) A photograph of an ultramicrotome. (b) A close-up view of the ultramicrotome arm, showing the specimen in a plastic block mounted on the end of the arm. As the ultramicrotome arm moves up and down, the block is advanced in small increments, and ultrathin sections are cut from the block face by the diamond knife.

advances the specimen in small increments toward a glass or diamond knife (Figure A-29). When the block reaches the knife blade, ultrathin sections are cut from the block face. The sections float from the blade onto a water surface, where they can be picked up on a circular copper specimen grid. The grid consists of a meshwork of very thin copper strips, which support the specimen while still allowing openings between adjacent strips through which the specimen can be observed.

Once in place on the grid, the sections are usually stained again, this time with solutions containing lead and uranium. This step enhances the contrast of the specimen because the lead and uranium give still greater electron density to specific parts of the cell. After poststaining, the specimen is ready for viewing or photography with the TEM.

Radioisotopes and Antibodies Can Localize Molecules in Electron Micrographs

In our discussion of light microscopy, we described how microscopic autoradiography can be used to locate radioactive molecules inside cells. Autoradiography can also be applied to transmission electron microscopy, with only minor differences. For the TEM, the specimen containing the radioactively labeled compounds is simply examined in ultrathin sections on copper specimen grids instead of in thin sections on glass slides.

We also described how fluorescently labeled antibodies can be used in conjunction with light microscopy to locate specific cellular components. Antibodies are likewise used in the electron microscopic technique called **immunoelectron microscopy (immunoEM)**; fluorescence cannot be seen in the electron microscope, so antibodies are instead visualized by linking them to substances that are electron dense and therefore visible as opaque dots. One of the most common approaches is to couple antibody molecules to colloidal gold particles. When ultrathin tissue sections are stained with gold-labeled antibodies directed against various proteins, electron microscopy can reveal the subcellular location of these proteins with great precision (**Figure A-30**).

A powerful approach that unites light microscopy and immunoEM is **correlative microscopy**. In correlative microscopy, dynamic images of a cell are acquired using the light microscope, often using antibodies and/or GFP. The very same cell is then processed and viewed using electron microscopy (EM). Commonly, immunoEM is used to determine where a protein is found at very high resolution. Correlative microscopy thus bridges the gap between dynamic imaging using the light microscope and the detailed images that can be acquired only via EM.

Negative Staining Can Highlight Small Objects in Relief Against a Stained Background

Although cutting tissues into ultrathin sections is the most common way of preparing specimens for transmission electron microscopy, other techniques are suitable for particular purposes. For example, the shape and surface

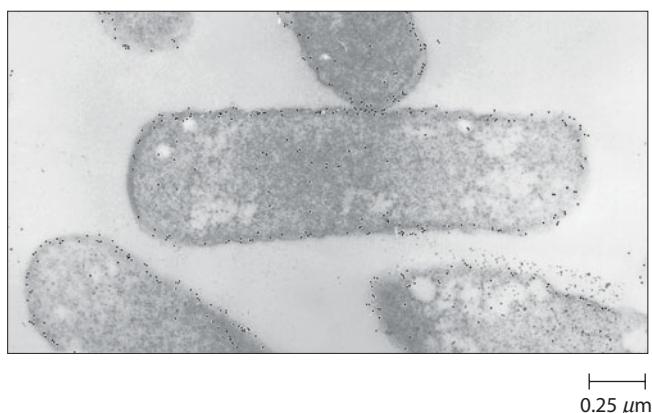

FIGURE A-30 The Use of Gold-Labeled Antibodies in Electron Microscopy. Cells of the bacterium *E. coli* were stained with gold-labeled antibodies directed against a plasma membrane protein. The small, dark granules distributed around the periphery of the cell are the gold-labeled antibody molecules.

appearance of very small objects, such as viruses or isolated organelles, can be examined without cutting the specimen into sections. In the **negative staining** technique, which is one of the simplest techniques in transmission electron microscopy, intact specimens are simply visualized in relief against a darkly stained background.

To carry out negative staining, the copper specimen grid must first be overlaid with an ultrathin plastic film. The specimen is then suspended in a small drop of liquid, applied to the overlay, and allowed to dry in air. After the specimen has dried on the grid, a drop of stain such as uranyl acetate or phosphotungstic acid is applied to the film surface. The edges of the grid are then blotted in several places with a piece of filter paper to absorb the excess stain. This draws the stain down and around the specimen and its ultrastructural features. When viewed in the TEM, the specimen is seen in *negative contrast* because the background is dark and heavily stained, whereas the specimen itself is lightly stained (**Figure A-31**).

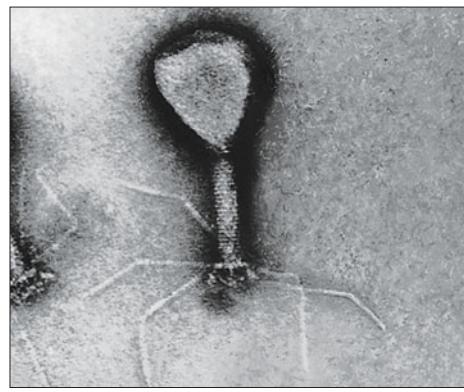

FIGURE A-31 Negative Staining. An electron micrograph of a bacteriophage as seen in a negatively stained preparation. This specimen was simply suspended in an electron-dense stain, allowing it to be visualized in relief against a darkly stained background (TEM).

FIGURE A-32 Shadowing. An electron micrograph of tobacco mosaic virus particles visualized by shadowing. In this technique, heavy metal vapor was sprayed at an angle across the specimen, causing an accumulation of metal on one side of each virus particle and a shadow region lacking metal on the other side (TEM).

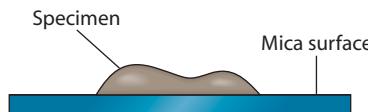

Shadowing Techniques Use Metal Vapor Sprayed Across a Specimen's Surface

Isolated particles or macromolecules can also be visualized by the technique of **shadowing** (Figure A-32), which involves spraying a thin layer of an electron-dense metal such as gold or platinum at an angle across the surface of a biological specimen. Figure A-33a illustrates the shadowing technique. The specimen is first spread on a clean mica surface and dried (step 1). It is then placed in a **vacuum evaporator**, a bell jar in which a vacuum is created by a system similar to that of an electron microscope (Figure A-33b). Also within the evaporator are two electrodes, one consisting of a carbon rod located directly over the specimen and the other consisting of a metal wire positioned at an angle of approximately 10–45° relative to the specimen.

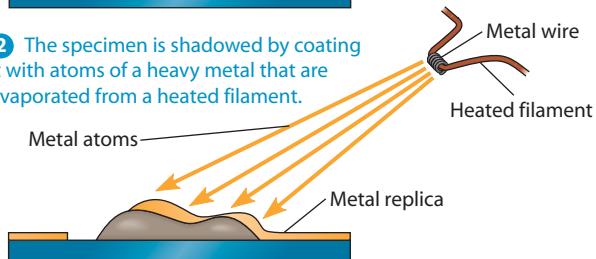

After a vacuum is created in the evaporator, current is applied to the metal electrode, causing the metal to evaporate from the electrode and spray over the surface of the specimen (Figure A-33a, 2). Because the metal-emitting electrode is positioned at an angle to the specimen, metal is deposited on only one side of the specimen, generating

FIGURE A-33 The Technique of Shadowing. (a) The specimen is spread on a mica surface and shadowed by coating it with atoms of a heavy metal (platinum or gold, shown in orange). This generates a metal replica (orange) whose thickness reflects the surface contours of the specimen. The replica is coated with carbon atoms to strengthen it, and it is then floated away and washed before viewing in the TEM. (b) The vacuum evaporator in which shadowing is done. The carbon electrode is located directly over the specimen; the heavy metal electrode is off to the side.

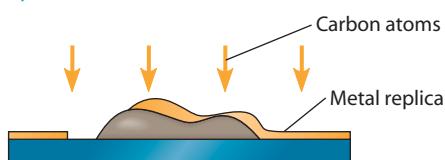

- 1 The specimen is spread on a mica surface and dried.

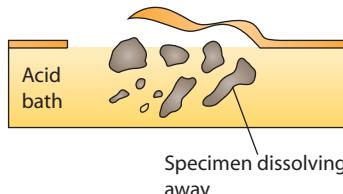

- 2 The specimen is shadowed by coating it with atoms of a heavy metal that are evaporated from a heated filament.

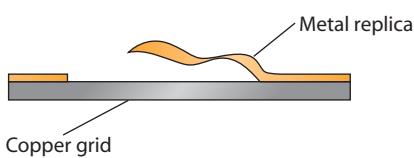

- 3 The specimen is coated with carbon atoms evaporated from an overhead electrode.

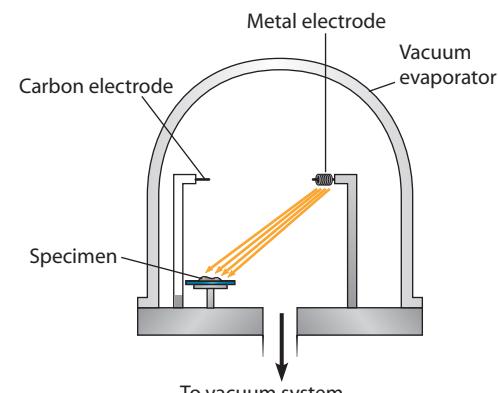

- 4 The replica is floated onto the surface of an acid bath to dissolve away the specimen, leaving a clean metal replica.

- 5 The replica is washed and picked up on a copper grid for examination in the TEM.

(a) Shadowing technique

(b) Vacuum evaporator

a metal *replica* of the surface. The opposite side of the specimen remains unstained; it is this unstained region that creates the “shadow” effect.

An overhead carbon-emitting electrode is then used to coat the specimen with evaporated carbon, thereby providing stability and support to the metal replicas (3). Next, the mica support containing the specimen is removed from the vacuum evaporator and lowered gently onto a water surface, causing the replica to float away from the mica surface. The replica is transferred into an acid bath, which dissolves any remaining bits of specimen, leaving a clean metal replica of the specimen (4). The replica is then transferred to a standard copper specimen grid (5) for viewing by transmission electron microscopy.

A related procedure is commonly used for visualizing purified molecules such as DNA and RNA. In this technique, a solution of DNA and/or RNA is spread on an air-water interface, creating a molecular monolayer that is collected on a thin film and visualized by uniformly depositing heavy metal on all sides.

Freeze Fracturing and Freeze Etching Are Useful for Examining the Interior of Membranes

Freeze fracturing is an approach to sample preparation that is fundamentally different from the methods described so far. Instead of cutting uniform slices through a tissue sample (or staining unsectioned material), specimens are rapidly frozen at the temperature of liquid

nitrogen or liquid helium, placed in a vacuum, and struck with a sharp knife edge. Samples frozen at such low temperatures are too hard to be cut. Instead, they fracture along lines of natural weakness—the hydrophobic interior of membranes, in most cases. Platinum/carbon shadowing is then used to create a replica of the fractured surface.

Freeze fracturing is illustrated in **Figure A-34**. It takes place in a modified vacuum evaporator with an internal microtome knife for fracturing the frozen specimen. The temperature of the specimen support and the microtome arm and knife is precisely controlled. Specimens are generally fixed prior to freeze fracturing, although some living tissues can be frozen fast enough to keep them in almost lifelike condition. Because cells contain large amounts of water, fixed specimens are usually treated with an antifreeze such as glycerol to provide *cryoprotection*—that is, to reduce the formation of ice crystals during freezing.

The cryoprotected specimen is mounted on a metal specimen support (Figure A-34, step 1) and immersed rapidly in freon cooled with liquid nitrogen (2). This procedure also reduces the formation of ice crystals in the cells. With the frozen specimen positioned on the specimen table in the vacuum evaporator (3), a high vacuum is established, the stage temperature is adjusted to around -100°C , and the frozen specimen is fractured with a blow from the microtome knife (4). A replica of the fractured specimen is made by shadowing with platinum and carbon as described in the previous section (5), and the replica is then ready to be viewed in the TEM (6).

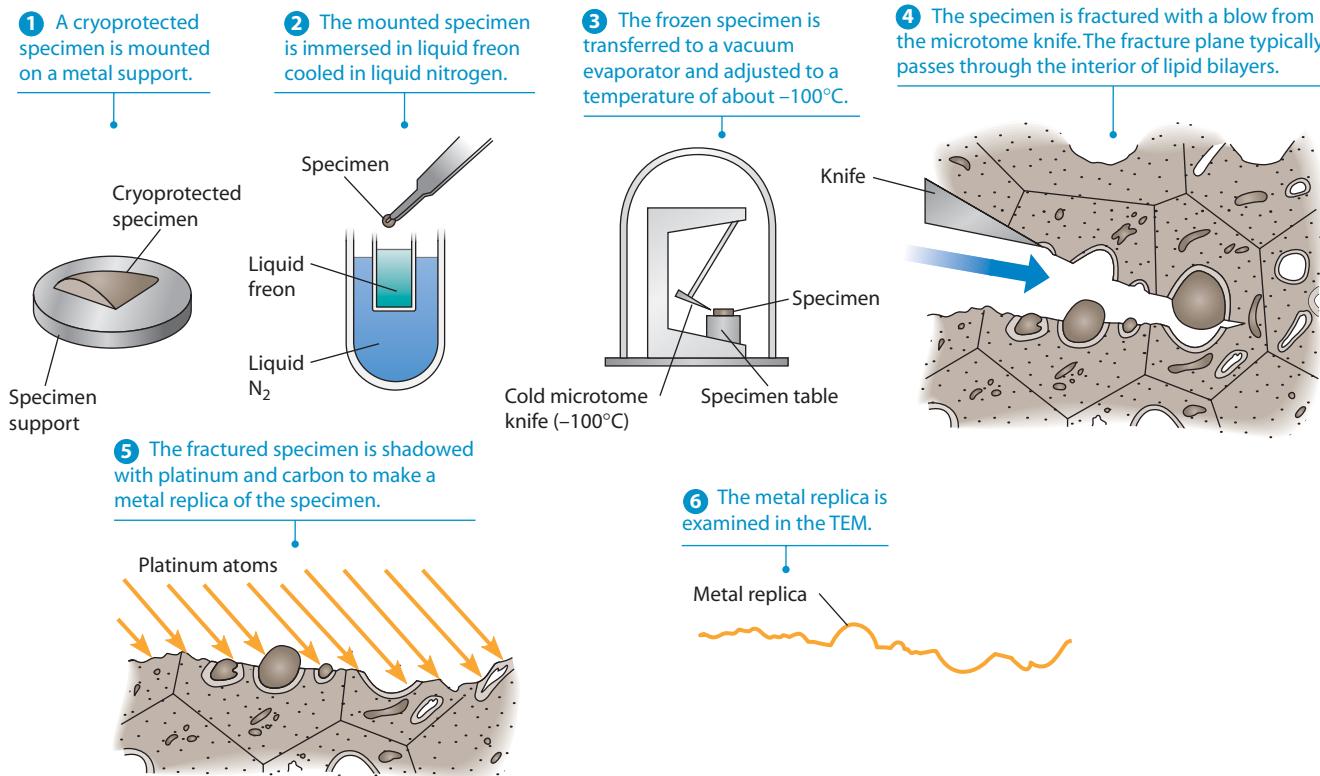

FIGURE A-34 The Technique of Freeze Fracturing. The result is a replica of a specimen, fractured through its lipid bilayer, that can be viewed in the TEM. The shadowing is performed as in Figure A-33.

Freeze-fractured membranes appear as smooth surfaces studded with **intramembranous particles (IMPs)**. These particles are integral membrane proteins that have remained with one lipid monolayer or the other as the fracture plane passes through the interior of the membrane.

The electron micrograph in **Figure A-35** shows the two faces of a plasma membrane revealed by freeze fracturing. The **P face** is the interior face of the inner monolayer; it is called the P face because this monolayer is on the *protoplasmic* side of the membrane. The **E face** is the interior face of the outer monolayer; it is called the E face because this monolayer is on the *exterior* side of the membrane. Notice that the P face has far more intramembranous particles than does the E face. In general, most of the particles in the membrane stay with the inner monolayer when the fracture plane passes down the middle of a membrane.

To have a P face and an E face appear side by side as in Figure A-35, the fracture plane must pass through two neighboring cells, such that one cell has its cytoplasm and the inner monolayer of its plasma membrane removed to reveal the E face, while the other cell has the outer monolayer of its plasma membrane and the associated intercellular space removed to reveal the P face. Accordingly, E faces are always separated from P faces of adjacent

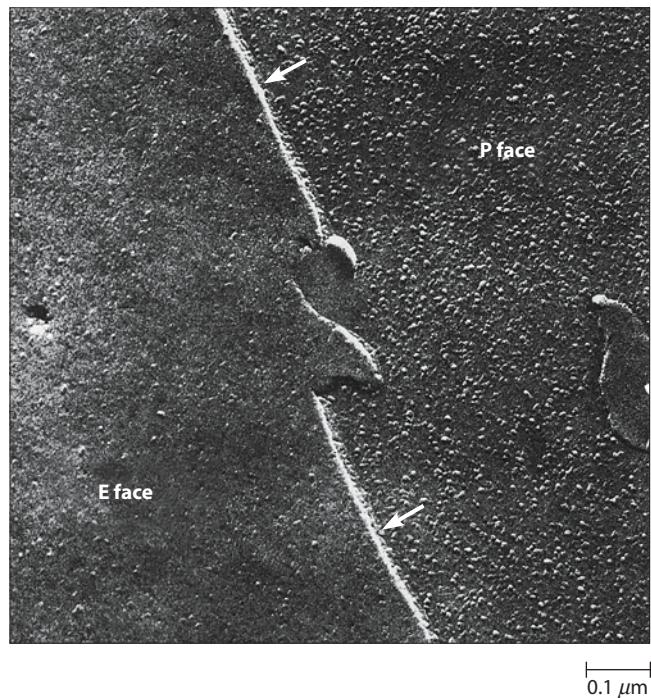

FIGURE A-35 Freeze Fracturing of the Plasma Membrane. This electron micrograph shows the exposed faces of the plasma membranes of two adjacent endocrine cells from a rat pancreas as revealed by freeze fracturing. The P face is the inner surface of the lipid monolayer on the protoplasmic side of the plasma membrane. The E face is the inner surface of the lipid monolayer on the exterior side of the plasma membrane. The P face is much more richly studded with intramembranous particles than the E face. The arrows indicate the “step” along which the fracture plane passed from the interior of the plasma membrane of one cell to the interior of the plasma membrane of a neighboring cell. The step therefore represents the thickness of the intercellular space (TEM).

cells by a “step” (marked by the arrows in Figure A-35) that represents the thickness of the intercellular space.

In a closely related technique called **freeze etching**, a further step is added to the conventional freeze-fracture procedure. Following the fracture of the specimen but prior to shadowing, the microtome arm is placed directly over the specimen for a short period of time (a few seconds to several minutes). This maneuver causes a small amount of water to evaporate (sublime) from the surface of the specimen to the cold knife surface, and this sublimation produces an *etching* effect—that is, an accentuation of surface detail. By using ultrarapid freezing techniques to minimize the formation of ice crystals during freezing, and by including a volatile cryoprotectant such as aqueous methanol, which sublimes very readily to a cold surface, the etching period can be extended and a deeper layer of ice can be removed, thereby exposing structures that are located deep within the cell interior. This modification, called **deep etching**, provides a fascinating look at cellular structure. Deep etching has been especially useful in exploring the cytoskeleton and examining its connections with other structures of the cell.

Stereo Electron Microscopy and 3-D Electron Tomography Allow Specimens to Be Viewed in Three Dimensions

Electron microscopists frequently want to visualize specimens in three dimensions. Shadowing, freeze fracturing, and scanning electron microscopy are useful for this purpose, as is another specialized technique called **stereo electron microscopy**. In stereo electron microscopy, three-dimensional information is obtained by photographing the same specimen at two slightly different angles. This is accomplished using a special specimen stage that can be tilted relative to the electron beam. The specimen is first tilted in one direction and photographed, then tilted an equal amount in the opposite direction and photographed again. The two micrographs are then mounted side by side as a *stereo pair*. When you view a stereo pair through a stereoscopic viewer, your brain uses the two independent images to construct a three-dimensional view that gives a striking sense of depth. **Figure A-36a** is a stereo pair of a *Drosophila* polytene chromosome imaged by high-voltage electron microscopy. Using a stereo viewer or allowing your eyes to fuse the two images visually creates a striking, three-dimensional view of the chromosome.

More recently, electron microscopists have used computer-based methods to make three-dimensional reconstructions of structures imaged in the TEM. In a process known as **3-D electron tomography**, serial thin sections containing a specimen are rotated and imaged at several different orientations; the resulting rotated views are then used to construct very thin, computer-generated “slices” of the specimen. Structures within these highly resolved slices can then be traced and reconstructed to provide three-dimensional information about the specimen. 3-D electron tomography has revolutionized our view of cellular structures, such as the organelles shown in

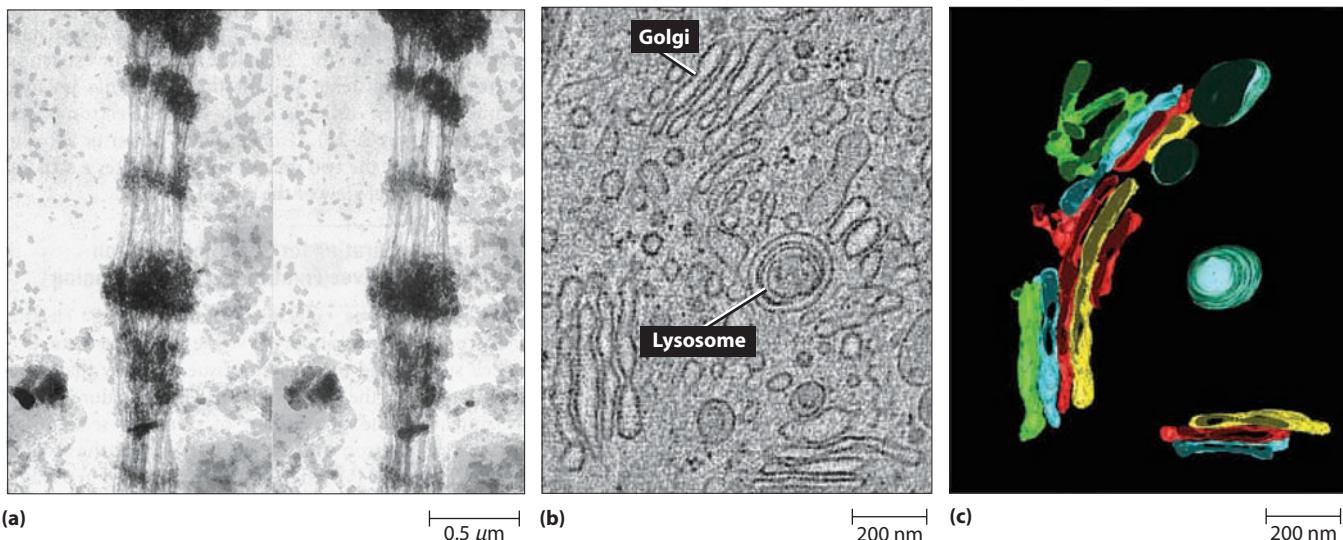

FIGURE A-36 Stereo Electron Microscopy and 3-D Electron Tomography. (a) The polytene chromosome in this micrograph is shown as a stereo pair. The two photographs were taken by tilting the specimen stage first 5° to the right and then 5° to the left of the electron beam. For a three-dimensional view, the stereo pair can be examined with a stereoscopic viewer. Alternatively, simply let your eyes cross slightly, fusing the two micrographs into a single image (HVEM). (b) A thin (3.2 nm) digital slice computed from a series of tilted images of a dendritic cell (TEM). A region of the Golgi apparatus and a lysosome are clearly visible. (c) A contour model of some of the structures visible in the tomogram shown in part b.

Figure A-36b, c, effectively extending the type of topographical data obtained by SEM to the level of TEM.

Specimen Preparation for Scanning Electron Microscopy Involves Fixation but Not Sectioning

When preparing a specimen for scanning electron microscopy, the biologist's goal is to preserve the structural features of the cell surface and to treat the tissue in a way that minimizes damage by the electron beam. The procedure is actually similar to preparing ultrathin sections for transmission electron microscopy but without the sectioning step. The tissue is fixed in aldehyde, post-fixed in osmium tetroxide, and dehydrated by processing through a series of alcohol solutions. The tissue is then placed in a fluid such as liquid carbon dioxide in a heavy metal canister called a **critical point dryer**, which is used to dry the specimen under conditions of controlled temperature and pressure. This helps keep structures on the surfaces of the tissue in almost the same condition as they were before dehydration.

The dried specimen is then attached to a metal specimen mount with a metallic paste. The mounted specimen is coated with a layer of gold or a mixture of gold and palladium, using a modified form of vacuum evaporation called **sputter coating**. Once the specimen has been mounted and coated, it is ready to be examined in the SEM.

Other Imaging Methods

Light and electron microscopy are direct imaging techniques in that they use photons or electrons to produce actual images of a specimen. However, some imaging

techniques are indirect. To understand what we mean by indirect imaging, suppose you are given an object to handle with your eyes closed. You might feel 6 flat surfaces, 12 edges, and 8 corners. If you then draw what you have felt, it would turn out to be a box. This is an example of an indirect imaging procedure.

The two indirect imaging methods we describe here are *scanning probe microscopy* and *X-ray crystallography*. Both approaches have the potential for showing molecular structures at near-atomic resolution, ten times better than the best electron microscope. They do have some shortcomings that limit their usefulness with biological specimens. But when these techniques can be applied successfully, the resulting images provide unique information about molecular structure that cannot be obtained using conventional microscopic techniques.

Scanning Probe Microscopy Reveals the Surface Features of Individual Molecules

Although “scanning” is involved in both scanning electron microscopy and scanning probe microscopy, the two methods are in fact quite different. The first example of a **scanning probe microscope**, called the *scanning tunneling microscope (STM)*, was developed in the early 1980s for the purpose of exploring the surface structure of specimens at the atomic level. The STM utilizes a tiny probe that does not emit an electron beam, but instead possesses a tip made of a conducting material such as platinum-iridium. The tip of the probe is extremely sharp; ideally, its point is composed of a single atom. It is under the precise control of an electronic circuit that can move it in three dimensions over a surface. The *x* and *y* dimensions scan

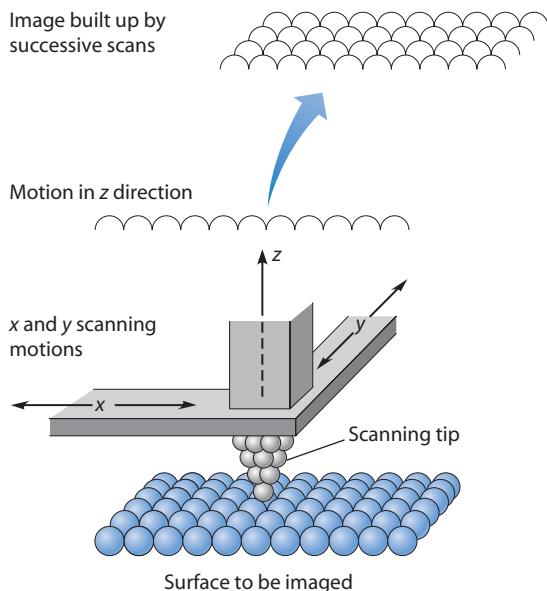

FIGURE A-37 Scanning Tunneling Microscopy. The scanning tunneling microscope (STM) uses electronic methods to move a metallic tip across the surface of a specimen. The tip is not drawn to scale in this illustration; the point of the tip is ideally composed of only one or a few atoms, shown here as balls. An electrical voltage is produced between the tip and the specimen surface. As the tip scans the specimen in the *x* and *y* directions, electron tunneling occurs at a rate dependent on the distance between the tip and the first layer of atoms in the surface. The instrument is designed to move the tip in the *z* direction to maintain a constant current flow. The movement is therefore a function of the tunneling current and is presented on a computer screen. Successive scans then build up an image of the surface at atomic resolution.

the surface, while the *z* dimension governs the distance of the tip above the surface (**Figure A-37**).

As the tip of the STM is moved across the surface of a specimen, voltages from a few millivolts to several volts are applied. If the tip is close enough to the surface and the surface is electrically conductive, electrons will begin to leak or “tunnel” across the gap between the probe and the sample. The tunneling is highly dependent on the distance, so that even small irregularities in the size range of single atoms will affect the rate of electron tunneling. As the probe scans the sample, the tip of the probe is automatically moved up and down to maintain a constant rate of electron tunneling across the gap. A computer measures this movement and uses the information to generate a map of the sample’s surface, which is viewed on a computer screen.

Despite the enormous power of the STM, it suffers from two limitations: The specimen must be an electrical conductor, and the technique provides information only about electrons associated with the specimen’s surface. Researchers have therefore begun to develop other kinds of scanning probe microscopes that scan a sample just like the STM but measure different kinds of interactions between the tip and the sample surface. For example, in the *atomic force microscope (AFM)*, the scanning tip is pushed right up against the surface of the sample. When it

scans, it moves up and down as it runs into the microscopic hills and valleys formed by the atoms present at the sample’s surface. A variety of scanning probe microscopes have been designed to detect other properties, such as friction, magnetic force, electrostatic force, van der Waals forces, heat, and sound.

One of the most important potential applications of scanning probe microscopy is the measurement of dynamic changes in the conformation of functioning biomolecules. Recently, it has become possible to visualize the movements of single myosin proteins as they change their shape during their power stroke. Such “molecular eavesdropping” is now entirely within the realm of possibility. It is even possible to use a modified form of atomic force microscopy to directly stretch large biomolecules to measure their mechanical properties.

X-Ray Crystallography Allows the Three-Dimensional Structure of Macromolecules to Be Determined

Though X-ray crystallography does not involve microscopy, it is such an important method for investigating the three-dimensional structure of individual molecules that we include it here. This method reconstructs images from the diffraction patterns of X-rays passing through a crystalline or fibrous specimen, thereby revealing molecular structure at the atomic level of resolution.

A good way to understand X-ray crystallography is to draw an analogy with visible light. As discussed earlier, light has certain properties that are best described as wavelike. If waves from two sources come into phase with one another, their total amplitude is additive (*constructive interference*); if they are out of phase, their amplitude is reduced (*destructive interference*). This effect can be seen when light passes through two pinholes in a piece of opaque material and then falls onto a white surface. Interference patterns result, with dark regions where light waves are out of phase and bright regions where they are in phase (**Figure A-38**). If the wavelength of the light (λ) is known, one can measure the angle α between the original beam and the first diffraction peak and then calculate the distance d between the two holes with the formula

$$d = \frac{\lambda}{\sin \alpha} \quad (\text{A-5})$$

The same approach can be used to calculate the distance between atoms in crystals or fibers of proteins and nucleic acids. Instead of a sheet of paper with two holes in it, imagine that we have multiple layers of atoms organized in a crystal or fiber. And instead of visible light, which has much too long a wavelength to interact with atoms, we will use a narrow beam of X-rays with wavelengths in the range of interatomic distances. As the X-rays pass through the specimen, they reflect off planes of atoms, and the reflected beams come into constructive and destructive interference. The reflected beams then fall onto photographic plates

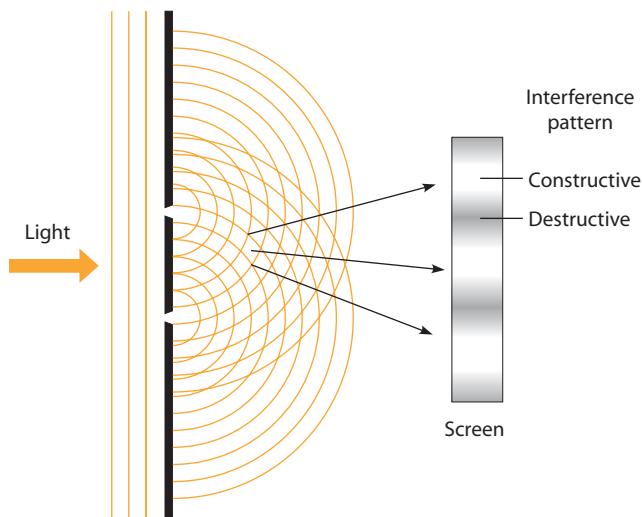

FIGURE A-38 Understanding Diffraction Patterns. Any energy in the form of waves will produce interference patterns if the waves from two or more sources are superimposed in space. One of the simplest patterns can be seen when monochromatic light passes through two neighboring pinholes and is allowed to fall on a screen. When the light passes through the two pinholes, the holes act as light sources, with waves radiating from each and falling on a white surface. Where the waves are in the same phase, a bright area appears (constructive interference). Where the waves are out of phase, they cancel each other out and produce dark areas (destructive interference).

behind the specimen, generating distinctive diffraction patterns. These patterns are then analyzed mathematically to deduce the three-dimensional structure of the original molecule. **Figure A-39** illustrates the use of this procedure to deduce the double-helical structure of DNA.

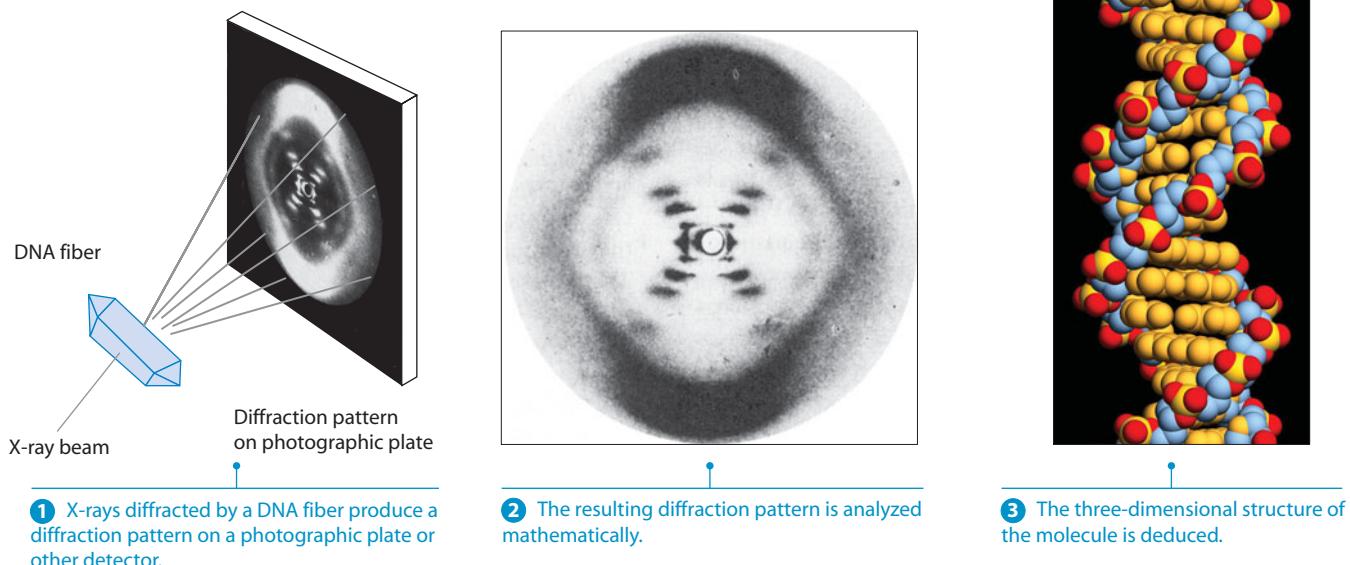

FIGURE A-39 X-Ray Crystallography. X-ray crystallography can be used to analyze molecular structure at near-atomic resolution. The specific example illustrated in this figure is a DNA fiber. The photograph in **2** depicts the actual X-ray diffraction pattern used by James Watson and Francis Crick to deduce the molecular structure of double-stranded DNA. The photograph in **3** is a computer graphic model of the DNA double helix.

The technique of X-ray diffraction was developed in 1912 by Sir William Bragg, who used it to establish the structures of relatively simple mineral crystals. Forty years later, Max Perutz and John Kendrew found ways to apply X-ray crystallography to crystals of hemoglobin and myoglobin, providing our first view of the intricacies of protein structure. Since then, many proteins and other biological molecules have been crystallized and analyzed by X-ray diffraction. Although membrane proteins are much more difficult to crystallize than the proteins typically analyzed by X-ray crystallography, Hartmut Michel and Johann Deisenhofer overcame this obstacle in 1985 by crystallizing the proteins of a bacterial photosynthetic reaction center. They then went on to describe the molecular organization of the reaction center at a resolution of 0.3 nm, an accomplishment that earned them a Nobel Prize.

CryoEM Bridges the Gap Between X-Ray Crystallography and Electron Microscopy

X-ray crystallography has provided unprecedented views of biological molecules down to the atomic level. However, crystallography requires large amounts of purified molecules. In addition, X-ray crystallography is not currently well suited for analyzing very large macromolecular assemblies, such as the ribosome (see Figure 22-1). For such large structures, another technique is needed. A technique that helps to bridge this gap is **cryoEM**. In cryoEM, purified molecules or macromolecular assemblies are rapidly frozen via

cryofixation. The rapid freezing prevents ice crystals from forming. Instead, the molecules are embedded in *vitreous ice*, noncrystalline frozen water, which better preserves the structures of the embedded molecules. The sample is then directly imaged at a very low temperature (-170°C) in an electron microscope. Often the specimens are imaged using three-dimensional electron tomography. To see how cryoEM can work together with X-ray crystallography, consider **Figure A-40**, in which a cryoEM image of the 30S and 50S ribosomal subunits and a releasing factor protein known as RF2 have been combined with a detailed structure of RF2 obtained from X-ray data. By using the two techniques together, cell biologists can see how the structure of the protein enables it to fit neatly within the overall structure of the ribosome to perform its function.

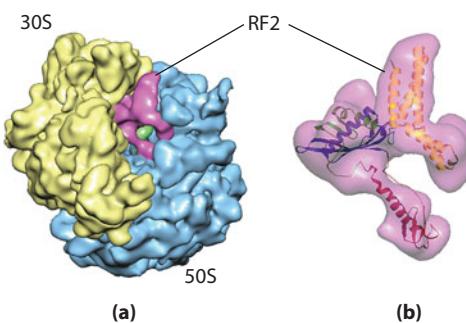

FIGURE A-40 CryoEM Bridges the Gap Between the Atomic and Molecular Levels. (a) A three-dimensional reconstruction of the 30S (yellow) and 50S (blue) ribosomal subunits bound to a releasing factor (RF2, in pink) obtained via cryoEM. X-ray crystallography provides a more detailed view of RF2 (b). Adapted by permission from Macmillan Publishers Ltd: *Nature*. From Urmila B. S. Rawat et al., "A Cryo-Electron Microscopic Study of Ribosome-Bound Termination factor RF2," (2 January 2003), 421: 87-90, Copyright 2003.

GLOSSARY

Note: The letter “A” preceding a page number refers to a page in the *Appendix: Visualizing Cells and Molecules*.

A

A: see *adenine*.

A band: region of a striated muscle myofibril that appears as a dark band when viewed by microscopy; contains thick myosin filaments and those regions of the thin actin filaments that overlap the thick filaments. (p. 461)

A site (aminoacyl site): site on the ribosome that binds each newly arriving tRNA with its attached amino acid. (p. 680)

A tubule: a complete microtubule that is fused to an incomplete microtubule (the B tubule) to make up an outer doublet in the axoneme of a eukaryotic cilium or flagellum. (p. 455)

ABC transporter: see *ABC-type ATPase*.

ABC-type ATPase: type of transport ATPase characterized by an “ATP-binding cassette” (hence the “ABC”), with the term *cassette* used to describe catalytic domains of the protein that bind ATP as an integral part of the transport process; also called ABC transporters. (p. 211) Also see *multidrug resistance transport protein*.

absolute refractory period: brief time during which the sodium channels of a nerve cell are inactivated and cannot be opened by depolarization. (p. 377)

absorption spectrum (plural, spectra): relative extent to which light of different wavelengths is absorbed by a pigment. (p. 297)

accelerating voltage: difference in voltage between the cathode and anode of an electron microscope, responsible for accelerating electrons prior to their emission from the electron gun. (p. A-18)

accessory pigments: molecules such as carotenoids and phycobilins that confer enhanced light-gathering properties on photosynthetic tissue by absorbing light of wavelengths not absorbed by chlorophyll; accessory pigments give distinctive colors to plant tissue, depending on their specific absorption properties. (p. 300)

acetyl CoA: high-energy, two-carbon compound generated by glycolysis and fatty acid oxidation; employed for transferring carbon atoms to the tricarboxylic acid cycle. (p. 259)

acetylcholine: the most common excitatory neurotransmitter used at synapses between neurons outside the central nervous system. (p. 383)

actin: principal protein of the microfilaments found in the cytoskeleton of nonmuscle cells and in the thin filaments of skeletal muscle; synthesized as a globular monomer (G-actin) that polymerizes into long, linear filaments (F-actin). (p. 434)

actin-binding proteins: proteins that bind to actin microfilaments, thereby regulating the length or assembly of microfilaments or mediating their association with each other or with other cellular structures, such as the plasma membrane. (p. 437)

action potential: brief change in membrane potential involving an initial depolarization followed by a rapid return to the normal resting potential; caused by the inward movement of Na^+ followed by the subsequent outward movement of K^+ ; serves as the means of transmission of a nerve impulse. (p. 375)

activated monomer: a monomer whose free energy has been increased by being linked to a carrier molecule. (p. 31)

activation domain: region of a transcription factor, distinct from the DNA-binding domain, that is responsible for activating transcription. (p. 738)

activation energy (E_A): energy required to initiate a chemical reaction. (p. 130)

activator (transcription): regulatory protein whose binding to DNA leads to an increase in the transcription rate of specific nearby genes. (p. 735)

active site: region of an enzyme molecule at which the substrate binds and the catalytic event occurs; also called the catalytic site. (p. 132)

active transport: membrane protein-mediated movement of a substance across a membrane against a concentration or electrochemical gradient; an energy-requiring process. (p. 208)

active zone: region of the presynaptic membrane of an axon where neurosecretory vesicles dock. (p. 385)

adaptor protein (AP): protein found along with clathrin in the coats of clathrin-coated vesicles. (p. 349)

adenine (A): nitrogen-containing aromatic base, chemically designated as a purine, that serves as an informational monomeric unit when present in nucleic acids with other bases in a specific sequence; forms a complementary base pair with thymine (T) or uracil (U) by hydrogen bonding. (p. 55)

adenosine diphosphate (ADP): adenosine with two phosphates linked to each other by a phosphoanhydride bond and to the 5' carbon of the ribose by a phosphoester bond. (p. 55)

adenosine monophosphate (AMP): adenosine with a phosphate linked to the 5' carbon of ribose by a phosphoester bond. (p. 55)

adenosine triphosphate (ATP): adenosine with three phosphates linked to each other by phosphoanhydride bonds and to the 5' carbon of the ribose by a phosphoester bond; principal energy storage compound of most cells, with energy stored in the high-energy phosphoanhydride bonds. (pp. 55, 225)

adenylyl cyclase: enzyme that catalyzes the formation of cyclic AMP from ATP; located on the inner surface of the plasma membrane of

many eukaryotic cells and activated by specific ligand-receptor interactions on the outer surface of the membrane. (p. 398)

adherens junction: junction for cell-cell adhesion that is connected to the cytoskeleton by actin microfilaments. (p. 482)

adhesive (anchoring) junction: type of cell junction that links the cytoskeleton of one cell either to the cytoskeleton of neighboring cells or to the extracellular matrix; examples include desmosomes, hemidesmosomes, and adherens junctions. (p. 482)

ADP: see *adenosine diphosphate*.

ADP ribosylation factor (ARF): a protein associated with COPI in the “fuzzy” coats of COPI-coated vesicles. (p. 350)

adrenergic hormone: epinephrine or norepinephrine. (p. 415)

adrenergic receptor: any of a family of G protein-linked receptors that bind to one or both of the adrenergic hormones, epinephrine and norepinephrine. (p. 416)

adrenergic synapse: a synapse that uses norepinephrine or epinephrine as the neurotransmitter. (p. 383)

aerobic respiration: exergonic process by which cells oxidize glucose to carbon dioxide and water using oxygen as the ultimate electron acceptor, with a significant portion of the released energy conserved as ATP. (p. 252)

agonist: substance that binds to a receptor and activates it. (p. 394)

Akt: protein kinase involved in the PI3K-Akt pathway; catalyzes the phosphorylation of several target proteins that suppress apoptosis and inhibit cell cycle arrest. (p. 417)

alcoholic fermentation: anaerobic catabolism of carbohydrates with ethanol and carbon dioxide as the end products. (p. 237)

allele: one of two or more alternative forms of a gene. (p. 601)

allosteric activator: a small molecule whose binding to an enzyme's allosteric site shifts the equilibrium to favor the high-affinity state of the enzyme. (p. 147)

allosteric effector: small molecule that causes a change in the state of an allosteric protein by binding to a site other than the active site. (p. 147)

allosteric enzyme: an enzyme exhibiting two alternative forms, each with a different biological property; interconversion of the two states is mediated by the reversible binding of a specific small molecule (allosteric effector) to a regulatory site called the allosteric site. (p. 147)

allosteric inhibitor: a small molecule whose binding to an enzyme's allosteric site shifts the equilibrium to favor the low-affinity state of the enzyme. (p. 147)

allosteric regulation: control of a reaction pathway by the effector-mediated reversible

- interconversion of the two forms of an allosteric enzyme. (pp. 147, 241, 263)
- allosteric (regulatory) site:** region of a protein molecule that is distinct from the active site at which the catalytic event occurs and that binds selectively to a small molecule, thereby regulating the protein's activity. (p. 147)
- alpha beta heterodimer ($\alpha\beta$ -heterodimer):** protein dimer composed of one α -tubulin molecule and one β -tubulin molecule that forms the basic building block of microtubules. (p. 426)
- alpha helix (α helix):** spiral-shaped secondary structure of protein molecules, consisting of a backbone of peptide bonds with R groups of amino acids jutting out. (p. 48)
- alpha tubulin (α -tubulin):** protein that joins with β -tubulin to form a heterodimer that is the basic building block of microtubules. (p. 426)
- alternating conformation model:** membrane transport model in which a carrier protein alternates between two conformational states, such that the solute-binding site of the protein is open or accessible first to one side of the membrane and then to the other. (p. 202)
- alternation of generations:** occurrence of alternating haploid and diploid multicellular forms within the life cycle of an organism. (p. 603)
- alternative splicing:** utilization of different combinations of intron/exon splice junctions in pre-mRNA to produce messenger RNAs that differ in exon composition, thereby allowing production of more than one type of polypeptide from the same gene. (pp. 673, 745)
- Ames test:** screening test for potential carcinogens that assesses whether a substance causes mutations in bacteria. (p. 767)
- amino acid:** monomeric unit of proteins, consisting of a carboxylic acid with an amino group and one of a variety of R groups attached to the α carbon; 20 different kinds of amino acids are normally found in proteins. (p. 41)
- amino terminus:** see *N-terminus*.
- aminoacyl site:** see *A site*.
- aminoacyl tRNA:** a tRNA molecule containing an amino acid attached to its 3' end. (p. 681)
- aminoacyl-tRNA synthetase:** enzyme that joins an amino acid to its appropriate tRNA molecule using energy provided by the hydrolysis of ATP. (p. 682)
- amoeboid movement:** mode of cell locomotion that depends on pseudopodia and involves cycles of gelation and solation of the actin cytoskeleton. (p. 473)
- AMP:** see *adenosine monophosphate*.
- amphibolic pathway:** series of reactions that can function both in a catabolic mode and as a source of precursors for anabolic pathways. (p. 266)
- amphipathic molecule:** molecule having spatially separated hydrophilic and hydrophobic regions. (p. 25)
- amylopectin:** branched-chain form of starch consisting of repeating glucose subunits linked together by $\alpha(1 \rightarrow 4)$ glycosidic bonds, with occasional $\alpha(1 \rightarrow 6)$ linkages creating branches every 12 to 25 units that commonly consist of 20 to 25 glucose units. (p. 63)
- amylose:** straight-chain form of starch consisting of repeating glucose subunits linked together by $\alpha(1 \rightarrow 4)$ glycosidic bonds. (p. 63)
- anabolic pathway:** series of reactions that results in the synthesis of cellular components. (p. 224)
- aerobic respiration:** cellular respiration in which the ultimate electron acceptor is a molecule other than oxygen. (p. 252)
- anaphase:** stage during mitosis (or meiosis) when the sister chromatids (or homologous chromo-
- somes) separate and move to opposite spindle poles. (p. 573)
- anaphase A:** movement of sister chromatids toward opposite spindle poles during anaphase. (p. 573)
- anaphase B:** movement of the spindle poles away from each other during anaphase. (p. 574)
- anaphase-promoting complex:** large multiprotein complex that targets selected proteins (e.g., securin and mitotic cyclin) for degradation, thereby initiating anaphase and the subsequent completion of mitosis. (p. 585)
- anchorage-dependent growth:** requirement that cells be attached to a solid surface such as the extracellular matrix before they can grow and divide. (p. 497)
- anchorage-independent growth:** a trait exhibited by cancer cells, which grow well not just when they are attached to a solid surface, but also when they are freely suspended in a liquid or semisolid medium. (p. 760)
- anchoring junction:** see *adhesive junction*.
- aneuploidy:** abnormal state in which a cell possesses an incorrect number of chromosomes. (p. 587)
- angiogenesis:** growth of new blood vessels. (p. 761)
- angular aperture:** half-angle of the cone of light entering the objective lens of a microscope from the specimen. (p. A-3)
- anion exchange protein:** antiport carrier protein that facilitates the reciprocal exchange of chloride and bicarbonate ions across the plasma membrane. (p. 204)
- anoxygenic phototroph:** a photosynthetic organism that uses an oxidizable substrate other than water as the electron donor in photosynthetic electron transduction. (p. 295)
- antagonist:** substance that binds to a receptor and prevents it from being activated. (p. 394)
- antenna pigment:** light-absorbing molecule of a photosystem that absorbs photons and passes the energy to a neighboring chlorophyll molecule or accessory pigment by resonance energy transfer. (p. 301)
- anterograde transport:** movement of material from the ER through the Golgi complex toward the plasma membrane. (p. 334)
- antibody:** class of proteins produced by lymphocytes that bind with extraordinary specificity to substances, referred to as antigens, that provoke an immune response. (p. 789)
- anticodon:** triplet of nucleotides located in one of the loops of a tRNA molecule that recognizes the appropriate codon in mRNA by complementary base pairing. (p. 681)
- antigen:** a foreign or abnormal substance that can trigger an immune response. (p. 789)
- antiport:** coupled transport of two solutes across a membrane in opposite directions. (p. 203)
- AP:** see *adaptor protein*.
- APC gene:** a tumor suppressor gene, frequently mutated in colon cancers, that codes for a protein involved in the Wnt pathway. (p. 780)
- apoptosis:** cell suicide mediated by a group of protein-degrading enzymes called caspases; involves a programmed series of events that leads to the dismantling of the internal contents of the cell. (p. 592)
- AQP:** see *aquaporin*.
- aquaporin (AQP):** any of a family of membrane channel proteins that facilitate the rapid movement of water molecules into or out of cells in tissues that require this capability, such as the proximal tubules of the kidneys. (p. 208)
- archaea:** one of the two groups of prokaryotes, the other being bacteria; many archaea thrive under harsh conditions, such as salty, acidic, or hot environments, that would be fatal to most other organisms. (p. 75) Also see *bacteria*.
- ARF:** see *ADP ribosylation factor*.
- Arp2/3 complex:** complex of actin-related proteins that allows actin monomers to polymerize as new "branches" on the sides of existing microfilaments. (p. 439)
- asexual reproduction:** form of reproduction in which a single parent is the only contributor of genetic information to the new organism. (p. 600)
- assisted self-assembly:** folding and assembly of proteins and protein-containing structures in which the appropriate molecular chaperone is required to ensure that correct assembly will predominate over incorrect assembly. (p. 34)
- astral microtubule:** type of microtubule that forms asters, which are dense starbursts of microtubules that radiate in all directions from each spindle pole. (p. 573)
- asymmetric carbon atom:** carbon atom that has four different substituents. Two different stereoisomers are possible for each asymmetric carbon atom in an organic molecule. (p. 21)
- ATP:** see *adenosine triphosphate*.
- ATP synthase:** alternative name for an F-type ATPase when it catalyzes the reverse process in which the exergonic flow of protons down their electrochemical gradient is used to drive ATP synthesis; examples include the CF_0CF_1 complex found in chloroplast thylakoid membranes, and the F_0F_1 complex found in mitochondrial inner membranes and bacterial plasma membranes. (pp. 211, 280, 307)
- attenuation:** mechanism for regulating bacterial gene expression based on the premature termination of transcription. (p. 719)
- autophagic lysosome:** mature lysosome containing hydrolytic enzymes involved in the digestion of materials of intracellular origin. (p. 354) Also see *heterophagic lysosome*.
- autophagic vacuole (autophagosome):** vacuole formed when an old or unwanted organelle or other cellular structure is wrapped in membranes derived from the endoplasmic reticulum prior to digestion by lysosomal enzymes. (p. 354)
- autophagosome:** see *autophagic vacuole*.
- autophagy:** intracellular digestion of old or unwanted organelles or other cell structures as it occurs within autophagic lysosomes; "self-eating." (p. 354)
- autophosphorylation:** phosphorylation of a receptor molecule by a receptor molecule of the same type. (p. 408)
- autoradiography:** procedure for detecting the location of radioactive molecules by overlaying a sample with photographic film, which becomes darkened upon exposure to radioactivity. (p. 519)
- axon:** extension of a nerve cell that conducts impulses away from the cell body. (p. 366)
- axon hillock:** region at the base of an axon where action potentials are initiated most easily. (p. 378)
- axonal transport:** see *fast axonal transport*.
- axonomal dynein:** motor protein in the axonemes of cilia and flagella that generates axonomal motility by moving along the surface of microtubules driven by energy derived from ATP hydrolysis. (p. 452)
- axonomal microtubules:** microtubules present in highly ordered bundles in the axonemes of eukaryotic cilia and flagella. (p. 424)
- axoneme:** group of interconnected microtubules that form the backbone of a eukaryotic cilium

or flagellum, usually arranged as nine outer doublet microtubules surrounding a pair of central microtubules. (p. 454)

axoplasm: cytoplasm within the axon of a nerve cell. (p. 366)

B

B tubule: an incomplete microtubule that is fused to a complete microtubule (the A tubule) to make up an outer doublet in the axoneme of a eukaryotic cilium or flagellum. (p. 455)

BAC: see *bacterial artificial chromosome*.

backcrossing: process in a genetic breeding experiment in which a heterozygote is cross-fertilized with one of the original homozygous parental organisms. (p. 613)

bacteria (singular, bacterium): one of the two groups of prokaryotes, the other being archaea; include most of the commonly encountered single-celled organisms with no nucleus that have traditionally been called bacteria. (p. 75)
Also see *archaea*.

bacterial artificial chromosome (BAC): bacterial cloning vector derived from the F-factor plasmid that is useful in cloning large DNA fragments. (p. 634)

bacterial chromosome: circular (or linear) DNA molecule with bound proteins that contains the main genome of a bacterial cell. (p. 529)

bacteriochlorophyll: type of chlorophyll found in bacteria that is able to extract electrons from donors other than water. (p. 299)

bacteriophage (phage): virus that infects bacterial cells. (p. 507)

bacteriorhodopsin: transmembrane protein complexed with rhodopsin, capable of transporting protons across the bacterial cell membrane to create a light-dependent electrochemical proton gradient. (p. 215)

basal body: microtubule-containing structure located at the base of a eukaryotic flagellum or cilium that consists of nine sets of triplet microtubules; identical in appearance to a centriole. (p. 454)

basal lamina: thin sheet of specialized extracellular matrix material that separates epithelial cells from underlying connective tissues. (p. 493)

base excision repair: DNA repair mechanism that removes and replaces single damaged bases in DNA. (p. 568)

base pair (bp): pair of nucleotides joined together by complementary hydrogen bonding. (p. 517)

base pairing: complementary relationship between purines and pyrimidines based on hydrogen bonding that provides a mechanism for nucleic acids to recognize and bind to each other; involves the pairing of A with T or U, and the pairing of G with C. (p. 59)

Bcl-2: protein located in the outer mitochondrial membrane that blocks cell death by apoptosis. (p. 594)

benign tumor: tumor that grows only locally, unable to invade neighboring tissues or spread to other parts of the body. (p. 759)

beta oxidation (β oxidation): pathway involving successive cycles of fatty acid oxidation in which the fatty acid chain is shortened each time by two carbon atoms released as acetyl CoA. (p. 265)

beta sheet (β sheet): extended sheetlike secondary structure of proteins in which adjacent polypeptides are linked by hydrogen bonds between amino and carbonyl groups. (p. 48)

beta tubulin (β -tubulin): protein that joins with α -tubulin to form a heterodimer that is the basic building block of microtubules. (p. 426)

bimetallic iron-copper (Fe-Cu) center: a complex formed between a single copper atom and the iron atom bound to the heme group of an oxygen-binding cytochrome such as cytochrome a_3 ; important in keeping an O_2 molecule bound to the cytochrome until it picks up four electrons and four protons, resulting in the release of two molecules of water. (p. 270)

binding change model: a mechanism involving the physical rotation of the γ subunit of an $F_o F_1$ ATP synthase postulated to explain how the exergonic flow of protons through the F_o component of the complex drives the otherwise endergonic phosphorylation of ADP to ATP by the F_1 component. (p. 282)

biochemistry: study of the chemistry of living systems; same as biological chemistry. (p. 3)

bioenergetics: area of science that deals with the application of thermodynamic principles to reactions and processes in the biological world. (p. 111)

bioinformatics: using computers to analyze the vast amounts of data generated by sequencing and expression studies on genomes and proteomes. (pp. 11, 523)

biological chemistry: study of the chemistry of living systems; called biochemistry for short. (p. 19)

bioluminescence: production of light by an organism as a result of the reaction of ATP with specific luminescent compounds. (p. 108)

biosynthesis: generation of new molecules through a series of chemical reactions within the cell. (p. 107)

BiP: member of the Hsp70 family of chaperones; present in the ER lumen, where it facilitates protein folding by reversibly binding to the hydrophobic regions of polypeptide chains. (p. 699)

bivalent: pair of homologous chromosomes that have synapsed during the first meiotic division; contains four chromatids, two from each chromosome. (p. 604)

BLAST (Basic Local Alignment Search Tool): software program that can search databases and locate DNA or protein sequences that resemble any known sequence of interest. (p. 524)

bond energy: amount of energy required to break one mole of a particular chemical bond. (p. 19)

bp: see *base pair*.

BRCA1 and BRCA2 genes: tumor suppressor genes in which inheritance of a single mutant copy creates a high risk for breast and ovarian cancer; code for proteins involved in repairing double-strand DNA breaks. (p. 781)

BRE (TFIIB recognition element): component of core promoters for RNA polymerase II, located immediately upstream from the TATA box. (p. 662)

brightfield microscopy: light microscopy of specimen that possesses color, has been stained, or has some other property that affects the amount of light that passes through, thereby allowing an image to be formed. (p. A-6)

bundle sheath cell: internal cell of the leaf of a C_4 plant located in close proximity to the vascular bundle (vein) of the leaf; site of the Calvin cycle in such plants. (p. 317)

buoyant density centrifugation: see *equilibrium density centrifugation*.

Burkitt lymphoma: a lymphocyte cancer associated with infection by Epstein-Barr virus along with a chromosome translocation in which the MYC gene is activated by moving it from chromosome 8 to 14. (p. 771)

C

C: see *cytosine*.

C value: amount of DNA in a single (haploid) set of chromosomes. (p. 609)

C_3 plant: plant that depends solely on the Calvin cycle for carbon dioxide fixation, creating the three-carbon compound 3-phosphoglycerate as the initial product. (p. 317)

C_4 plant: plant that uses the Hatch-Slack pathway in mesophyll cells to carry out the initial fixation of carbon dioxide, creating the four-carbon compound oxaloacetate; the assimilated carbon is subsequently released again in bundle sheath cells and recaptured by the Calvin cycle. (p. 317)

cadherin: any of a family of plasma membrane glycoproteins that mediate Ca^{2+} -dependent adhesion between cells. (p. 479)

cal: see *calorie*.

calcium ATPase: membrane protein that transports calcium ions across a membrane using energy derived from ATP hydrolysis; prominent example occurs in the sarcoplasmic reticulum (SR), where it pumps calcium ions into the SR lumen. (pp. 403, 468)

calcium indicator: a dye or genetically engineered protein whose fluorescence changes in response to the local cytosolic calcium concentration. (p. 402)

calcium ionophore: a molecule that increases the permeability of membranes to calcium ions. (p. 402)

calmodulin: calcium-binding protein involved in mediating many of the intracellular effects of calcium ions in eukaryotic cells. (p. 404)

calnexin: a membrane-bound ER protein that forms a protein complex with a newly synthesized glycoprotein and assists in its proper folding. (p. 334)

calorie (cal): unit of energy; amount of energy needed to raise the temperature of 1 gram of water 1°C. (pp. 20, 112)

calreticulin: a soluble ER protein that forms a protein complex with a newly synthesized glycoprotein and assists in its proper folding. (p. 334)

Calvin cycle: cyclic series of reactions used by photosynthetic organisms for the fixation of carbon dioxide and its reduction to form carbohydrates. (p. 309)

CAM: see *crassulacean acid metabolism*.

CAM plant: plant that carries out crassulacean acid metabolism. (p. 320)

cAMP: see *cyclic AMP*.

cancer: uncontrolled, growing mass of cells that is capable of invading neighboring tissues and spreading via body fluids, especially the bloodstream, to other parts of the body; also called a *malignant tumor*. (p. 759)

CAP: see *catabolite activator protein*.

cap (5' cap): methylated structure at the 5' end of eukaryotic mRNAs created by adding 7-methylguanosine and methylating the ribose rings of the first, and often the second, nucleotides of the RNA chain. (p. 668)

capping protein: protein that binds to the end of an actin microfilament, thereby preventing the further addition or loss of subunits. (p. 437)

carbohydrate: general name given to molecules that contain carbon, hydrogen, and oxygen in a ratio $C_n(H_2O)_n$; examples include starch, glycogen, and cellulose. (p. 62)

carbon assimilation reactions: portion of the photosynthetic pathway in which fully oxidized carbon atoms from carbon dioxide are fixed (covalently attached) to organic acceptor molecules and then reduced and rearranged to form

- carbohydrates** and other organic compounds required for building a living cell. (p. 293)
- carbon atom**: the most important atom in biological molecules, capable of forming up to four covalent bonds. (p. 19)
- carboxyl terminus**: see *C-terminus*.
- carcinogen**: any cancer-causing agent. (p. 767)
- carcinoma**: a malignant tumor (cancer) arising from the epithelial cells that cover external and internal body surfaces. (p. 758)
- cardiac (heart) muscle**: striated muscle of the heart, highly dependent on aerobic respiration. (p. 468)
- caretaker gene**: a tumor suppressor gene involved in DNA repair or chromosome sorting; loss-of-function mutations in such genes contribute to genetic instability. (p. 782)
- carotenoid**: any of several accessory pigments found in most plant species that absorb in the blue region of the visible spectrum (420–480 nm) and are therefore yellow or orange in color. (p. 300)
- carrier molecule**: a molecule that joins to a monomer, thereby activating the monomer for a subsequent reaction. (p. 31)
- carrier protein**: membrane protein that transports solutes across the membrane by binding to the solute on one side of the membrane and then undergoing a conformational change that transfers the solute to the other side of the membrane. (p. 202)
- caspase**: any of a family of proteases that degrade other cellular proteins as part of the process of apoptosis. (p. 593)
- cassette mechanism**: process of DNA rearrangement in which alternative alleles for yeast mating type are inserted into the *MAT* locus for transcription. (p. 726)
- catabolic pathway**: series of reactions that results in the breakdown of cellular components. (p. 224)
- catabolite activator protein (CAP)**: bacterial protein that binds cyclic AMP and then activates the transcription of catabolite-repressible genes. (p. 716)
- catalyst**: agent that enhances the rate of a reaction by lowering the activation energy without itself being consumed; catalysts change the rate at which a reaction approaches equilibrium, but not the position of equilibrium. (p. 131)
- catalytic subunit**: a subunit of a multisubunit enzyme that contains the enzyme's catalytic site. (p. 147)
- catecholamine**: any of several compounds derived from the amino acid tyrosine that functions as a hormone and/or neurotransmitter. (p. 383)
- caveolae**: small invaginations of the plasma membrane that are coated with the protein caveolin; a type of lipid raft enriched in cholesterol that may be involved in cholesterol uptake or signal transduction. (p. 348)
- CBP**: transcriptional coactivator that exhibits histone acetyltransferase activity and associates with RNA polymerase to facilitate assembly of the transcription machinery at gene promoters. (p. 742)
- Cdc42**: member of a family of monomeric G proteins, which also includes Rac and Rho, that stimulate formation of various actin-containing structures within cells. (p. 440)
- Cdk**: see *cyclin-dependent kinase*.
- Cdk inhibitor**: any of several proteins that restrain cell growth and division by inhibiting Cdk-cyclin complexes. (p. 519)
- cDNA**: see *complementary DNA*.
- cDNA library**: collection of recombinant DNA clones produced by copying the entire mRNA population of a particular cell type with reverse transcriptase and then cloning the resulting cDNAs. (p. 633)
- cell**: the basic structural and functional unit of living organisms; the smallest structure capable of performing the essential functions characteristic of life. (p. 1)
- cell body**: portion of a nerve cell that contains the nucleus and other organelles and has extensions called axons and dendrites projecting from it. (p. 366)
- cell-cell junction**: specialized connection between the plasma membranes of adjoining cells for the purpose of adhesion, sealing, or communication. (p. 481)
- cell cycle**: stages involved in preparing for and carrying out cell division; begins when two new cells are formed by the division of a single parental cell and is completed when one of these cells divides again into two cells. (p. 549)
- cell differentiation**: process by which cells acquire the specialized properties that distinguish different types of cells from each other. (p. 722)
- cell division**: process by which one cell gives rise to two. (p. 549)
- cell membrane**: see *plasma membrane*.
- cell plate**: flattened sac representing a stage in plant cell wall formation, leading to separation of the two daughter nuclei during plant cell division. (p. 579)
- cell theory**: theory of cellular organization stating that all organisms consist of one or more cells, that the cell is the basic unit of structure for all organisms, and that all cells arise only from preexisting cells. (p. 2)
- cell wall**: rigid, nonliving structure exterior to the plasma membrane of bacterial, algal, fungal, and plant cells; plant cell walls consist of cellulose microfibrils embedded in a noncellulosic matrix. (pp. 98, 498)
- cellular respiration**: oxidation-driven flow of electrons from reduced coenzymes to an electron acceptor, usually accompanied by the generation of ATP. (p. 252)
- cellulose**: structural polysaccharide present in plant cell walls, consisting of repeating glucose units linked by $\beta(1 \rightarrow 4)$ bonds. (pp. 65, 498)
- central pair**: two parallel microtubules located in the center of the axoneme of a eukaryotic cilium or flagellum. (p. 454)
- central vacuole**: large membrane-bounded organelle present in many plant cells; helps maintain turgor pressure of the plant cell, plays a limited storage role, and is also capable of a lysosome-like function in intracellular digestion. (p. 93)
- centrifugation**: process of rapidly spinning a tube containing a fluid to subject its contents to a centrifugal force. (p. 327)
- centrifuge**: machine for rapidly spinning a tube containing a fluid to subject its contents to a centrifugal force. (p. 327)
- centriole**: structure consisting of nine sets of triplet microtubules embedded within the centrosome of animal cells, where two centrioles lie at right angles to each other; identical in structure to the basal body of eukaryotic cilia and flagella. (p. 430)
- centromere**: chromosome region where sister chromatids are held together prior to anaphase and where kinetochores are attached; contains simple-sequence, tandemly repeated DNA. (pp. 526, 573)
- centrosome**: small zone of granular material surrounding two centrioles located adjacent to the nucleus of animal cells; functions as a cell's main microtubule-organizing center. (pp. 430, 572)
- cerebroside**: an uncharged glycolipid containing the amino alcohol sphingosine. (p. 163)
- CF**: see *cystic fibrosis*.
- CF₁**: component of the chloroplast ATP synthase complex that protrudes from the stromal side of thylakoid membranes and contains the catalytic site for ATP synthesis. (p. 307)
- CF_o**: component of the chloroplast ATP synthase complex that is embedded in thylakoid membranes and serves as the proton translocator. (p. 307)
- CF_oCF₁ complex**: ATP synthase complex found in chloroplast thylakoid membranes; catalyzes the process by which the exergonic flow of protons down their electrochemical gradient is used to drive ATP synthesis. (p. 307)
- CFTR**: see *cystic fibrosis transmembrane conductance regulator*.
- CGN**: see *cis-Golgi network*.
- channel gating**: closing of a membrane ion channel in such a way that it can reopen immediately in response to an appropriate stimulus. (p. 374)
- channel inactivation**: closing of a membrane ion channel in such a way that it cannot reopen immediately. (p. 374)
- channel protein**: membrane protein that forms a hydrophilic channel through which solutes can pass across the membrane without any change in the conformation of the channel protein. (p. 202)
- chaperone**: see *molecular chaperone*.
- Chargaff's rules**: observation, first made by Erwin Chargaff, that in DNA the number of adenines is equal to the number of thymines ($A = T$) and the number of guanines is equal to the number of cytosines ($G = C$). (p. 510)
- charge repulsion**: force driving apart two ions, molecules, or regions of molecules of the same electric charge. (p. 226)
- checkpoint**: pathway that monitors conditions within the cell and transiently halts the cell cycle if conditions are not suitable for continuing. (p. 587) Also see *DNA damage checkpoint*, *DNA replication checkpoint*, and *mitotic spindle checkpoint*.
- chemical synapse**: junction between two nerve cells where a nerve impulse is transmitted between the cells by neurotransmitters that diffuse across the synaptic cleft from the presynaptic cell to the postsynaptic cell. (p. 381)
- chemiosmotic coupling model**: model postulating that electron transport pathways establish proton gradients across membranes and that the energy stored in such gradients can then be used to drive ATP synthesis. (p. 277)
- chemotaxis**: cell movement toward a chemical attractant or away from a chemical repellent. (p. 472)
- chemotroph**: organism that is dependent on the bond energies of organic molecules such as carbohydrates, fats, and proteins to satisfy energy requirements. (p. 109)
- chemotrophic energy metabolism**: reactions and pathways by which cells catabolize nutrients such as carbohydrates, fats, and proteins, conserving as ATP some of the free energy that is released in the process. (p. 229)
- chiasma** (plural, **chiasmata**): connection between homologous chromosomes produced by crossing over during prophase I of meiosis. (p. 605)
- chitin**: structural polysaccharide found in insect exoskeletons and crustacean cells; consists of N-acetylglucosamine units linked by $\beta(1 \rightarrow 4)$ bonds. (p. 65)

- chlorophyll:** light-absorbing molecule that donates photoenergized electrons to organic molecules, initiating photochemical events that lead to the generation of the NADPH and ATP required for the Calvin cycle; because of its absorption properties, chlorophyll gives plants their characteristic green color. (p. 298)
- chlorophyll-binding protein:** any of several proteins that bind to and stabilize the arrangement of chlorophyll molecules within a photosystem. (p. 300)
- chloroplast:** double membrane-enclosed cytoplasmic organelle of plants and algae that contains chlorophyll and the enzymes needed to carry out photosynthesis. (pp. 86, 295)
- cholesterol:** lipid constituent of animal cell plasma membrane; serves as a precursor to the steroid hormones. (pp. 70, 165)
- cholinergic synapse:** a synapse that uses acetylcholine as the neurotransmitter. (p. 383)
- chromatid:** see *sister chromatid*.
- chromatin:** DNA-protein fibers that make up chromosomes; constructed from nucleosomes spaced regularly along a DNA chain. (pp. 84, 530)
- chromatin fiber (30 nm):** fiber formed by packing together the nucleosomes of a 10-nm chromatin fiber. (p. 533)
- chromatin remodeling protein:** protein that induces alterations in nucleosome structure, packing, and/or position designed to give transcription factors access to DNA target sites in the promoter region of a gene. (p. 732)
- chromatography:** a group of related techniques that utilize the flow of a fluid phase over a nonmobile absorbing phase to separate molecules based on their relative affinities for the two phases, which in turn reflect differences in size, charge, hydrophobicity, or affinity for a particular chemical group. (p. 9)
- chromosome:** in eukaryotes a single DNA molecule, complexed with histones and other proteins, that becomes condensed into a compact structure at the time of mitosis or meiosis. (pp. 10, 81, 530) Also see *bacterial chromosome*.
- chromosome puff:** uncoiled region of a polytene chromosome that is undergoing transcription. (p. 728)
- chromosome theory of heredity:** theory stating that hereditary factors are located in the chromosomes within the nucleus. (p. 10)
- cilium (plural, cilia):** membrane-bounded appendage on the surface of a eukaryotic cell, composed of a specific arrangement of microtubules and responsible for motility of the cell or the fluids around cells; shorter and more numerous than closely related organelles called flagella. (p. 453) Also see *flagellum*.
- cis-acting element:** a DNA sequence to which a regulatory protein can bind. (p. 716)
- cis-Golgi network (CGN):** region of the Golgi complex consisting of a network of membrane-bounded tubules that are located closest to the transitional elements. (p. 332)
- cisterna (plural, cisternae):** membrane-bounded flattened sac, such as in the endoplasmic reticulum or Golgi complex. (p. 89)
- cisternal maturation model:** model postulating that Golgi cisternae are transient compartments that gradually change from *cis*-Golgi network cisternae into medial cisternae and then into *trans*-Golgi network cisternae. (p. 332)
- cis-trans test:** analysis used to determine whether a mutation in a bacterial operon affects a regulatory protein or the DNA sequence to which it binds. (p. 715)
- clathrin:** large protein that forms a “cage” around the coated vesicles and coated pits involved in endocytosis and other intracellular transport processes. (p. 348)
- clathrin-dependent endocytosis:** see *receptor-mediated endocytosis*.
- claudin:** transmembrane protein that forms the main structural component of a tight junction. (p. 486)
- cleavage:** process of cytoplasmic division in animal cells, in which a band of actinmicrofilaments lying beneath the plasma membrane constricts the cell at the midline and eventually divides it in two. (p. 578)
- cleavage furrow:** groove formed during the division of an animal cell that encircles the cell and deepens progressively, leading to cytoplasmic division. (p. 578)
- clone:** organism (or cell or molecule) that is genetically identical to another organism (or cell or molecule) from which it is derived. (pp. 722, 764)
- cloning vector:** DNA molecule to which a selected DNA fragment can be joined prior to rapid replication of the vector in a host cell (usually a bacterium); phage and plasmid DNA are the most common cloning vectors. (p. 628)
- CNVs:** see *copy number variations*.
- CoA:** see *coenzyme A*.
- coactivator:** class of proteins that mediate interactions between activators and the genes they regulate; include histone-modifying enzymes such as HAT, chromatin-remodeling proteins such as SWI/SNF, and Mediator. (p. 736)
- coated vesicle:** any of several types of membrane vesicles involved in vesicular traffic within the endomembrane system; surrounded by a coat protein such as clathrin, COPI, COPII, or caveolin. (p. 344)
- coding strand:** the nontemplate strand of a DNA double helix, which is base-paired to the template strand; identical in sequence to the single-stranded RNA molecules transcribed from the template strand, except that RNA has uracil (U) where the coding strand has thymine (T). (p. 652)
- codon:** triplet of nucleotides in an mRNA molecule that serves as a coding unit for an amino acid (or a start or stop signal) during protein synthesis. (p. 654)
- coenzyme:** small organic molecule that functions along with an enzyme by serving as a carrier of electrons or functional groups. (p. 230)
- coenzyme A (CoA):** organic molecule that serves as a carrier of acyl groups by forming a high-energy thioester bond with an organic acid. (p. 259)
- coenzyme Q (CoQ):** nonprotein (quinone) component of the mitochondrial electron transport system that serves as the collection point for electrons from both FMN- and FAD-linked dehydrogenases; also called ubiquinone. (p. 271)
- coenzyme Q-cytochrome c oxidoreductase:** see *complex III*.
- cohesin:** protein that holds sister chromatids together prior to anaphase. (p. 586)
- colchicine:** plant-derived drug that binds to tubulin and prevents its polymerization into microtubules. (p. 428)
- collagen:** a family of closely related proteins that form high-strength fibers found in high-concentration in the extracellular matrix of animals. (p. 488)
- collagen fiber:** extremely strong fibers measuring several micrometers in diameter found in the extracellular matrix; constructed from collagen fibrils that are, in turn, composed of collagen molecules lined up in a staggered array. (p. 489)
- combinatorial model for gene regulation:** model proposing that complex patterns of tissue-specific gene expression can be achieved by a relatively small number of DNA control elements and their respective transcription factors acting in different combinations. (p. 737)
- complementary:** in nucleic acids, the ability of guanine (G) to form a hydrogen-bonded base pair with cytosine (C), and adenine (A) to form a hydrogen-bonded base pair with thymine (T) or uracil (U). (p. 512)
- complementary DNA (cDNA):** DNA molecule copied from an mRNA template by the enzyme reverse transcriptase. (p. 633)
- complex I (NADH-coenzyme Q oxidoreductase):** multiprotein complex of the electron transport system that catalyzes the transfer of electrons from NADH to coenzyme Q. (p. 274)
- complex II (succinate-coenzyme Q oxidoreductase):** multiprotein complex of the electron transport system that catalyzes the transfer of electrons from succinate to coenzyme Q. (p. 274)
- complex III (coenzyme Q-cytochrome c oxidoreductase):** multiprotein complex of the electron transport system that catalyzes the transfer of electrons from coenzyme Q to cytochrome c. (p. 274)
- complex IV (cytochrome c oxidase):** multiprotein complex of the electron transport system that catalyzes the transfer of electrons from cytochrome c to oxygen. (p. 274)
- compound microscope:** light microscope that uses several lenses in combination; usually has a condenser lens, an objective lens, and an ocular lens. (p. A-5)
- concentration gradient:** transmembrane gradient in concentration of a molecule or ion, expressed as a ratio of the concentration of the substance on one side of the membrane to its concentration on the other side of the membrane; the sole driving force for transport of molecules across a membrane, but only one of two components of the electrochemical potential that serves as the driving force for transport of ions across a membrane. (p. 196)
- concentration work:** use of energy to transport ions or molecules across a membrane against an electrochemical or concentration gradient. (p. 107)
- condensation reaction:** chemical reaction that results in the joining of two molecules by the removal of a water molecule. (p. 30)
- condenser lens:** lens of a light microscope (or electron microscope) that is the first lens to direct the light rays (or electron beam) from the source toward the specimen. (pp. A-5, A-19)
- confocal microscope:** specialized type of light microscope that employs a laser beam to illuminate a single plane of the specimen at a time. (p. A-11)
- conformation:** three-dimensional shape of a polypeptide or other biological macromolecule. (p. 44)
- conjugation:** cellular mating process by which DNA is transferred from one bacterial cell to another. (p. 621)
- connexon:** assembly of six protein subunits with a hollow center that forms a channel through the plasma membrane at a gap junction. (p. 486)
- consensus sequence:** the most common version of a DNA base sequence when that sequence occurs in slightly different forms at different sites. (p. 657)
- constitutive heterochromatin:** chromosomal regions that are condensed in all cells of an

- organism at virtually all times and are therefore genetically inactive.** (p. 543) Also see *facultative heterochromatin*.
- constitutive secretion:** continuous fusion of secretory vesicles with the plasma membrane and expulsion of their contents to the cell exterior, independent of specific extracellular signals. (p. 340)
- constitutively active mutation:** mutation that causes a receptor to be active even when no activating ligand is present. (p. 412)
- contractile ring:** beltlike bundle of actin microfilaments that forms beneath the plasma membrane and acts to constrict the cleavage furrow during the division of an animal cell. (p. 578)
- contractility:** shortening of muscle cells. (p. 449)
- cooperativity:** property of enzymes possessing multiple catalytic sites in which the binding of a substrate molecule to one catalytic site causes conformational changes that influence the affinity of the remaining sites for substrate. (p. 148)
- COPI:** main protein component of the “fuzzy” coats of COPI-coated vesicles, which are involved in retrograde transport from the Golgi complex back to the ER and between Golgi complex cisternae. (p. 350)
- COPII:** main protein component of COPII-coated vesicles, which are involved in transport from the ER to the Golgi complex. (p. 350)
- copy number variations (CNVs):** variations in the number of copies of DNA segments, thousands of bases long, that occur among individuals of the same species. (p. 525)
- CoQ:** see *coenzyme Q*.
- core oligosaccharide:** initial oligosaccharide segment joined to an asparagine residue during N-glycosylation of a polypeptide chain; consists of two N-acetylglucosamine units, nine mannose units, and three glucose units. (p. 334)
- core promoter:** minimal set of DNA sequences sufficient to direct the accurate initiation of transcription by RNA polymerase. (p. 661)
- core protein:** a protein molecule to which numerous glycosaminoglycan chains are attached to form a proteoglycan. (p. 491)
- corepressor:** effector molecule required along with the repressor to prevent transcription of a bacterial operon. (p. 717)
- correlative microscopy:** combination of light and electron-based microscopy that allows the fine structure associated with a fluorescent signal to be examined at high resolution, often using immunoelectron microscopy. (p. A-22)
- cotranslational import:** transfer of a growing polypeptide chain across (or, in the case of integral membrane proteins, into) the ER membrane as polypeptide synthesis proceeds. (p. 696)
- coupled transport:** coordinated transport of two solutes across a membrane in such a way that transport of either stops if the other is stopped or interrupted; the two solutes may move in the same direction (*symport*) or in opposite directions (*antiport*). (p. 203)
- covalent bond:** strong chemical bond in which two atoms share two or more electrons. (p. 19)
- covalent modification:** type of regulation in which the activity of an enzyme (or other protein) is altered by the addition or removal of specific chemical groups. (p. 148)
- crassulacean acid metabolism (CAM):** pathway in which plants use PEP carboxylase to fix CO₂ at night, generating the four-carbon acid, malate. The malate is then decarboxylated during the day to release CO₂, which is fixed by the Calvin cycle. (p. 320)
- CREB:** transcription factor that activates the transcription of cyclic AMP-inducible genes by binding to cAMP response elements in DNA. (p. 742)
- crista (plural, cristae):** infolding of the inner mitochondrial membrane into the matrix of the mitochondrion, thereby increasing the total surface area of the inner membrane; contains the enzymes of electron transport and oxidative phosphorylation. (pp. 85, 255)
- critical concentration:** tubulin concentration at which the rate of assembly of tubulin subunits into a polymer is exactly balanced with the rate of disassembly. (p. 427)
- critical point dryer:** heavy metal canister used to dry a specimen under conditions of controlled temperature and pressure. (p. A-26)
- cross-bridge:** structure formed by contact between the myosin heads of thick filaments and the thin filaments in muscle myofibrils. (p. 464)
- crossing over:** exchange of DNA segments between homologous chromosomes. (p. 605)
- cryoEM:** technique in which cryofixed biological samples are directly imaged in a transmission electron microscope at low temperature; often used to examine suspensions of isolated macromolecules. (p. A-28)
- cryofixation:** rapid freezing of small samples so that cellular structures can be immobilized in milliseconds; often followed by freeze substitution, in which an organic solvent replaces the frozen water in the sample. (p. A-21)
- C-terminus (carboxyl terminus):** the end of a polypeptide chain that contains the last amino acid to be incorporated during mRNA translation; usually retains a free carboxyl group. (p. 44)
- current:** movement of positive or negative ions. (p. 368)
- cyclic AMP (cAMP):** adenosine monophosphate with the phosphate group linked to both the 3' and 5' carbons by phosphodiester bonds; functions in both prokaryotic and eukaryotic gene regulation; in eukaryotes, acts as a second messenger that mediates the effects of various signaling molecules by activating protein kinase A. (p. 398)
- cyclic electron flow:** light-driven transfer of electrons from photosystem I through a sequence of electron carriers that returns them to a chlorophyll molecule of the same photosystem, with the released energy used to drive ATP synthesis. (p. 308)
- cyclin:** any of a group of proteins that activate the cyclin-dependent kinases (Cdks) involved in regulating progression through the eukaryotic cell cycle. (p. 583)
- cyclin-dependent kinase (Cdk):** any of several protein kinases that are activated by different cyclins and that control progression through the eukaryotic cell cycle by phosphorylating various target proteins. (p. 583)
- cyclosis:** see *cytoplasmic streaming*.
- cystic fibrosis (CF):** a disease whose symptoms result from an inability to secrete chloride ions that is, in turn, caused by a genetic defect in a membrane protein that functions as a chloride ion channel. (p. 206)
- cystic fibrosis transmembrane conductance regulator (CFTR):** a membrane protein that functions as a chloride ion channel, a mutant form of which can lead to cystic fibrosis. (p. 206)
- cytochalasins:** family of drugs produced by certain fungi that inhibit a variety of cell movements by preventing actin polymerization. (p. 435)
- cytochrome:** family of heme-containing proteins of the electron transport system; involved in the transfer of electrons from coenzyme Q to oxygen by the oxidation and reduction of the central iron atom of the heme group. (p. 270)
- cytochrome b₆/f complex:** multiprotein complex within the thylakoid membrane that transfers electrons from a plastoquinol to plastocyanin as part of the energy transduction reactions of photosynthesis. (p. 305)
- cytochrome c:** heme-containing protein of the electron transport system that also plays a role in triggering apoptosis when released from mitochondria. (p. 594)
- cytochrome c oxidase:** see *complex IV*.
- cytochrome P-450:** family of heme-containing proteins, located mainly in the liver, that catalyze hydroxylation reactions involved in drug detoxification and steroid biosynthesis. (p. 330)
- cytokinesis:** division of the cytoplasm of a parent cell into two daughter cells; usually follows mitosis. (p. 549)
- cytology:** study of cellular structure, based primarily on microscopic techniques. (p. 3)
- cytoplasm:** that portion of the interior of a eukaryotic cell that is not occupied by the nucleus; includes organelles, such as mitochondria and components of the endomembrane system, as well as the cytosol. (p. 95)
- cytoplasmic dynein:** cytoplasmic motor protein that moves along the surface of microtubules in the plus-to-minus direction, driven by energy derived from ATP hydrolysis; associated with dynactin, which links cytoplasmic dynein to cargo vesicles. (p. 452)
- cytoplasmic microtubules:** microtubules arranged in loosely organized, dynamic networks in the cytoplasm of eukaryotic cells. (p. 424)
- cytoplasmic streaming:** movement of the cytoplasm driven by interactions between actin filaments and specific types of myosin; also called cyclosis in plant cells. (p. 473)
- cytosine (C):** nitrogen-containing aromatic base, chemically designated as a pyrimidine, that serves as an informational monomeric unit when present in nucleic acids with other bases in a specific sequence; forms a complementary base pair with guanine (G) by hydrogen bonding. (p. 55)
- cytoskeleton:** three-dimensional, interconnected network of microtubules, microfilaments, and intermediate filaments that provides structure to the cytoplasm of a eukaryotic cell and plays an important role in cell movement. (pp. 95, 422)
- cytosol:** the semifluid substance in which the organelles of the cytoplasm are suspended. (p. 95)

D

- DAG:** see *diacylglycerol*.
- deep etching:** modification of freeze-etching technique in which ultrarapid freezing and a volatile cryoprotectant are used to extend the etching period, thereby removing a deeper layer of ice and allowing the interior of a cell to be examined in depth. (p. A-25)
- degenerate code:** ability of the genetic code to use more than one triplet code to specify the same amino acid. (p. 652)
- degron:** amino acid sequence within a protein that is used in targeting the protein for destruction. (p. 752)
- dehydrogenation:** removal of electrons plus hydrogen ions (protons) from an organic molecule; oxidation. (p. 229)
- denaturation:** loss of the natural three-dimensional structure of a macromolecule, usually resulting in a loss of its biological activity; caused by agents such as heat, extremes of pH, urea, salt,

- and other chemicals. (p. 32) Also see *DNA denaturation*.
- dendrite:** extension of a nerve cell that receives impulses and transmits them inward toward the cell body. (p. 366)
- density-dependent inhibition of growth:** tendency of cell division to stop when cells growing in culture reach a high population density. (p. 760)
- density gradient (rate-zonal) centrifugation:** type of centrifugation in which the sample is applied as a thin layer on top of a gradient of solute, and centrifugation is stopped before the particles reach the bottom of the tube; separates organelles and molecules based mainly on differences in size. (p. 329)
- deoxyribonucleic acid:** see *DNA*.
- deoxyribose:** five-carbon sugar present in DNA. (p. 54)
- dephosphorylation:** removal of a phosphate group. (p. 148)
- depolarization:** change in membrane potential to a less-negative value. (p. 370)
- desmosome:** junction for cell-cell adhesion that is connected to the cytoskeleton by intermediate filaments; creates buttonlike points of strong adhesion between adjacent animal cells that give tissue structural integrity and allow the cells to function as a unit and resist stress. (p. 482)
- diacylglycerol (DAG):** glycerol esterified to two fatty acids; formed, along with inositol trisphosphate (IP_3), upon hydrolysis of phosphatidylinositol-4,5-bisphosphate by phospholipase C; remains membrane-bound after hydrolysis and functions as a second messenger by activating protein kinase C, which then phosphorylates specific serine and threonine groups in a variety of target proteins. (p. 401)
- diakinesis:** final stage of prophase I of meiosis; associated with chromosome condensation, disappearance of nucleoli, breakdown of the nuclear envelope, and initiation of spindle formation. (p. 605)
- DIC microscopy:** see *differential interference contrast microscopy*.
- Dicer:** enzyme that cleaves double-stranded RNAs into short fragments about 21–22 base pairs in length. (p. 749)
- differential centrifugation:** technique for separating organelles or molecules that differ in size and/or density by subjecting cellular fractions to centrifugation at high speeds and separating particles based on their different rates of sedimentation. (p. 327)
- differential interference contrast (DIC) microscopy:** technique that resembles phase-contrast microscopy in principle, but is more sensitive because it employs a special prism to split the illuminating light beam into two separate rays. (p. A-6)
- differential scanning calorimetry:** technique for determining a membrane's transition temperature by monitoring the uptake of heat during the transition of the membrane from the gel to fluid state. (p. 169)
- differentiation:** see *cell differentiation*.
- diffraction:** pattern of either additive or canceling interference exhibited by light waves. (p. A-2)
- diffusion:** free, unassisted movement of a solute, with direction and rate dictated by the difference in solute concentration between two different regions. (p. 77)
- digital deconvolution microscopy:** technique in which fluorescence microscopy is used to acquire a series of images through the thickness of a specimen, followed by computer analysis to remove the contribution of out-of-focus light to the image in each focal plane. (p. A-13)
- digital microscopy:** technique in which microscopic images are recorded and stored electronically by placing a video camera in the image plane produced by the ocular lens. (p. A-13)
- diploid:** containing two sets of chromosomes and therefore two copies of each gene; can describe a cell, nucleus, or organism composed of such cells. (p. 601)
- diploctene:** stage during prophase I of meiosis when the two homologous chromosomes of each bivalent begin to separate from each other, revealing the chiasmata that connect them. (p. 605)
- direct active transport:** membrane transport in which the movement of solute molecules or ions across a membrane is coupled directly to an exergonic chemical reaction, most commonly the hydrolysis of ATP. (p. 209)
- directionality:** having two ends that are chemically different from each other; used to describe a polymer chain such as a protein, nucleic acid, or carbohydrate; also used to describe membrane transport systems that selectively transport solutes across a membrane in one direction. (pp. 31, 209)
- disaccharide:** carbohydrate consisting of two covalently linked monosaccharide units. (p. 63)
- dissociation constant (K_d):** the concentration of free ligand needed to produce a state in which half the receptors are bound to ligand. (p. 394)
- disulfide bond:** covalent bond formed between two sulfur atoms by oxidation of sulfhydryl groups. The disulfide bond formed between two cysteines is important in stabilizing the tertiary structure of proteins. (p. 44)
- DNA (deoxyribonucleic acid):** macromolecule that serves as the repository of genetic information in all cells; constructed from nucleotides consisting of deoxyribose phosphate linked to either adenine, thymine, cytosine, or guanine; forms a double helix held together by complementary base pairing between adenine and thymine, and between cytosine and guanine. (p. 54)
- DNA cloning:** generating multiple copies of a specific DNA sequence, either by replication of a recombinant plasmid or bacteriophage within bacterial cells or by use of the polymerase chain reaction. (p. 628)
- DNA damage checkpoint:** mechanism that monitors for DNA damage and halts the cell cycle at various points, including late G1, S, and late G2, if damage is detected. (p. 588)
- DNA denaturation:** separation of the two strands of the DNA double helix caused by disruption of complementary base pairing. (p. 515)
- DNA fingerprinting:** technique for identifying individuals based on small differences in DNA fragment patterns detected by electrophoresis. (p. 526)
- DNA gyrase:** a type II topoisomerase that can relax positive supercoiling and induce negative supercoiling of DNA; involved in unwinding the DNA double helix during DNA replication. (p. 515)
- DNA helicase:** any of several enzymes that unwind the DNA double helix, driven by energy derived from ATP hydrolysis. (p. 562)
- DNA ligase:** enzyme that joins two DNA fragments together by catalyzing the formation of a phosphoester bond between the 3' end of one fragment and the 5' end of the other fragment. (p. 558)
- DNA melting temperature (T_m):** temperature at which the transition from double-stranded to single-stranded DNA is halfway complete when DNA is denatured by increasing the temperature. (p. 516)
- DNA methylation:** addition of methyl groups to nucleotides in DNA; associated with suppression of gene transcription when selected cytosine groups are methylated in eukaryotic DNA. (p. 729)
- DNA microarray:** tiny chip that has been spotted at fixed locations with thousands of different DNA fragments for use in gene expression studies. (p. 733)
- DNA packing ratio:** ratio of the length of a DNA molecule to the length of the chromosome or fiber into which it is packaged; used to quantify the extent of DNA coiling and folding. (p. 533)
- DNA polymerase:** any of a group of enzymes involved in DNA replication and repair that catalyze the addition of successive nucleotides to the 3' end of a growing DNA strand, using an existing DNA strand as template. (p. 555)
- DNA rearrangement:** movement of DNA segments from one location to another within the genome. (p. 726)
- DNA renaturation:** binding together of the two separated strands of a DNA double helix by complementary base pairing, thereby regenerating the double helix. (p. 515)
- DNA replication checkpoint:** mechanism that monitors the state of DNA replication to help ensure that DNA synthesis is completed prior to permitting the cell to exit from G2 and begin mitosis. (p. 587)
- DNA sequencing:** technology used to determine the linear order of bases in DNA molecules or fragments. (pp. 11, 520)
- DNA-binding domain:** region of a transcription factor that recognizes and binds to a specific DNA base sequence. (p. 738)
- DNase I hypersensitive site:** location near an active gene that shows extreme sensitivity to digestion by the nuclease DNase I; thought to correlate with binding sites for transcriptional factors or other regulatory proteins. (p. 729)
- domain:** a discrete, locally folded unit of protein tertiary structure, often containing regions of α helices and β sheets packed together compactly. (p. 51)
- dominant (allele):** allele that determines how the trait will appear in an organism, whether present in the heterozygous or homozygous form. (p. 601)
- dominant negative mutation:** a loss-of-function mutation involving proteins consisting of more than one copy of the same polypeptide chain, in which a single mutant polypeptide chain disrupts the function of the protein even though the other polypeptide chains are normal. (p. 412)
- double bond:** chemical bond formed between two atoms as a result of the sharing of two pairs of electrons. (p. 19)
- double helix (model):** two intertwined helical chains of a DNA molecule, held together by complementary base pairing between adenine (A) and thymine (T) and between cytosine (C) and guanine (G). (pp. 59, 512)
- double-reciprocal plot:** graphic method for analyzing enzyme kinetic data by plotting $1/v$ versus $1/[S]$. (p. 142)
- downstream:** located toward the 3' end of the DNA coding strand. (p. 657)
- downstream promoter element:** see *DPE*.
- DPE (downstream promoter element):** component of core promoters for RNA polymerase II, located about 30 nucleotides downstream from the transcriptional startpoint. (p. 662)
- Drosha:** nuclear enzyme that cleaves the primary transcript of microRNA genes (pri-microRNAs) to form the smaller precursor microRNAs (pre-microRNAs). (p. 750)

dynactin: protein complex that helps link cytoplasmic dynein to the cargo (e.g., a vesicle) that it transports along microtubules. (p. 452)

dynamic instability model: model for microtubule behavior that presumes two populations of microtubules, one growing in length by continued polymerization at their plus ends and the other shrinking in length by depolymerization. (p. 429)

dynamin: cytosolic GTPase required for coated pit constriction and the closing of a budding, clathrin-coated vesicle. (p. 349)

dynein: motor protein that moves along the surface of microtubules in the plus-to-minus direction, driven by energy derived from ATP hydrolysis; present both in the cytoplasm and in the arms that reach between adjacent microtubule doublets in the axoneme of a flagellum or cilium. (p. 450)

dystrophin: a large protein found at muscle costameres that is part of a complex of proteins that attaches the muscle cell plasma membrane to the extracellular matrix (p. 497)

E

E: see *internal energy*.

E face: interior face of the outer monolayer of a membrane as revealed by the technique of freeze fracturing; called the E face because this monolayer is on the *exterior* side of the membrane. (p. A-25)

E site (exit site): site on the ribosome to which the empty tRNA is moved during translocation prior to its release from the ribosome. (p. 680)

E⁻: see *standard reduction potential*.

E2F transcription factor: protein that, when not bound to the Rb protein, activates the transcription of genes coding for proteins required for DNA replication and entrance into the S phase of the cell cycle. (p. 587)

E_A: see *activation energy*.

Eadie–Hofstee equation: alternative to the Lineweaver–Burk equation in which enzyme kinetic data are analyzed by plotting $v/[S]$ versus v . (p. 143)

early endosome: vesicles budding off the *trans*-Golgi network that are sites for the sorting and recycling of extracellular material brought into the cell by endocytosis. (p. 338)

EBV: see *Epstein–Barr virus*.

ECM: see *extracellular matrix*.

effector: see *allosteric effector*.

EGF: see *epidermal growth factor*.

egg (ovum): haploid female gamete, usually a relatively large cell with many stored nutrients. (p. 602)

EJC: see *exon junction complex*.

elastin: protein subunit of the elastic fibers that impart elasticity and flexibility to the extracellular matrix. (p. 490)

electrical excitability: ability to respond to certain types of stimuli with a rapid series of changes in membrane potential known as an action potential. (p. 367)

electrical potential (voltage): tendency of oppositely charged ions to flow toward each other. (p. 368)

electrical synapse: junction between two nerve cells where nerve impulses are transmitted by direct movement of ions through gap junctions without the involvement of chemical neurotransmitters. (p. 380)

electrical work: use of energy to transport ions across a membrane against a potential gradient. (p. 108)

electrochemical equilibrium: condition in which a transmembrane concentration gradient of a

specific ion is balanced with an electrical potential across the same membrane, such that there is no net movement of the ion across the membrane. (p. 369)

electrochemical gradient: see *electrochemical potential*.

electrochemical potential: transmembrane gradient of an ion, with both an electrical component due to the charge separation quantified by the membrane potential and a concentration component; also called electrochemical gradient. (p. 196)

electrochemical proton gradient: transmembrane gradient of protons, with both an electrical component due to charge separation and a chemical component due to a difference in proton concentration (pH) across the membrane. (p. 276)

electron gun: assembly of several components that generates the electron beam in an electron microscope. (p. A-18)

electron micrograph: photographic image of a specimen produced by the exposure of a photographic plate to the image-forming electron beam of an electron microscope. (p. A-19)

electron microscope: instrument that uses a beam of electrons to visualize cellular structures and thereby examine cellular architecture; the resolution is much greater than that of the light microscope, allowing detailed ultrastructural examination. (pp. 8, A-1)

electron shuttle system: any of several mechanisms whereby electrons from a reduced coenzyme such as NADH are moved across a membrane; consists of one or more electron carriers that can be reversibly reduced, with transport proteins present in the membrane for both the oxidized and reduced forms of the carrier. (p. 285)

electron tomography: see *three-dimensional electron tomography*.

electron transport: process of coenzyme reoxidation under aerobic conditions, involving stepwise transfer of electrons to oxygen by means of a series of electron carriers. (p. 267)

electron transport system (ETS): group of membrane-bound electron carriers that transfer electrons from the coenzymes NADH and FADH₂ to oxygen. (pp. 270, 302)

electronegative: property of an atom that tends to draw electrons toward it. (p. 23)

electrophoresis: a group of related techniques that utilize an electrical field to separate electrically charged molecules. (pp. 9, 178)

elongation (of microtubules): growth of microtubules by addition of tubulin heterodimers to either end. (p. 427)

elongation factors: group of proteins that catalyze steps involved in the elongation phase of protein synthesis; examples include EF-Tu and EF-Ts. (p. 688)

embryonic stem (ES) cells: see *stem cells*.

Emerson enhancement effect: achievement of greater photosynthetic activity with red light of two slightly different wavelengths than is possible by summing the activities obtained with the individual wavelengths separately. (p. 301)

endergonic: an energy-requiring reaction characterized by a positive free energy change ($\Delta G > 0$). (p. 115)

endocytic vesicle: membrane vesicle formed by pinching off of a small segment of plasma membrane during the process of endocytosis. (p. 342)

endocytosis: uptake of extracellular materials by infolding of the plasma membrane, followed by pinching off of a membrane-bound vesicle containing extracellular fluid and materials. (p. 342)

endomembrane system: interconnected system of cytoplasmic membranes in eukaryotic cells composed of the endoplasmic reticulum, Golgi complex, endosomes, lysosomes, and nuclear envelope. (p. 324)

endonuclease: an enzyme that degrades a nucleic acid (usually DNA) by cutting the molecule internally. (p. 559) Also see *restriction endonuclease*.

endoplasmic reticulum (ER): network of interconnected membranes distributed throughout the cytoplasm and involved in the synthesis, processing, and transport of proteins in eukaryotic cells. (pp. 89, 324)

endosome: see *early endosome* or *late endosome*.

endosymbiont theory: theory postulating that mitochondria and chloroplasts arose from ancient bacteria that were ingested by ancestral eukaryotic cells about a billion years ago. (pp. 89, 298)

endothermic: a reaction or process that absorbs heat. (p. 113)

end-product inhibition: see *feedback inhibition*.

end-product repression: regulation of an anabolic pathway based on the ability of an end product to repress further synthesis of enzymes involved in production of that end product. (p. 711)

energy: capacity to do work; ability to cause specific changes. (p. 106)

energy transduction reactions: portion of the photosynthetic pathway in which light energy is converted to chemical energy in the form of ATP and the coenzyme NADPH, which subsequently provide energy and reducing power for the carbon assimilation reactions. (p. 293)

enhancer: DNA sequence containing a binding site for transcription factors that stimulates transcription and whose position and orientation relative to the promoter can vary significantly without interfering with the ability to regulate transcription. (p. 734)

enthalpy (H): the heat content of a substance, quantified as the sum of its internal energy, E , plus the product of pressure and volume: $H = E + PV$. (p. 113)

entropy (S): measure of the randomness or disorder in a system. (p. 114)

enzyme: biological catalyst; protein (or in certain cases, RNA) molecule that acts on one or more specific substrates, converting them to products with different molecular structures. (pp. 9, 132) Also see *ribozyme*.

enzyme catalysis: involvement of an organic molecule, usually a protein but in some cases RNA, in speeding up the rate of a specific chemical reaction or class of reactions. (p. 129) Also see *catalyst*.

enzyme kinetics: quantitative analysis of enzyme reaction rates and the manner in which they are influenced by a variety of factors. (p. 138)

epidermal growth factor (EGF): protein that stimulates the growth and division of a wide variety of epithelial cell types. (p. 590)

epigenetic change: alteration in the expression of a gene rather than a change in the structure of the gene itself. (p. 730)

EPSP: see *excitatory postsynaptic potential*.

Epstein–Barr virus (EBV): virus associated with Burkitt lymphoma (as well as nononcancerous condition, infectious mononucleosis). (p. 771)

equilibrium constant (K_{eq}): ratio of product concentrations to reactant concentrations for a given chemical reaction when the reaction has reached equilibrium. (p. 119)

equilibrium density (buoyant density) centrifugation: technique used to separate cellular components by subjecting them to centrifuga-

- tion in a solution that increases in density from the top to the bottom of the centrifuge tube; during centrifugation, an organelle or molecule sediments to the density layer equal to its own density, at which point movement stops because no further net force acts on the material. (pp. 329, 551)
- equilibrium (or reversal) potential:** membrane potential that exactly offsets the effect of the concentration gradient for a given ion. (p. 369)
- ER:** see *endoplasmic reticulum*.
- ER-associated degradation (ERAD):** quality control mechanism in the ER that recognizes misfolded or unassembled proteins and exports or “retrotranslocates” them back across the ER membrane to the cytosol, where they are degraded by proteasomes. (p. 701)
- ER cisterna (plural, cisternae):** flattened sac of the endoplasmic reticulum. (p. 324)
- ER lumen:** the internal space enclosed by membranes of the endoplasmic reticulum. (p. 324)
- ER signal sequence:** amino acid sequence in a newly forming polypeptide chain that directs the ribosome-mRNA-polypeptide complex to the surface of the rough ER, where the complex becomes anchored. (p. 698)
- ERAD:** see *ER-associated degradation*.
- ETS:** see *electron transport system*.
- euchromatin:** loosely packed, uncondensed form of chromatin present during interphase; contains DNA that is being actively transcribed. (p. 533) Also see *heterochromatin*.
- eukarya:** one of the three domains of organisms, the other two being bacteria and archaea; the domain consisting of one-celled and multicellular organisms called eukaryotes whose cells are characterized by a membrane-bound nucleus and other membrane-bound organelles. (p. 75)
- eukaryote:** category of organisms whose cells are characterized by the presence of a membrane-bound nucleus and other membrane-bound organelles; includes plants, animals, fungi, algae, and protozoa. (p. 75)
- excision repair:** DNA repair mechanism that removes and replaces abnormal nucleotides. (p. 568)
- excitatory postsynaptic potential (EPSP):** small depolarization of the postsynaptic membrane triggered by binding of an excitatory neurotransmitter to its receptor; if the EPSP exceeds a threshold level, it can trigger an action potential. (p. 388) Also see *inhibitory postsynaptic potential*.
- exergonic:** an energy-releasing reaction characterized by a negative free energy change ($\Delta G < 0$). (p. 115)
- exit site:** see *E site*.
- exocytosis:** fusion of vesicle membranes with the plasma membrane so that contents of the vesicle can be expelled or secreted to the extracellular environment. (p. 341)
- exon:** nucleotide sequence in a primary RNA transcript that is preserved in the mature, functional RNA molecule. (p. 670) Also see *intron*.
- exon junction complex (EJC):** protein complex deposited at exon-exon junctions created by pre-mRNA splicing. (p. 672)
- exonuclease:** an enzyme that degrades a nucleic acid (usually DNA) from one end, rather than cutting the molecule internally. (p. 559)
- exosome:** macromolecular complex involved in mRNA degradation in eukaryotic cells; contains multiple $3' \rightarrow 5'$ exonucleases. (p. 748)
- exothermic:** a reaction or process that releases heat. (p. 113)
- exportin:** nuclear receptor protein that binds to the nuclear export signal of proteins in the nucleus and then transports the bound protein out through the nuclear pore complex and into the cytosol. (p. 540)
- extensin:** group of related glycoproteins that form rigid, rodlike molecules tightly woven into the cell walls of plants and fungi. (p. 499)
- extracellular digestion:** degradation of components outside a cell, usually by lysosomal enzymes that are released from the cell by exocytosis. (p. 355)
- extracellular matrix (ECM):** material secreted by animal cells that fills the spaces between neighboring cells; consists of a mixture of structural proteins (e.g., collagen, elastin) and adhesive glycoproteins (e.g., fibronectin, laminin) embedded in a matrix composed of protein-polysaccharide complexes called proteoglycans. (pp. 98, 487)
- F**
- F factor:** DNA sequence that enables an *E. coli* cell to act as a DNA donor during bacterial conjugation. (p. 622)
- F₁ complex:** knoblike sphere protruding into the matrix from mitochondrial inner membranes (or into the cytosol from the bacterial plasma membrane) that contains the ATP-synthesizing site of aerobic respiration. (p. 257)
- F₁ generation:** offspring of the P₁ generation in a genetic breeding experiment. (p. 613)
- F₂ generation:** offspring of the F₁ generation in a genetic breeding experiment. (p. 613)
- F2,6BP:** see *fructose-2,6-bisphosphate*.
- facilitated diffusion:** membrane protein-mediated movement of a substance across a membrane that does not require energy because the ion or molecule being transported is moving down an electrochemical gradient. (p. 202)
- F-actin:** component of microfilaments consisting of G-actin monomers that have been polymerized into long, linear strands. (p. 434)
- facultative heterochromatin:** chromosomal regions that have become specifically condensed and inactivated in a particular cell type at a specific time. (p. 543) Also see *constitutive heterochromatin*.
- facultative organism:** organism that can function in either an anaerobic or aerobic mode. (p. 231)
- FAD:** see *flavin adenine dinucleotide*.
- familial hypercholesterolemia (FH):** genetic predisposition to high blood cholesterol levels and heart disease caused by an inherited defect in the gene coding for the LDL receptor. (p. 346)
- fast axonal transport:** microtubule-mediated movement of vesicles and organelles back and forth along a nerve cell axon. (p. 450)
- fatty acid:** long, unbranched hydrocarbon chain that has a carboxyl group at one end and is therefore amphipathic; usually contains an even number of carbon atoms and may be of varying degrees of unsaturation. (p. 68)
- fatty acid-anchored membrane protein:** protein located on a membrane surface that is covalently bound to a fatty acid embedded with the lipid bilayer. (p. 178)
- Fd:** see *ferredoxin*.
- feedback (end-product) inhibition:** ability of the end product of a biosynthetic pathway to inhibit the activity of the first enzyme in the pathway, thereby ensuring that the functioning of the pathway is sensitive to the intracellular concentration of its product. (p. 146)
- fermentation:** partial oxidation of carbohydrates by oxygen-independent (anaerobic) pathways, resulting often (but not always) in the production of either ethanol and carbon dioxide or lactate. (p. 231)
- ferredoxin (Fd):** iron-sulfur protein in the chloroplast stroma involved in the transfer of electrons from photosystem I to NADP⁺ during the energy transduction reactions of photosynthesis. (p. 306)
- ferredoxin-NADP⁺ reductase (FNR):** enzyme located on the stroma side of the thylakoid membrane that catalyzes the transfer of electrons from ferredoxin to NADP⁺. (p. 306)
- fertilization:** union of two haploid gametes to form a diploid cell, the zygote, that develops into a new organism. (p. 602)
- FGF:** see *fibroblast growth factor*.
- FH:** see *familial hypercholesterolemia*.
- fibroblast growth factor (FGF):** any of several related signaling proteins that stimulate growth and cell division in fibroblasts as well as numerous other cell types, both in adults and during embryonic development. (p. 411)
- fibronectin:** adhesive glycoprotein found in the extracellular matrix and loosely associated with the cell surface; binds cells to the extracellular matrix and is important in determining cell shape and guiding cell migration. (p. 492)
- fibrous protein:** protein with extensive α helix or β sheet structure that confers a highly ordered, repetitive structure. (p. 50)
- filopodium (plural, filopodia):** thin, pointed cytoplasmic protrusion that transiently emerges from the surface of eukaryotic cells during cell movements. (p. 471)
- first law of thermodynamics:** law of conservation of energy; principle that energy can be converted from one form to another but can never be created or destroyed. (p. 112)
- Fischer projection:** model depicting the chemical structure of a molecule as a chain drawn vertically with the most oxidized atom on top and horizontal projections that are understood to be coming out of the plane of the paper. (p. 62)
- fixative:** chemical that kills cells while preserving their structural appearance for microscopic examination. (p. A-17)
- flagellum (plural, flagella):** membrane-bound appendage on the surface of a eukaryotic cell composed of a specific arrangement of microtubules and responsible for motility of the cell; longer and less numerous (usually limited to one or a few per cell) than closely related organelles called cilia. (p. 453) Also see *cilium*.
- flavin adenine dinucleotide (FAD):** coenzyme that accepts two electrons and two protons from an oxidizable organic molecule to generate the reduced form, FADH₂; important electron carrier in energy metabolism. (p. 262)
- flavoprotein:** protein that has a tightly bound flavin coenzyme (FAD or FMN) and that serves as a biological electron donor or acceptor. Several examples occur in the mitochondrial electron transport system. (p. 270)
- flippase:** see *phospholipid translocator*.
- flow cytometry:** technique for automated rapid analysis of cells stained with fluorescent dyes as they pass in a narrow stream through a laser beam. (p. 551)
- fluid mosaic model:** model for membrane structure consisting of a lipid bilayer with proteins associated as discrete globular entities that penetrate the bilayer to various extents and are free to move laterally in the membrane. (p. 161)
- fluid-phase endocytosis:** nonspecific uptake of extracellular fluid by infolding of the plasma membrane, followed by budding off of a membrane vesicle. (p. 347)
- fluorescence:** property of molecules that absorb light and then reemit the energy as light of a longer wavelength. (p. A-8)

fluorescence microscopy: light microscopic technique that focuses ultraviolet rays on the specimen, thereby causing fluorescent compounds in the specimen to emit visible light. (p. A-8)

fluorescence recovery after photobleaching: technique for measuring the lateral diffusion rate of membrane lipids or proteins in which such molecules are linked to a fluorescent dye and a tiny membrane region is then bleached with a laser. (p. 169)

fluorescence resonance energy transfer (FRET): an extremely short-distance interaction between two fluorescent molecules in which excitation is transferred from a donor molecule to an acceptor molecule directly; can be used to determine whether two molecules are in contact, or to produce “biosensors” that detect where proteins are activated or identify changes in local ion concentration. (p. A-16)

fluorescent antibody: antibody containing covalently linked fluorescent dye molecules that allow the antibody to be used to locate antigen molecules microscopically. (p. 187)

FNR: see *ferreredoxin-NADP⁺ reductase*.

F_o-F₁ complex: group of hydrophobic membrane proteins that anchor the F₁ complex to either the inner mitochondrial membrane or the bacterial plasma membrane; serves as the proton translocator channel through which protons flow when the electrochemical gradient across the membrane is used to drive ATP synthesis. (p. 257)

F_o-F₁ complex: protein complex in the mitochondrial inner membrane and the bacterial plasma membrane that consists of the F₁ complex bound to the F_o complex; the flow of protons through the F_o component leads to the synthesis of ATP by the F₁ component. (p. 257)

focal adhesion: localized points of attachment between cell surface integrin molecules and the extracellular matrix; contain clustered integrin molecules that interact with bundles of cytoskeletal actin microfilaments via several linker proteins. (p. 495)

focal length: distance between the midline of a lens and the point at which rays passing through the lens converge to a focus. (p. A-3)

frameshift mutation: insertion or deletion of one or more base pairs in a DNA molecule, causing a change in the reading frame of the mRNA molecule that usually garbles the message. (p. 651)

free energy (G): thermodynamic function that measures the extractable energy content of a molecule; under conditions of constant temperature and pressure, the change in free energy is a measure of the system's ability to do work. (p. 115)

free energy change (ΔG): thermodynamic parameter used to quantify the net free energy liberated or required by a reaction or process; measure of thermodynamic spontaneity. (p. 115)

freeze etching: cleaving a quick-frozen specimen, as in freeze fracturing, followed by the subsequent sublimation of ice from the specimen surface to expose small areas of the true cell surface. (p. A-25)

freeze fracturing: sample preparation technique for electron microscopy in which a frozen specimen is cleaved by a sharp blow followed by examination of the fractured surface, often the interior of a membrane. (pp. 174, A-24)

FRET: see *fluorescence resonance energy transfer*.
fructose-2,6-bisphosphate (F2,6BP): a doubly phosphorylated fructose molecule, formed by the action of phosphofructokinase-2 on fructose-6-phosphate, that plays an important role

in regulating both glycolysis and gluconeogenesis. (p. 245)

F-type ATPase: type of transport ATPase found in bacteria, mitochondria, and chloroplasts that can use the energy of ATP hydrolysis to pump protons against their electrochemical gradient; can also catalyze the reverse process, in which the exergonic flow of protons down their electrochemical gradient is used to drive ATP synthesis. (p. 211) Also see *ATP synthase*.

functional group: group of chemical elements covalently bonded to each other that confers characteristic chemical properties upon any molecule to which it is covalently linked. (p. 21)

G

G: see *guanine* or *free energy*.

ΔG : see *free energy change*.

ΔG° : see *standard free energy change*.

G protein: any of numerous GTP-binding regulatory proteins located in the plasma membrane that mediate signal transduction pathways, usually by activating a specific target protein such as an enzyme or channel protein. (p. 396)

G protein-linked receptor family: group of plasma membrane receptors that activate a specific G protein upon binding of the appropriate ligand. (p. 396)

G protein-linked receptor kinase (GRK): any of several protein kinases that catalyze the phosphorylation of activated G protein-linked receptors, thereby leading to receptor desensitization. (p. 396)

G0 (G zero): designation applied to eukaryotic cells that have become arrested in the G1 phase of the cell cycle and thus are no longer proliferating. (p. 550)

G1 phase: stage of the eukaryotic cell cycle between the end of the previous division and the onset of chromosomal DNA synthesis. (p. 550)

G2 phase: stage of the eukaryotic cell cycle between the completion of chromosomal DNA replication and the onset of cell division. (p. 550)

G-actin: globular monomeric form of actin that polymerizes to form F-actin. (p. 434)

GAG: see *glycosaminoglycan*.

gamete: haploid cells produced by each parent that fuse together to form the diploid offspring; for example, sperm or egg. (p. 602)

gametogenesis: the process that produces gametes. (p. 602)

gametophyte: haploid generation in the life cycle of an organism that alternates between haploid and diploid forms; form that produces gametes. (p. 603)

gamma tubulin (γ -tubulin): form of tubulin located in the centrosome, where it functions in the nucleation of microtubules. (p. 430)

gamma tubulin ring complexes (γ TuRCs): rings of γ -tubulin that emerge from centrosomes and nucleate the assembly of new microtubules. (p. 430)

gamma-TuRCs (γ TuRCs): see *gamma tubulin ring complexes*.

ganglioside: a charged glycolipid containing the amino alcohol sphingosine and negatively charged sialic acid residues. (p. 163)

GAP: see *GTPase activating protein*.

gap junction: type of cell junction that provides a point of intimate contact between two adjacent cells through which ions and small molecules can pass. (p. 486)

gatekeeper gene: a tumor suppressor gene directly involved in restraining cell proliferation; loss-of-function mutations in such genes

can lead to excessive cell proliferation and tumor formation. (p. 782)

Gb: gigabases; a billion base pairs (p. 517)

GEF: see *guanine-nucleotide exchange factor*.

gel electrophoresis: technique in which proteins or nucleic acids are separated in gels made of polyacrylamide or agarose by placing the gel in an electric field. (p. 519)

gene: “hereditary factor” that specifies an inherited trait; consists of a DNA base sequence that codes for the amino acid sequence of one or more polypeptide chains, or alternatively, for one of several types of RNA that perform functions other than coding for polypeptide chains (e.g., rRNA, tRNA, siRNA, or microRNA). (pp. 9, 505)

gene amplification: mechanism for creating extra copies of individual genes by selectively replicating specific DNA sequences. (p. 723)

gene conversion: phenomenon in which genes undergo nonreciprocal recombination during meiosis, such that one of the recombining genes ends up on both chromosomes of a homologous pair rather than being exchanged from one chromosome to the other. (p. 626)

gene deletion: selective removal within a cell of specific DNA sequences whose products are not required. (p. 726)

gene locus (plural, loci): location within a chromosome that contains the DNA sequence for a particular gene. (p. 601)

general transcription factor: a protein that is always required for RNA polymerase to bind to its promoter and initiate RNA synthesis, regardless of the identity of the gene involved. (p. 663)

genetic code: set of rules specifying the relationship between the sequence of bases in a DNA or mRNA molecule and the order of amino acids in the polypeptide chain encoded by that DNA or mRNA. (p. 646)

genetic engineering: application of recombinant DNA technology to practical problems, primarily in medicine and agriculture. (p. 635)

genetic instability: trait of cancer cells in which abnormally high mutation rates are caused by defects in DNA repair and/or chromosome sorting mechanisms. (p. 780)

genetic mapping: determining the sequential order and spacing of genes on a chromosome based on recombination frequencies. (p. 620)

genetic recombination: exchange of DNA segments between two different DNA molecules. (p. 605)

genetics: study of the behavior of genes, which are the chemical units involved in the storage and transmission of hereditary information. (p. 4)

genome: the DNA (or for some viruses, RNA) that contains one complete copy of all the genetic information of an organism or virus (p. 517)

genomic control: a regulatory change in the makeup or structural organization of the genome. (p. 723)

genomic library: collection of recombinant DNA clones produced by cleaving an organism's entire genome into fragments, usually using restriction endonucleases, and then cloning all the fragments in an appropriate cloning vector. (p. 632)

genotype: genetic makeup of an organism. (p. 601)

globular protein: protein whose polypeptide chains are folded into compact structures rather than extended filaments. (p. 51)

glucagon: peptide hormone, produced by the islets of Langerhans in the pancreas, that acts to increase blood glucose by promoting the breakdown of glycogen. (p. 417)

gluconeogenesis: synthesis of glucose from precursors such as amino acids, glycerol, or

- lactate:** occurs in the liver via a pathway that is essentially the reverse of glycolysis. (p. 239)
- glucose:** a six-carbon sugar that is widely used as the starting molecule in cellular energy metabolism. (p. 231)
- glucose transporter (GLUT):** membrane carrier protein responsible for the facilitated diffusion of glucose. (p. 203)
- GLUT:** see *glucose transporter*.
- glycerol:** three-carbon alcohol with a hydroxyl group on each carbon; serves as the backbone for triacylglycerols. (p. 68)
- glycerol phosphate shuttle:** mechanism for carrying electrons from cytosolic NADH into the mitochondrion, where the electrons are delivered to FAD in the respiratory complexes. (p. 286)
- glycocalyx:** carbohydrate-rich zone located at the outer boundary of many animal cells. (p. 186)
- glycogen:** highly branched storage polysaccharide in animal cells; consists of glucose repeating subunits linked by $\alpha(1 \rightarrow 4)$ bonds and $\alpha(1 \rightarrow 6)$ bonds. (p. 63)
- glycolate pathway:** light-dependent pathway that decreases the efficiency of photosynthesis by oxidizing reduced carbon compounds without capturing the released energy; occurs when oxygen substitutes for carbon dioxide in the reaction catalyzed by rubisco, thereby generating phosphoglycolate that is then converted to 3-phosphoglycerate in the peroxisome and mitochondrion; also called photorespiration. (p. 316)
- glycolipid:** lipid molecule containing a bound carbohydrate group. (pp. 70, 163)
- glycolysis (glycolytic pathway):** series of reactions by which glucose or some other monosaccharide is catabolized to pyruvate without the involvement of oxygen, generating two molecules of ATP per molecule of monosaccharide metabolized. (p. 232)
- glycolytic pathway:** see *glycolysis*.
- glycoprotein:** protein with one or more carbohydrate groups linked covalently to amino acid side chains. (pp. 185, 334)
- glycosaminoglycan (GAG):** polysaccharide constructed from a repeating disaccharide unit containing one sugar with an amino group and one sugar that usually has a negatively charged sulfate or carboxyl group; component of the extracellular matrix. (p. 491)
- glycosidic bond:** bond linking a sugar to another molecule, which may be another sugar molecule. (p. 63)
- glycosylation:** addition of carbohydrate side chains to specific amino acid residues of proteins, usually beginning in the lumen of the endoplasmic reticulum and completed in the Golgi complex. (pp. 185, 334)
- glyoxylate cycle:** modified version of the TCA cycle occurring in plant glyoxysomes; an anabolic pathway that converts two molecules of acetyl CoA to one molecule of succinate, thereby permitting the synthesis of carbohydrates from lipids. (p. 268)
- glyoxysome:** specialized type of plant peroxisome that contains some of the enzymes responsible for the conversion of stored fat to carbohydrate in germinating seeds. (pp. 93, 268, 359)
- Goldman equation:** modification of the Nernst equation that calculates the resting membrane potential by adding together the effects of all relevant ions, each weighted for its relative permeability. (p. 371)
- Golgi complex:** stacks of flattened, disk-shaped membrane cisternae in eukaryotic cells that are important in the processing and packaging of secretory proteins and in the synthesis of complex polysaccharides. (pp. 90, 332)
- golgin:** one of a class of tethering proteins that connect vesicles to the Golgi and Golgi cisternae to each other. (p. 352)
- GPI-anchored membrane protein:** protein bound to the outer surface of the plasma membrane by linkage to glycosylphosphatidylinositol (GPI), a glycolipid found in the external monolayer of the plasma membrane. (p. 178)
- grading:** see *tumor grading*.
- grana (plural, grana):** stack of thylakoid membranes in a chloroplast. (pp. 87, 297)
- green fluorescent protein (GFP):** a protein that exhibits bright green fluorescence when exposed to blue light. Using genetic engineering techniques, GFP can be fused to non-fluorescent proteins, allowing them to be followed using fluorescence microscopy. (p. A-10)
- GRK:** see *G protein-linked receptor kinase*.
- group specificity:** ability of an enzyme to act on any of a whole group of substrates as long as they possess some common structural feature. (p. 133)
- group transfer reaction:** chemical reaction that involves the movement of a chemical group from one molecule to another. (p. 228)
- growth factor:** any of a number of extracellular signaling proteins that stimulate cell division in specific types of target cells; examples include platelet-derived growth factor (PDGF) and epidermal growth factor (EGF). (p. 407)
- GTPase activating protein (GAP):** a protein that speeds up the inactivation of Ras by facilitating the hydrolysis of bound GTP. (p. 409)
- guanine (G):** nitrogen-containing aromatic base, chemically designated as a purine, which serves as an informational monomeric unit when present in nucleic acids with other bases in a specific sequence; forms a complementary base pair with cytosine (C) by hydrogen bonding. (p. 55)
- guanine-nucleotide exchange factor (GEF):** a protein that triggers the release of GDP from the Ras protein, thereby permitting Ras to acquire a molecule of GTP. (p. 408)
- gyrase:** see *DNA gyrase*.
- H**
- H:** see *enthalpy*.
- H zone:** light region located in the middle of the A band of striated muscle myofibrils. (p. 461)
- hairpin loop:** looped structure formed when two adjacent segments of a nucleic acid chain are folded back on one another and held in that conformation by base pairing between complementary base sequences. (p. 659)
- haploid:** containing a single set of chromosomes and therefore a single copy of the genome; can describe a cell, nucleus, or organism composed of such cells. (p. 601)
- haploid spore:** haploid product of meiosis in organisms that display an alternation of generations; gives rise upon spore germination to the haploid form of the organism (the gametophyte, in the case of higher plants). (p. 603)
- haplotype:** group of SNPs located near one another on the same chromosome that tend to be inherited as a unit. (p. 524)
- HAT:** see *histone acetyl transferase*.
- Hatch–Slack cycle:** series of reactions in C₄ plants in which carbon dioxide is fixed in the mesophyll cells and transported as a four-carbon compound to the bundle sheath cells, where subsequent decarboxylation results in a higher concentration of carbon dioxide and therefore a higher rate of carbon fixation by rubisco. (p. 317)
- Haworth projection:** model that depicts the chemical structure of a molecule in a way that suggests the spatial relationship of different parts of the molecule. (p. 62)
- HCI:** see *heme-controlled inhibitor*.
- HDL:** see *high-density lipoprotein*.
- heart muscle:** see *cardiac muscle*.
- heat:** transfer of energy as a result of a temperature difference. (p. 108)
- heat-shock gene:** gene whose transcription is activated when cells are exposed to elevated temperatures or other stressful conditions; some heat-shock genes code for molecular chaperones that, in addition to guiding normal protein folding, can facilitate the refolding of heat-damaged proteins. (p. 743)
- heat-shock response element:** DNA base sequence located adjacent to heat-shock genes that functions as a binding site for the heat-shock transcription factor. (p. 743)
- helicase:** see *DNA helicase*.
- helix:** see *alpha helix* or *double helix*.
- helix-loop-helix:** DNA-binding motif found in transcription factors that is composed of a short α helix connected by a loop to a longer α helix. (p. 740)
- helix-turn-helix:** DNA-binding motif found in many regulatory transcription factors; consists of two regions of α helix separated by a bend in the polypeptide chain. (p. 738)
- hemicellulose:** heterogeneous group of polysaccharides deposited along with cellulose in the cell walls of plants and fungi to provide added strength; each consists of a long, linear chain of a single kind of sugar with short side chains. (p. 498)
- hemidesmosome:** point of attachment between cell surface integrin molecules of epithelial cells and the basal lamina; contains integrin molecules that are anchored via linker proteins to intermediate filaments of the cytoskeleton. (p. 495)
- heterochromatin:** highly compacted form of chromatin present during interphase; contains DNA that is not being transcribed. (p. 533)
Also see *euchromatin*.
- heterodimer ($\alpha\beta$ -heterodimer):** see *alpha beta heterodimer*.
- heterophagic lysosome:** mature lysosome containing hydrolytic enzymes involved in the digestion of materials of extracellular origin. (p. 353) Also see *autophagic lysosome*.
- heterophilic interaction:** binding of two different molecules to each other. (p. 478) Also see *homophilic interaction*.
- heterozygous:** having two different alleles for a given gene. (p. 601) Also see *homozygous*.
- Hfr cell:** bacterial cell in which the F factor has become integrated into the bacterial chromosome, allowing the cell to transfer genomic DNA during conjugation. (p. 622)
- hierarchical assembly:** synthesis of biological structures from simple starting molecules to progressively more complex structures, usually by self-assembly. (p. 36)
- high-density lipoprotein (HDL):** cholesterol-containing protein-lipid complex that transports cholesterol through the bloodstream and is taken up by cells; exhibits high density because of its low cholesterol content. (p. 346)
- high-voltage electron microscope (HVEM):** an electron microscope that uses accelerating voltages up to a thousand or more kilovolts, thereby allowing the examination of thicker samples than is possible with a conventional electron microscope. (p. A-19)

- histone:** class of basic proteins found in eukaryotic chromosomes; an octamer of histones forms the core of nucleosomes. (p. 530)
- histone acetyltransferase (HAT):** enzyme that catalyzes the addition of acetyl groups to histones. (p. 731)
- histone deacetylase (HDAC):** enzyme that catalyzes removal of acetyl groups from histones. (p. 731)
- Holliday junction:** X-shaped structure produced when two DNA molecules are joined together by single-strand crossovers during genetic recombination. (p. 626)
- homeobox:** highly conserved DNA sequence found in homeotic genes; codes for a DNA-binding protein domain present in transcription factors that are important regulators of gene expression during development. (p. 744)
- homeodomain:** amino acid sequence, about 60 amino acids long, found in transcription factors encoded by homeotic genes; contains a helix-turn-helix DNA-binding motif. (p. 744)
- homeotic gene:** family of genes that control formation of the body plan during embryonic development; they code for transcription factors possessing homeodomains. (p. 743)
- homeoviscous adaptation:** alterations in membrane lipid composition that keep the viscosity of membranes approximately the same despite changes in environmental temperature. (p. 172)
- homogenate:** suspension of cell organelles, smaller cellular components, and molecules produced by disrupting cells or tissues using techniques such as grinding, ultrasonic vibration, or osmotic shock. (p. 327)
- homogenization:** disruption of cells or tissues using techniques such as grinding, ultrasonic vibration, or osmotic shock. (p. 327)
- homologous chromosomes:** two copies of a specific chromosome, one derived from each parent, that pair with each other and exchange genetic information during meiosis. (p. 600)
- homologous recombination:** exchange of genetic information between two DNA molecules exhibiting extensive sequence similarity; also used in repairing double-strand DNA breaks. (pp. 570, 624)
- homophilic interaction:** binding of two identical molecules to each other. (p. 478) Also see *heterophilic interaction*.
- homozygous:** having two identical alleles for a given gene. (p. 601) Also see *heterozygous*.
- hormone:** chemical that is synthesized in one organ, secreted into the blood, and able to cause a physiological change in cells or tissues of another organ. (p. 414)
- hormone response element:** DNA base sequence that selectively binds to a hormone-receptor complex, resulting in the activation (or inhibition) of transcription of nearby genes. (p. 741)
- HPV:** see *human papillomavirus*.
- human papillomavirus (HPV):** virus responsible for cervical cancer; possesses oncogenes that block the actions of the proteins produced by the *RB* and *p53* tumor suppressor genes. (p. 778)
- HVEM:** see *high-voltage electron microscope*.
- hyaluronate:** a glycosaminoglycan found in high concentration in the extracellular matrix where cells are actively proliferating or migrating, and in the joints between movable bones. (p. 492)
- hybrid:** product of the cross of two genetically different parents. (p. 613)
- hybridization:** see *nucleic acid hybridization*.
- hydrocarbon:** an organic molecule consisting only of carbon and hydrogen atoms; not generally compatible with living cells. (p. 21)
- hydrogen bond:** weak attractive interaction between an electronegative atom and a hydrogen atom that is covalently linked to a second electronegative atom. (pp. 23, 46)
- hydrogenation:** addition of electrons plus hydrogen ions (protons) to an organic molecule; reduction. (p. 229)
- hydrolysis:** reaction in which a chemical bond is broken by the addition of a water molecule. (p. 32)
- hydropathy index:** a value representing the average of the hydrophobicity values for a short stretch of contiguous amino acids within a protein. (p. 180)
- hydropathy (hydrophobicity) plot:** graph showing the location of hydrophobic amino acid clusters within the primary sequence of a protein molecule; used to determine the likely locations of transmembrane segments within integral membrane proteins. (p. 180)
- hydrophilic:** describing molecules or regions of molecules that readily associate with or dissolve in water because of a preponderance of polar groups; “water-loving.” (p. 24)
- hydrophobic:** describing molecules or regions of molecules that are poorly soluble in water because of a preponderance of nonpolar groups; “water-hating.” (p. 24)
- hydrophobic interaction:** tendency of hydrophobic groups to be excluded from interactions with water molecules. (p. 46)
- hydrophobicity plot:** see *hydropathy plot*.
- hydroxylation:** chemical reaction in which a hydroxyl group is added to an organic molecule. (p. 330)
- hyperpolarization (undershoot):** state in which the membrane potential is more negative than the normal membrane potential. (p. 377)
- hypothesis:** a statement or explanation that is consistent with most of the observational and experimental evidence to date. (p. 13)
- I band:** region of a striated muscle myofibril that appears as a light band when viewed by microscopy; contains those regions of the thin actin filaments that do not overlap the thick myosin filaments. (p. 461)
- IF:** see *intermediate filament*.
- IgSF:** see *immunoglobulin superfamily*.
- immunoEM:** electron microscopic technique for visualizing antibodies within cells by linking them to substances that are electron dense and therefore visible as opaque dots. (p. A-22)
- immunoEM:** see *immunoelectron microscopy*.
- immunoglobulin superfamily (IgSF):** family of cell surface proteins involved in cell-cell adhesion that are structurally related to the immunoglobulin subunits of antibody molecules. (p. 478)
- immunostaining:** technique in which antibodies are labeled with a fluorescent dye to enable them to be identified and localized microscopically based on their fluorescence. (p. A-9)
- immunotherapy:** treatment of a disease, such as cancer, by stimulating the immune system or administering antibodies made by the immune system. (p. 788)
- IMP:** see *intramembranous particle*.
- importin:** receptor protein that binds to the nuclear localization signal of proteins in the cytosol and then transports the bound protein through the nuclear pore complex and into the nucleus. (p. 540)
- imprinting:** a process that causes some genes to be expressed differently depending on whether they are inherited from a person's mother or father; such behavior can be caused by differences in DNA methylation. (p. 730)
- indirect active transport:** membrane transport involving the cotransport of two solutes in which the movement of one solute down its gradient drives the movement of the other solute up its gradient. (p. 209)
- indirect immunofluorescence:** type of fluorescence microscopy in which a specimen is first exposed to an unlabeled antibody that attaches to specific antigenic sites within the specimen and is then stained with a secondary, fluorescent antibody that binds to the first antibody. (p. A-9)
- induced-fit model:** model postulating that the active site of an enzyme is relatively specific for its substrate before it binds, but even more so thereafter because of a conformational change in the enzyme induced by the substrate. (p. 136)
- induced pluripotent stem (IPS) cells:** differentiated cells forced to express transcription factor proteins found in embryonic stem cells, allowing them to become many different types of cells (p. 725)
- inducer:** any effector molecule that activates the transcription of an inducible operon. (p. 714)
- inducible enzyme:** enzyme whose synthesis is regulated by the presence or absence of its substrate. (p. 711)
- inducible operon:** group of adjoining genes whose transcription is activated in the presence of an inducer. (p. 714)
- informational macromolecule:** polymer of non-identical subunits ordered in nonrandom sequence that stores and transmits information important to the function or utilization of the macromolecule; DNA and RNA are informational macromolecules. (p. 29)
- inhibition (of enzyme activity):** decreasing the catalytic activity of an enzyme, either by a change in conformation or by chemical modification of one of its functional groups. (p. 144)
- inhibitory postsynaptic potential (IPSP):** small hyperpolarization of the postsynaptic membrane triggered by binding of an inhibitory neurotransmitter to its receptor, thereby reducing the amplitude of subsequent excitatory postsynaptic potentials and possibly preventing the firing of an action potential. (p. 388) Also see *excitatory postsynaptic potential*.
- initial reaction velocity (v):** Reaction rate measured over a period of time during which the substrate concentration has not decreased enough to affect the rate and the accumulation of product is still too small to cause any measurable back reaction. (p. 139)
- initiation complex (30S):** complex formed by the association of mRNA, the 30S ribosomal subunit, an initiator aminoacyl tRNA molecule, and initiation factor IF2. (p. 686)
- initiation complex (70S):** complex formed by the association of a 30S initiation complex with a 50S ribosomal subunit; contains an initiator aminoacyl tRNA at the P site and is ready to commence mRNA translation. (p. 686)
- initiation factors:** group of proteins that promote the binding of ribosomal subunits to mRNA and initiator tRNA, thereby initiating the process of protein synthesis. (p. 685)
- initiation (stage of carcinogenesis):** irreversible conversion of a cell to a precancerous state by agents that cause DNA mutation. (p. 769)
- initiator (Inr):** short DNA sequence surrounding the transcription startpoint that forms part of the promoter for RNA polymerase II. (p. 661)

- initiator tRNA:** type of transfer RNA molecule that starts the process of translation; recognizes the AUG start codon and carries formylmethionine in prokaryotes or methionine in eukaryotes. (p. 686)
- inner membrane:** the inner of the two membranes that surround a mitochondrion, chloroplast, or nucleus. (pp. 255, 297)
- inositol-1,4,5-trisphosphate (IP₃):** triply phosphorylated inositol molecule formed as a product of the cleavage of phosphatidylinositol-4,5-bisphosphate catalyzed by phospholipase C; functions as a second messenger by triggering the release of calcium ions from storage sites within the endoplasmic reticulum. (p. 401)
- Inr:** see *initiator*.
- insertional mutagenesis:** change in gene structure or activity resulting from the integration of DNA derived from another source, usually a virus. (p. 774)
- insulin:** peptide hormone, produced by the islets of Langerhans in the pancreas, that acts to decrease blood glucose by stimulating glucose uptake into muscle and adipose cells and by stimulating glycogen synthesis. (p. 417)
- integral membrane protein:** hydrophobic protein localized within the interior of a membrane but possessing hydrophilic regions that protrude from one or both membrane surfaces. (p. 177)
- integral monotopic protein:** an integral membrane protein embedded in only one side of the lipid bilayer. (p. 177)
- integrin:** any of several plasma membrane receptors that bind to extracellular matrix components at the outer membrane surface and interact with cytoskeletal components at the inner membrane surface; includes receptors for fibronectin, laminin, and collagen. (p. 494)
- intercalated disc:** membrane partition enriched in gap junctions that divides cardiac muscle into separate cells containing single nuclei. (p. 469)
- interdoublet link:** link between adjacent doublets in the axoneme of a eukaryotic cilium or flagellum; believed to limit the extent of doublet movement with respect to each other as the axoneme bends. (p. 456)
- interference:** process by which two or more waves of light combine to reinforce or cancel one another, producing a wave equal to the sum of the combining waves. (p. A-2)
- intermediate filament (IF):** group of protein filaments that are the most stable components of the cytoskeleton of eukaryotic cells; exhibits a diameter of 8–12 nm, which is intermediate between the diameters of actin microfilaments and microtubules. (pp. 97, 442)
- intermediate lens (electron microscope):** electromagnetic lens positioned between the objective and projector lenses in a transmission electron microscope. (p. A-19)
- intermediate lens (light microscope):** lens positioned between the ocular and objective lenses in a light microscope. (p. A-6)
- intermembrane space:** region of a mitochondrion or chloroplast between the inner and outer membranes. (pp. 255, 297)
- internal energy (E):** total energy stored within a system; cannot be measured directly, but the change in internal energy, ΔE , is measurable. (p. 113)
- interphase:** growth phase of the eukaryotic cell cycle situated between successive division phases (M phases); composed of G1, S, and G2 phases. (p. 550)
- interspersed repeated DNA:** repeated DNA sequences whose multiple copies are scattered around the genome. (p. 527)
- intracellular membrane:** any cellular membrane internal to the plasma membrane; such membranes serve to compartmentalize functions within eukaryotic cells. (p. 156)
- intraflagellar transport (IFT):** movement of components to and from the tips of flagella driven by both plus- and minus-end directed microtubule motor proteins. (p. 459)
- intramembranous particle (IMP):** integral membrane protein that is visible as a particle when the interior of a membrane is visualized by freeze-fracture microscopy. (p. A-24)
- intron:** nucleotide sequence in an RNA molecule that is part of the primary transcript but not the mature, functional RNA molecule. (p. 669) Also see *exon*.
- invasion:** direct spread of cancer cells into neighboring tissues. (p. 762)
- inverted repeat:** DNA segment containing two copies of the same base sequence oriented in opposite directions. (p. 742)
- ion channel:** membrane protein that allows the passage of specific ions through the membrane; generally regulated by either changes in membrane potential (voltage-gated channels) or binding of a specific ligand (ligand-gated channels). (pp. 205, 372)
- ionic bond:** attractive force between a positively charged chemical group and a negatively charged chemical group. (p. 46)
- ionizing radiation:** high-energy forms of radiation that remove electrons from molecules, thereby generating highly reactive ions that cause DNA damage; includes X-rays and radiation emitted by radioactive elements. (p. 770)
- IP₃:** see *inositol-1,4,5-trisphosphate*.
- IP₃ receptor:** ligand-gated calcium channel in the ER membrane that opens when bound to IP₃, allowing calcium ions to flow from the ER lumen into the cytosol. (p. 401)
- IPSP:** see *inhibitory postsynaptic potential*.
- IRE:** see *iron-response element*.
- iron-response element (IRE):** short base sequence found in mRNAs whose translation or stability is controlled by iron; binding site for an IRE-binding protein. (p. 747)
- iron-sulfur protein:** protein that contains iron and sulfur atoms complexed with four cysteine groups and that serves as an electron carrier in the electron transport system. (p. 270)
- irreversible inhibitor:** molecule that binds to an enzyme covalently, causing an irrevocable loss of catalytic activity. (p. 145)
- isoenzyme:** any of several, physically distinct proteins that catalyze the same reaction. (p. 314)
- isoprenylated membrane protein:** protein located on a membrane surface that is covalently bound to a prenyl group embedded within the lipid bilayer. (p. 178)
- J**
- J:** see *joule*.
- Jak:** see *Janus activated kinase*.
- Janus kinase (Jak):** cytoplasmic protein kinase that, after activation by cell surface receptors, catalyzes the phosphorylation and activation of STAT transcription factors. (p. 743)
- joule (J):** a unit of energy corresponding to 0.239 calories. (p. 112)
- K**
- karyotype:** picture of the complete set of chromosomes for a particular cell type, organized as homologous pairs arranged on the basis of differences in size and shape. (p. 573)
- Kb:** kilobases; a thousand base pairs (p. 517)
- K_{cat}:** see *turnover number*.
- K_d:** see *dissociation constant*.
- K_{eq}:** see *equilibrium constant*.
- kilocalorie (kcal):** unit of energy; 1 kcal = 1000 calories. (p. 112)
- kinesin:** family of motor proteins that generate movement along microtubules using energy derived from ATP hydrolysis. (p. 450)
- kinetochore:** multiprotein complex located at the centromere region of a chromosome that provides the attachment site for spindle microtubules during mitosis or meiosis. (p. 573)
- kinetochore microtubule:** spindle microtubule that attaches to chromosomal kinetochores. (p. 573)
- K_m:** see *Michaelis constant*.
- Knockout mice:** Mice that have been genetically engineered to contain a deletion of DNA sequences in a particular gene using homologous recombination in embryonic stem cells.
- Krebs cycle:** see *tricarboxylic acid cycle*.
- L**
- lac operon:** group of adjoining bacterial genes that code for enzymes involved in lactose metabolism and whose transcription is inhibited by the *lac* repressor. (p. 712)
- lactate fermentation:** anaerobic catabolism of carbohydrates with lactate as the end product. (p. 237)
- lagging strand:** strand of DNA that grows in the 3' → 5' direction during DNA replication by discontinuous synthesis of short fragments in the 5' → 3' direction, followed by ligation of adjacent fragments. (p. 558) Also see *leading strand*.
- lamellipodium (plural, lamellipodia):** thin sheet of flattened cytoplasm that transiently protrudes from the surface of eukaryotic cells during cell crawling; supported by actin filaments. (p. 471)
- laminin:** adhesive glycoprotein of the extracellular matrix, localized predominantly in the basal lamina of epithelial cells. (p. 493)
- large ribosomal subunit:** component of a ribosome with a sedimentation coefficient of 60S in eukaryotes and 50S in prokaryotes; associates with a small ribosomal subunit to form a functional ribosome. (p. 95)
- late endosome:** vesicle containing newly synthesized acid hydrolases plus material fated for digestion; activated either by lowering the pH of the late endosome or transferring its material to an existing lysosome. (p. 338)
- lateral diffusion:** diffusion of a membrane lipid or protein in the plane of the membrane. (p. 167)
- latrunculin A:** chemical compound derived from marine sponges that causes depolymerization of actin microfilaments. (p. 435)
- law:** a theory that has been so thoroughly tested and confirmed over a long period of time by a large number of investigators that virtually no doubt remains as to its validity. (p. 14)
- law of independent assortment:** principle stating that the alleles of each gene separate independently of the alleles of other genes during gamete formation. (p. 615)
- law of segregation:** principle stating that the alleles of each gene separate from each other during gamete formation. (p. 615)
- LDL:** see *low-density lipoprotein*.
- LDL receptor:** plasma membrane protein that serves as a receptor for binding extracellular LDL, which is then taken into the cell by receptor-mediated endocytosis. (p. 347)

- leading strand:** strand of DNA that grows as a continuous chain in the $5' \rightarrow 3'$ direction during DNA replication. (p. 558) Also see *lagging strand*.
- leaf peroxisome:** special type of peroxisome found in the leaves of photosynthetic plant cells that contains some of the enzymes involved in photorespiration. (pp. 93, 316, 358)
- lectin:** any of numerous carbohydrate-binding proteins that can be isolated from plant or animal cells and that promote cell-cell adhesion. (p. 480)
- leptotene:** first stage of prophase I of meiosis, characterized by condensation of chromatin fibers into visible chromosomes. (p. 605)
- leucine zipper:** DNA-binding motif found in many transcription factors; formed by an interaction between α helices in two polypeptide chains that are "zipped" together by hydrophobic interactions between leucine residues. (p. 739)
- leukemia:** cancer of blood or lymphatic origin in which the cancer cells proliferate and reside mainly in the bloodstream rather than growing as solid masses of tissue. (p. 758)
- LHC: see *light-harvesting complex*.
- LHCl: see *light-harvesting complex I*.
- LHCII: see *light-harvesting complex II*.
- licensing:** process of making DNA competent for replication; normally occurs only once per cell cycle. (p. 555)
- ligand:** substance that binds to a specific receptor, thereby initiating the particular event or series of events for which that receptor is responsible. (p. 392)
- ligand-gated ion channel:** an integral membrane protein that forms an ion-conducting pore that opens when a specific molecule (ligand) binds to the channel. (p. 372)
- light microscope:** instrument consisting of a source of visible light and a system of glass lenses that allows an enlarged image of a specimen to be viewed. (pp. 6, A-1)
- light-harvesting complex (LHC):** collection of light-absorbing pigments, usually chlorophylls and carotenoids, linked together by proteins; unlike a photosystem, does not contain a reaction center, but absorbs photons of light and funnels the energy to a nearby photosystem. (p. 301)
- light-harvesting complex I (LHCl):** the light-harvesting complex associated with photosystem I. (p. 306)
- light-harvesting complex II (LHCII):** the light-harvesting complex associated with photosystem II. (p. 304)
- lignin:** insoluble polymers of aromatic alcohols that occur mainly in woody plant tissues, where they contribute to the hardening of the cell wall and the structural strength we associate with wood. (p. 499)
- limit of resolution:** measurement of how far apart adjacent objects must be in order to be distinguished as separate entities. (pp. 6, A-4)
- LINEs (long interspersed nuclear elements):** class of interspersed repeated DNA sequences 6000–8000 base pairs in length that function as transposable elements and account for roughly 20% of the human genome; contain genes coding for enzymes needed for copying LINE sequences (and other mobile elements) and inserting the copies elsewhere in the genome. (p. 527)
- Lineweaver-Burk equation:** linear equation obtained by inverting the Michaelis-Menten equation, useful in determining parameters V_{max} and K_m and in the analysis of enzyme inhibition. (p. 142)
- linkage group:** group of genes that are transmitted, inherited, and assort together. (p. 619)
- linked genes:** genes that are usually inherited together because they are located relatively close to each other on the same chromosome. (p. 619)
- lipid:** any of a large and chemically diverse class of organic compounds that are poorly soluble or insoluble in water but soluble in organic solvents. (p. 65)
- lipid bilayer:** unit of membrane structure, consisting of two layers of lipid molecules (mainly phospholipid) arranged so that their hydrophobic tails face toward each other and the polar region of each faces the aqueous environment on one side or the other of the bilayer. (pp. 26, 83, 159)
- lipid raft:** localized region of membrane lipids, often characterized by elevated levels of cholesterol and glycosphingolipids, that sequester proteins involved in cell signaling; also called lipid microdomain. (p. 173)
- lipid-anchored membrane protein:** protein located on a membrane surface that is covalently bound to one or more lipid molecules residing within the lipid bilayer. (p. 178) Also see *fatty acid-anchored membrane protein*, *prenylated membrane protein*, and *GPI-anchored membrane protein*.
- looped domain:** folding of a 30-nm chromatin fiber into loops 50,000–100,000 bp in length by periodic attachment of the DNA to an insoluble network of nonhistone proteins. (p. 533)
- low-density lipoprotein (LDL):** cholesterol-containing protein-lipid complex that transports cholesterol through the bloodstream and is taken up by cells; exhibits low density because of its high cholesterol content. (p. 346)
- lumen:** internal space enclosed by a membrane, usually the endoplasmic reticulum or related membrane systems. (p. 89)
- lymphoma:** cancer of lymphatic origin in which the cancer cells grow as solid masses of tissue. (p. 758)
- lysosomal storage disease:** disease resulting from a deficiency of one or more lysosomal enzymes and characterized by the undesirable accumulation of excessive amounts of specific substances that would normally be degraded by the deficient enzymes. (p. 355)
- lysosome:** membrane-bound organelle containing digestive enzymes capable of degrading all the major classes of biological macromolecules. (pp. 91, 352)
- M**
- M line:** dark line running down the middle of the H zone of a striated muscle myofibril. (p. 461)
- M phase:** stage of the eukaryotic cell cycle when the nucleus and the rest of the cell divide. (p. 549)
- macromolecule:** polymer built from small repeating monomer units, with molecular weights ranging from a few thousand to hundreds of millions. (p. 27)
- macrophagy:** process by which an organelle becomes wrapped in a double membrane derived from the endoplasmic reticulum, creating an autophagic vacuole that acquires lysosomal enzymes which degrade the organelle. (p. 354)
- malignant tumor:** tumor that can invade neighboring tissues and spread through the body via fluids, especially the bloodstream, to other parts of the body; also called a cancer. (p. 759)
- MAP:** see *microtubule-associated protein*.
- MAP kinase:** see *mitogen-activated protein kinase*.
- MAPK:** see *mitogen-activated protein kinase*.
- mass spectrometry:** high-speed, extremely sensitive technique that uses magnetic and electric fields to separate proteins or protein fragments based on differences in mass and charge. (pp. 9, 524)
- MAT locus:** site in the yeast genome where the active allele for mating type resides. (p. 726)
- mating bridge:** transient cytoplasmic connection through which DNA is transferred from a male bacterial cell to a female cell during conjugation. (p. 622)
- mating type:** equivalent of sexuality (male or female) in lower organisms, where the molecular properties of a gamete determine the type of gamete it can fuse with. (p. 602)
- matrix:** unstructured semifluid substance that fills the interior of a mitochondrion. (pp. 85, 257)
- maximum ATP yield:** maximum amount of ATP produced per molecule of glucose oxidized by aerobic respiration; usually 38 molecules of ATP for prokaryotic cells and either 36 or 38 for eukaryotic cells. (p. 284)
- maximum velocity (V_{max}):** upper limiting reaction rate approached by an enzyme-catalyzed reaction as the substrate concentration approaches infinity. (p. 139)
- Mb:** megabases; a million base pairs. (p. 517)
- MDR:** see *multidrug resistance transport protein*.
- mechanical work:** use of energy to bring about a physical change in the position or orientation of a cell or some part of it. (p. 107)
- mechanoenzyme:** see *motor protein*.
- medial cisterna:** flattened membrane sac of the Golgi complex located between the membrane tubules of the *cis*-Golgi network and the *trans*-Golgi network. (p. 333)
- Mediator:** large multiprotein complex that functions as a transcriptional coactivator by binding both to activator proteins associated with an enhancer and to RNA polymerase; acts as a central coordinating unit of gene regulation, receiving both positive and negative inputs and transmitting the information to the transcription machinery. (p. 736)
- meiosis:** series of two cell divisions, preceded by a single round of DNA replication, that converts a single diploid cell into four haploid cells (or haploid nuclei). (p. 602)
- meiosis I:** the first meiotic division, which produces two haploid cells with chromosomes composed of sister chromatids. (p. 604)
- meiosis II:** the second meiotic division, which separates the sister chromatids of the haploid cell generated by the first meiotic division. (p. 607)
- membrane:** permeability barrier surrounding and delineating cells and organelles; consists of a lipid bilayer with associated proteins. (pp. 25, 156)
- membrane asymmetry:** a membrane property based on differences between the molecular compositions of the two lipid monolayers and the proteins associated with each. (p. 167)
- membrane potential:** voltage across a membrane created by ion gradients; usually the inside of a cell is negatively charged with respect to the outside. (pp. 196, 367)
- Mendel's laws of inheritance:** principles derived by Mendel from his work on the inheritance of traits in pea plants. (p. 615). Also see *law of segregation* and *law of independent assortment*.
- mesophyll cell:** outer cell in the leaf of a C₄ plant that serves as the site of carbon fixation by the Hatch-Slack cycle. (p. 309)

- messenger RNA (mRNA):** RNA molecule containing the information that specifies the amino acid sequence of one or more polypeptides. (p. 645)
- metabolic pathway:** series of cellular enzymatic reactions that convert one molecule to another via a series of intermediates. (p. 224)
- metabolism:** all chemical reactions occurring within a cell. (p. 224)
- metaphase:** stage during mitosis or meiosis when the chromosomes become aligned at the spindle equator. (p. 573)
- metastable state:** condition where potential reactants are thermodynamically unstable but have insufficient energy to exceed the activation energy barrier for the reaction. (p. 130)
- metastasis:** spread of tumor cells to distant organs via the bloodstream or other body fluids. (p. 762)
- MF:** see *microfilament*.
- Michaelis constant (K_m):** substrate concentration at which an enzyme-catalyzed reaction is proceeding at one-half of its maximum velocity. (p. 141)
- Michaelis-Menten equation:** widely used equation describing the relationship between velocity and substrate concentration for an enzyme-catalyzed reaction:
- $$V = V_{max}[S]/(K_m + [S]).$$
- (p. 141)

microautophagy: process by which lysosomes take up and degrade cytosolic proteins. (p. 752)

microfibril: aggregate of several dozen cellulose molecules laterally crosslinked by hydrogen bonds; serves as a structural component of plant and fungal cell walls. (p. 498)

microfilament (MF): polymer of actin, with a diameter of about 7 nm, that is an integral part of the cytoskeleton, contributing to the support, shape, and motility of eukaryotic cells. (pp. 97, 433)

micrometer (μm): unit of measure: 1 micrometer = 10^{-6} meters. (p. 3)

microphagy: process by which small bits of cytoplasm are surrounded by ER membrane to form an autophagic vesicle whose contents are then digested either by accumulation of lysosomal enzymes or by fusion of the vesicle with a late endosome. (p. 354)

microRNA (miRNA): class of single-stranded RNAs, about 21–22 nucleotides long, produced by cellular genes for the purpose of inhibiting the translation of mRNAs produced by other genes. (p. 750)

microsome: vesicle formed by fragments of endoplasmic reticulum when tissue is homogenized. (p. 326)

microtome: instrument used to slice an embedded biological specimen into thin sections for light microscopy. (p. A-18)

microtubule (MT): polymer of the protein tubulin, with a diameter of about 25 nm, that is an integral part of the cytoskeleton and that contributes to the support, shape, and motility of eukaryotic cells; also found in eukaryotic cilia and flagella. (pp. 97, 424)

microtubule-associated protein (MAP): any of various accessory proteins that bind to microtubules and modulate their assembly, structure, and/or function. (p. 432)

microtubule-organizing center (MTOC): structure that initiates the assembly of microtubules, the primary example being the centrosome. (p. 430)

microvillus (plural, microvilli): fingerlike projection from the cell surface that increases membrane surface area; important in cells that

have an absorption function, such as those that line the intestine. (p. 438)

middle lamella: first layer of the plant cell wall to be synthesized; ends up farthest away from the plasma membrane, where it functions to hold adjacent cells together. (p. 499)

minus end (of microtubule): slower-growing (or non-growing or shrinking) end of a microtubule. (p. 427)

miRISC: complex between microRNA and several proteins that together silence the expression of messenger RNAs containing sequences complementary to those of the microRNA. (p. 750). Also see *siRISC* and *RISC*.

miRNA: see *microRNA*.

mismatch repair: DNA repair mechanism that detects and corrects base pairs that are improperly hydrogen-bonded. (p. 569)

mitochondrion (plural, **mitochondria**): double membrane-enclosed cytoplasmic organelle of eukaryotic cells that is the site of aerobic respiration and hence of ATP generation. (pp. 84, 254)

mitogen-activated protein kinase (MAP kinase, or MAPK): a family of protein kinases that are activated when cells receive a signal to grow and divide. (p. 409)

mitosis: process by which two genetically identical daughter nuclei are produced from one nucleus as the duplicated chromosomes of the parent cell segregate into separate nuclei; usually followed by cell division. (p. 549)

mitotic index: percentage of cells in a population that are in any stage of mitosis at a certain point in time; used to estimate the relative length of the M phase of the cell cycle. (p. 550)

mitotic spindle: microtubular structure responsible for separating chromosomes during mitosis. (p. 572)

mitotic spindle checkpoint: mechanism that halts mitosis at the junction between metaphase and anaphase if chromosomes are not properly attached to the spindle. (p. 587)

MLCK: see *myosin light-chain kinase*.

model organism: an organism that is widely studied, well characterized, easy to manipulate, and has particular advantages for various experimental studies; examples include *E. coli*, yeast, *Drosophila*, *C. elegans*, *Arabidopsis*, and mice. (p. 12)

molecular chaperone: a protein that facilitates the folding of other proteins but is not a component of the final folded structure. (pp. 33, 690)

molecular targeting: development of drugs designed to specifically target molecules that are critical to cancer cells. (p. 790)

monoclonal antibody: a highly purified antibody, directed against a single antigen, that is produced by a cloned population of antibody-producing cells. (p. 789)

monomer: small organic molecule that serves as a subunit in the assembly of a macromolecule. (p. 29)

monomeric protein: protein that consists of a single polypeptide chain. (p. 44)

monosaccharide: simple sugar; the repeating unit of polysaccharides. (p. 61)

motif: region of protein secondary structure consisting of small segments of α helix and/or β sheet connected by looped regions of varying length. (p. 50)

motility (cellular): movement or shortening of a cell, movement of components within a cell, or movement of environmental components past or through a cell. (p. 449)

motor protein (mechanoenzyme): protein that uses energy derived from ATP to change shape

in a way that exerts force and causes attached structures to move; includes three families of proteins (myosin, dynein, and kinesin) that interact with cytoskeletal elements (microtubules and microfilaments) to produce movements. (pp. 449, 576)

MPF: a mitotic Cdk-cyclin complex that drives progression from G2 into mitosis by phosphorylating proteins involved in key stages of mitosis. (p. 583)

mRNA: see *messenger RNA*.

mRNA-binding site: place on the ribosome where mRNA binds during protein synthesis. (p. 680)

MT: see *microtubule*.

MTOC: see *microtubule-organizing center*.

multidrug resistance (MDR) transport protein: an ABC-type ATPase that uses the energy of ATP hydrolysis to pump hydrophobic drugs out of cells. (p. 211)

multimeric protein: protein that consists of two or more polypeptide chains. (p. 44)

multiphoton excitation microscopy: specialized type of fluorescence light microscope employing a laser beam that emits rapid pulses of light; images are similar in sharpness to confocal microscopy, but photodamage is minimized because there is little out-of-focus light. (p. A-12)

multiprotein complex: two or more proteins (usually enzymes) bound together in a way that allows each protein to play a sequential role in the same multistep process. (p. 54)

muscle contraction: generation of tension in muscle cells by the sliding of thin (actin) filaments past thick (myosin) filaments. (p. 460)

muscle fiber: long, thin, multinucleate cell specialized for contraction. (p. 460)

mutagen: chemical or physical agent capable of inducing mutations. (p. 650)

mutation: change in the base sequence of a DNA molecule. (p. 567)

myelin sheath: concentric layers of membrane that surround an axon and serve as electrical insulation that allows rapid transmission of nerve impulses. (p. 366)

myofibril: cylindrical structure composed of an organized array of thin actin filaments and thick myosin filaments; found in the cytoplasm of skeletal muscle cells. (p. 461)

myosin: family of motor proteins that create movements by exerting force on actin microfilaments using energy derived from ATP hydrolysis; makes up the thick filaments that move the actin thin filaments during muscle contraction. (p. 459)

myosin light-chain kinase (MLCK): enzyme that phosphorylates myosin light chains, thereby triggering smooth muscle contraction. (p. 470)

myosin subfragment 1 (S1): proteolytic fragment of myosin that binds to actin microfilaments in a way that yields a distinctive arrowhead pattern, with all the S1 molecules pointing in the same direction. (p. 434)

N

NA: see *numerical aperture*.

Na⁺/glucose symporter: a membrane transport protein that simultaneously transports glucose and sodium ions into cells, with the movement of sodium ions down their electrochemical gradient driving the transport of glucose against its concentration gradient. (p. 213)

Na⁺/K⁺ ATPase: see *Na⁺/K⁺ pump*.

Na⁺/K⁺ pump: membrane carrier protein that couples ATP hydrolysis to the inward transport of potassium ions and the outward transport of

- sodium ions to maintain the Na^+ and K^+ gradients that exist across the plasma membrane of most animal cells. (pp. 213, 369)
- NAD⁺:** see *nicotinamide adenine dinucleotide*.
- NADH-coenzyme Q oxidoreductase:** see *complex I*.
- NADP⁺:** see *nicotinamide adenine dinucleotide phosphate*.
- nanometer (nm):** unit of measure: 1 nanometer = 10^{-9} meters. (p. 3)
- native conformation:** three-dimensional folding of a polypeptide chain into a shape that represents the most stable state for that particular sequence of amino acids. (p. 50)
- negative staining:** technique in which an unstained specimen is visualized in a transmission electron microscope against a darkly stained background. (p. A-22)
- NER:** see *nucleotide excision repair*.
- Nernst equation:** equation for calculating the equilibrium membrane potential for a given ion: $E_x = (RT/zF) \ln[X]_{\text{outside}}/[X]_{\text{inside}}$. (p. 369)
- nerve:** a tissue composed of bundles of axons. (p. 366)
- nerve impulse:** signal transmitted along nerve cells by a wave of depolarization-repolarization events propagated along the axonal membrane. (p. 378)
- NES:** see *nuclear export signal*.
- N-ethylmaleimide-sensitive factor (NSF):** soluble cytoplasmic protein that acts in conjunction with several soluble NSF attachment proteins (SNAPs) to mediate the fusion of membranes brought together by interactions between v-SNAREs and t-SNAREs. (p. 351)
- neuromuscular junction:** site where a nerve cell axon makes contact with a skeletal muscle cell for the purpose of transmitting electrical impulses. (p. 467)
- neuron:** specialized cell directly involved in the conduction and transmission of nerve impulses; nerve cell. (p. 365)
- neuropeptide:** a molecule consisting of a short chain of amino acids that is involved in transmitting signals from neurons to other cells (neurons as well as other cell types). (p. 384)
- neurosecretory vesicle:** a small vesicle containing neurotransmitter molecules; located in the terminal bulb of an axon. (p. 384)
- neurotoxin:** toxic substance that disrupts the transmission of nerve impulses. (p. 385)
- neurotransmitter:** chemical released by a neuron that transmits nerve impulses across a synapse. (p. 381)
- neurotransmitter reuptake:** mechanism for removing neurotransmitters from the synaptic cleft by pumping them back into the presynaptic axon terminals or nearby support cells. (p. 387)
- nexin:** protein that connects and maintains the spatial relationship of adjacent outer doublets in the axoneme of eukaryotic cilia and flagella. (p. 457)
- N-glycosylation:** see *N-linked glycosylation*.
- nicotinamide adenine dinucleotide (NAD⁺):** coenzyme that accepts two electrons and one proton to generate the reduced form, NADH; important electron carrier in energy metabolism. (p. 230)
- nicotinamide adenine dinucleotide phosphate (NADP⁺):** coenzyme that accepts two electrons and one proton to generate the reduced form, NADPH; important electron carrier in the Calvin cycle and other biosynthetic pathways. (p. 302)
- nitric oxide (NO):** a gas molecule that transmits signals to neighboring cells by stimulating guanylyl cyclase. (p. 398)
- N-linked glycosylation (N-glycosylation):** addition of oligosaccharide units to the terminal amino group of asparagine residues in protein molecules. (p. 334)
- NLS:** see *nuclear localization signal*.
- NO:** see *nitric oxide*.
- nocodazole:** synthetic drug that inhibits microtubule assembly; frequently used instead of colchicine because its effects are more readily reversible when the drug is removed. (p. 428)
- nodes of Ranvier:** small segments of bare axon between successive segments of myelin sheath. (p. 366)
- noncovalent bonds and interactions:** binding forces that do not involve the sharing of electrons; examples include ionic bonds, hydrogen bonds, van der Waals interactions, and hydrophobic interactions. (pp. 34, 45)
- noncyclic electron flow:** continuous, unidirectional flow of electrons from water to NADP¹ during the energy transduction reactions of photosynthesis, with light providing the energy that drives the transfer. (p. 306)
- nondisjunction:** failure of the two members of a homologous chromosome pair to separate during anaphase I of meiosis, resulting in a joined chromosome pair that moves into one of the two daughter cells. (p. 609)
- nonhomologous end-joining:** mechanism for repairing double-strand DNA breaks that uses proteins that bind to the ends of the two broken DNA fragments and join the ends together. (p. 570)
- nonreceptor protein kinase:** any protein kinase that is not an intrinsic part of a cell surface receptor. (p. 776)
- nonrepeated DNA:** DNA sequences present in single copies within an organism's genome. (p. 526)
- nonsense-mediated decay:** mechanism for destroying mRNAs containing premature stop codons. (p. 694)
- nonsense mutation:** change in base sequence converting a codon that previously coded for an amino acid into a stop codon. (p. 693)
- nonstop decay:** mechanism for destroying mRNAs containing no stop codons. (p. 694)
- NOR:** see *nucleolus organizer region*.
- Northern blotting:** technique in which RNA molecules are size-fractionated by gel electrophoresis and then transferred to a special type of "blotter" paper (nitrocellulose or nylon), which is then hybridized with a radioactive DNA probe. (p. 733)
- NPC:** see *nuclear pore complex*.
- NSF:** see *N-ethylmaleimide-sensitive factor*.
- N-terminus (amino terminus):** the end of a polypeptide chain that contains the first amino acid to be incorporated during mRNA translation; usually retains a free amino group. (p. 44)
- nuclear envelope:** double membrane around the nucleus that is interrupted by numerous small pores. (pp. 83, 537)
- nuclear export signal (NES):** amino acid sequence that targets a protein for export from the nucleus. (p. 540)
- nuclear lamina:** thin, dense meshwork of fibers that lines the inner surface of the inner nuclear membrane and helps support the nuclear envelope. (p. 542)
- nuclear localization signal (NLS):** amino acid sequence that targets a protein for transport into the nucleus. (p. 540)
- nuclear matrix (nucleoskeleton):** insoluble fibrous network that provides a supporting framework for the nucleus. (p. 542)
- nuclear pore:** small opening in the nuclear envelope through which molecules enter and exit the nucleus; lined by an intricate protein structure called the nuclear pore complex (NPC). (p. 537)
- nuclear pore complex (NPC):** intricate protein structure, composed of 30 or more different polypeptide subunits, that lines the nuclear pores through which molecules enter and exit the nucleus, both by simple diffusion of smaller molecules and active transport of larger molecules. (p. 538)
- nuclear transfer:** experimental technique in which the nucleus from one cell is transferred into another cell (usually an egg cell) whose own nucleus has been removed. (p. 724)
- nucleation:** act of providing a small aggregate of molecules from which a polymer can grow. (p. 427)
- nucleic acid:** a linear polymer of nucleotides joined together in a genetically determined order. Each nucleotide is composed of ribose or deoxyribose, a phosphate group, and the nitrogenous base guanine, cytosine, adenosine, or thymine (for DNA) or uracil (for RNA). (p. 54) Also see *DNA* and *RNA*.
- nucleic acid hybridization:** family of techniques in which single-stranded nucleic acids are allowed to bind to each other by complementary base pairing; used for assessing whether two nucleic acids contain similar base sequences. (p. 516)
- nucleic acid probe:** see *probe*.
- nucleoid:** region of cytoplasm in which the genetic material of a prokaryotic cell is located. (p. 529)
- nucleolus (plural, nucleoli):** large, spherical structure present in the nucleus of a eukaryotic cell; the site of ribosomal RNA synthesis and processing and of the assembly of ribosomal subunits. (pp. 84, 543)
- nucleolus organizer region (NOR):** stretch of DNA in certain chromosomes where multiple copies of the genes for ribosomal RNA are located and where nucleoli form. (p. 544)
- nucleoplasm:** the interior space of the nucleus, other than that occupied by the nucleolus. (p. 537)
- nucleoside:** molecule consisting of a nitrogen-containing base (purine or pyrimidine) linked to a five-carbon sugar (ribose or deoxyribose); a nucleotide with the phosphate removed. (p. 55)
- nucleoside monophosphate:** see *nucleotide*.
- nucleoskeleton (nuclear matrix):** insoluble fibrous network that provides a supporting framework for the nucleus. (p. 542)
- nucleosome:** basic structural unit of eukaryotic chromosomes, consisting of about 200 base pairs of DNA associated with an octamer of histones. (p. 531)
- nucleotide:** molecule consisting of a nitrogen-containing base (purine or pyrimidine) linked to a five-carbon sugar (ribose or deoxyribose) attached to a phosphate group; also called a nucleoside monophosphate. (p. 54)
- nucleotide excision repair (NER):** DNA repair mechanism that recognizes and repairs damage involving major distortions of the DNA double helix, such as that caused by pyrimidine dimers. (p. 569)
- nucleus:** large, double membrane-enclosed organelle that contains the chromosomal DNA of a eukaryotic cell. (pp. 83, 536)
- numerical aperture (NA):** property of a microscope corresponding to the quantity $n \sin \alpha$,

where n is the refractive index of the medium between the specimen and the objective lens and α is the aperture angle. (p. A-4)

O

objective lens (electron microscope): electromagnetic lens within which the specimen is placed in a transmission electron microscope. (p. A-19)

objective lens (light microscope): lens located immediately above the specimen in a light microscope. (p. A-5)

obligate aerobe: organism that has an absolute requirement for oxygen as an electron acceptor and therefore cannot live under anaerobic conditions. (p. 231)

obligate anaerobe: organism that cannot use oxygen as an electron acceptor and therefore has an absolute requirement for an electron acceptor other than oxygen. (p. 231)

ocular lens: lens through which the observer looks in a light microscope; also called the eyepiece. (p. A-6)

OEC: see *oxygen-evolving complex*.

Okazaki fragments: short fragments of newly synthesized, lagging-strand DNA that are joined together by DNA ligase during DNA replication. (p. 558)

oligodendrocyte: cell type in the central nervous system that forms the myelin sheath around nerve axons. (p. 379)

O-linked glycosylation: addition of oligosaccharide units to hydroxyl groups of serine or threonine residues in protein molecules. (p. 334)

oncogene: any gene whose presence can cause cancer; arises by mutation from normal cellular genes called proto-oncogenes. (p. 772)

oncogenic virus: a virus that can cause cancer. (p. 771)

operator (O): base sequence in an operon to which a repressor protein can bind. (p. 712)

operon: cluster of genes with related functions that is under the control of a single operator and promoter, thereby allowing transcription of these genes to be turned on and off together. (p. 712)

optical tweezers: technique in which laser light focused through the objective lens of a microscope traps a small plastic bead, which is then used to manipulate the molecules it is attached to. (p. A-16)

organelle: any membrane-bound, intracellular structure that is specialized for carrying out a particular function. Eukaryotic cells contain several kinds of membrane-enclosed organelles, including the nucleus, mitochondria, Golgi complex, endoplasmic reticulum, lysosomes, peroxisomes, secretory vesicles, and, in the case of plants, chloroplasts. (p. 78)

organic chemistry: the study of carbon-containing compounds. (p. 19)

origin of replication: specific base sequence within a DNA molecule where replication is initiated. (p. 554)

origin of transfer: point on an F-factor plasmid where the transfer of the plasmid from an F⁺ donor bacterial cell to an F⁻ recipient cell begins during conjugation. (p. 622)

osmolarity: solute concentration on one side of a membrane relative to that on the other side of the membrane; drives the osmotic movement of water across the membrane. (p. 200)

osmosis: movement of water through a semipermeable membrane driven by a difference in solute concentration on the two sides of the membrane. (p. 199)

outer doublet: pair of fused microtubules, arranged in groups of nine around the

periphery of the axoneme of a eukaryotic cilium or flagellum. (p. 454)

outer membrane: the outer of the two membranes that surround a mitochondrion, chloroplast, or nucleus. (pp. 255, 295)

ovum (plural, ova): see egg.

oxidation: chemical reaction involving the removal of electrons; oxidation of organic molecules frequently involves the removal of both electrons and hydrogen ions (protons) and is therefore also called a dehydrogenation reaction. (p. 229) Also see *beta oxidation*.

oxidative phosphorylation: formation of ATP from ADP and inorganic phosphate by coupling the exergonic oxidation of reduced coenzyme molecules by oxygen to the phosphorylation of ADP, with an electrochemical proton gradient as the intermediate. (p. 276)

oxygen-evolving complex (OEC): assembly of manganese ions and proteins included within photosystem II that catalyzes the oxidation of water to oxygen. (p. 305)

oxygenic phototroph: organism that utilizes water as the electron donor in photosynthesis, with release of oxygen. (p. 295)

P

P face: interior face of the inner, or cytoplasmic, monolayer of a membrane as revealed by the technique of freeze fracturing; called the P face because this monolayer is on the *protoplasmic* side of the membrane. (p. A-25)

P site (peptidyl site): site on the ribosome that contains the growing polypeptide chain at the beginning of each elongation cycle. (p. 680)

P₁ generation: the first parental generation of a genetic breeding experiment. (p. 613)

p21 protein: Cdk inhibitor that halts progression through the cell cycle by inhibiting several different Cdk-cyclins. (p. 588)

p53 gene: tumor suppressor gene that codes for the p53 protein, a transcription factor involved in preventing genetically damaged cells from proliferating; most frequently mutated gene in human cancers. (p. 778)

p53 protein: transcription factor that accumulates in the presence of damaged DNA and activates genes whose products halt the cell cycle and trigger apoptosis. (p. 588)

P680: the pair of chloroplast molecules that make up the reaction center of photosystem II. (p. 301)

P700: the pair of chloroplast molecules that make up the reaction center of photosystem I. (p. 301)

pachytene: stage during prophase I of meiosis when crossing over between homologous chromosomes takes place. (p. 605)

packing ratio: see *DNA packing ratio*.

Pap smear: screening technique for early detection of cervical cancer in which cells obtained from a sample of vaginal secretions are examined with a microscope. (p. 787)

paracellular transport: a type of cellular transport in which ions move between, rather than through, cells. (p. 486)

passive spread of depolarization: process in which cations (mostly K⁺) move away from the site of membrane depolarization to regions of membrane where the potential is more negative. (p. 378)

patch clamping: technique in which a tiny micropipette placed on the surface of a cell is used to measure the movement of ions through individual ion channels. (p. 372)

P bodies: microscopic structures present in the cytoplasm of eukaryotic cells that are

involved in the storage and degradation of mRNAs. (p. 748)

PC: see *plastocyanin*.

PCR: see *polymerase chain reaction*.

PDGF: see *platelet-derived growth factor*.

pectin: branched polysaccharides, rich in galacturonic acid and rhamnose; found in plant cell walls, where they form a matrix in which cellulose microfibrils are embedded. (p. 498)

pellet: material that sediments to the bottom of a centrifuge tube during centrifugation. (p. 328)

peptide bond: a covalent bond between the amino group of one amino acid and the carboxyl group of a second amino acid. (p. 44)

peptidyl site: see *P site*.

peptidyl transferase: enzymatic activity, exhibited by the rRNA of the large ribosomal subunit, that catalyzes peptide bond formation during protein synthesis. (p. 688)

perinuclear space: space between the inner and outer nuclear membranes that is continuous with the lumen of the endoplasmic reticulum. (p. 537)

peripheral membrane protein: hydrophilic protein bound through weak ionic interactions and hydrogen bonds to a membrane surface. (p. 177)

peroxisome: single membrane-bounded organelle that contains catalase and one or more hydrogen peroxide-generating oxidases and is therefore involved in the metabolism of hydrogen peroxide. (pp. 91, 356) Also see *leaf peroxisome*.

PFK-2: see *phosphofructokinase-2*.

phage: see *bacteriophage*.

phagocyte: specialized white blood cell that carries out phagocytosis as a defense mechanism. (p. 343)

phagocytic vacuole: membrane-bounded structure containing ingested particulate matter that fuses with a late endosome or matures directly into a lysosome, forming a large vesicle in which the ingested material is digested. (p. 343)

phagocytosis: type of endocytosis in which particulate matter or even an entire cell is taken up from the environment and incorporated into vesicles for digestion. (p. 343)

pharmacogenetics: study of how inherited differences in genes cause people to respond differently to drugs and medications. (p. 330)

phase transition: change in the state of a membrane between a fluid state and a gel state. (p. 169)

phase-contrast microscopy: light microscopic technique that improves contrast without sectioning and staining by exploiting differences in thickness and refractive index; produces an image using an optical material that is capable of bringing undiffracted rays into phase with those that have been diffracted by the specimen. (p. A-6)

phenotype: observable physical characteristics of an organism attributable to the expression of its genotype. (p. 601)

phosphatidic acid: basic component of phosphoglycerides; consists of two fatty acids and a phosphate group linked by ester bonds to glycerol; key intermediate in the synthesis of other phosphoglycerides. (p. 69)

phosphoanhydride bond: high-energy bond between phosphate groups. (p. 225)

phosphodiester bridge (3', 5' phosphodiester bridge): covalent linkage in which two parts of a molecule are joined through oxygen atoms to the same phosphate group. (p. 58)

phosphodiesterase: enzyme that catalyzes the hydrolysis of cyclic AMP to AMP. (p. 399)

- phosphoester bond:** covalent linkage in which a molecule is joined through an oxygen atom to a phosphate group. (p. 225)
- phosphofructokinase-2 (PFK-2):** an enzyme that catalyzes the ATP-dependent phosphorylation of fructose-6-phosphate on carbon atom 2 to form fructose-2,6-bisphosphate (F2,6BP), an important regulator of both glycolysis and gluconeogenesis. (p. 245)
- phosphoglyceride:** predominant phospholipid component of cell membranes, consisting of a glycerol molecule esterified to two fatty acids and a phosphate group. (pp. 69, 163)
- phosphoglycolate:** two-carbon compound produced by the oxygenase activity of rubisco. Because it cannot be metabolized during the next step of the Calvin cycle, the production of phosphoglycolate decreases photosynthetic efficiency. (p. 316)
- phospholipase C:** enzyme that catalyzes the hydrolysis of phosphatidylinositol-4,5-bisphosphate into inositol-1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). (p. 401)
- phospholipid:** lipid possessing a covalently attached phosphate group and therefore exhibiting both hydrophilic and hydrophobic properties; main component of the lipid bilayer that forms the structural backbone of all cell membranes. (pp. 69, 163)
- phospholipid exchange protein:** any of a group of proteins located in the cytosol that transfer specific phospholipid molecules from the ER membrane to the outer mitochondrial, chloroplast, or plasma membranes. (p. 332)
- phospholipid translocator (flippase):** a membrane protein that catalyzes the flip-flop of membrane phospholipids from one monolayer to the other. (pp. 169, 331)
- phosphorylation:** addition of a phosphate group. (p. 148)
- photoactivation:** light-induced activation of an inert molecule to an active state; generally associated with the ultraviolet light-induced release of a caging group that had blocked the fluorescence of a molecule that it had been attached to. (p. A-15)
- photoautotroph:** organism capable of obtaining energy from the sun and using this energy to drive the synthesis of energy-rich organic molecules, using carbon dioxide as a source of carbon. (p. 293)
- photobleaching:** technique in which an intense beam of light within a well-defined area is used to render fluorescent molecules non-fluorescent; the rate at which unbleached fluorescent molecules repopulate the bleached area provides information about the dynamic movements of the molecule of interest. (p. A-15)
- photochemical reduction:** transfer of photoexcited electrons from one molecule to another. (p. 298)
- photoexcitation:** excitation of an electron to a higher energy level by the absorption of a photon of light. (p. 297)
- photoheterotroph:** organism capable of obtaining energy from the sun but dependent on organic compounds, rather than carbon dioxide, for carbon. (p. 293)
- photon:** fundamental particle of light with an energy content that is inversely proportional to its wavelength. (p. 297)
- photophosphorylation:** light-dependent generation of ATP driven by an electrochemical proton gradient established and maintained as excited electrons of chlorophyll return to their ground state via an electron transport system. (p. 307)
- photoreduction:** light-dependent generation of NADPH by the transfer of energized electrons from photoexcited chlorophyll molecules to $NADP^+$ via a series of electron carriers. (p. 302)
- photorepiration:** light-dependent pathway that decreases the efficiency of photosynthesis by oxidizing reduced carbon compounds without capturing the released energy; occurs when oxygen substitutes for carbon dioxide in the reaction catalyzed by rubisco, thereby generating phosphoglycolate that is then converted to 3-phosphoglycerate in the peroxisome and mitochondrion; also called the glycolate pathway. (p. 316)
- photosynthesis:** process by which plants and certain bacteria convert light energy to chemical energy that is then used in synthesizing organic molecules. (p. 293)
- photosystem:** assembly of chlorophyll molecules, accessory pigments, and associated proteins embedded in thylakoid membranes or bacterial photosynthetic membranes; functions in the light-requiring reactions of photosynthesis. (p. 300)
- photosystem I (PSI):** photosystem containing a pair of chlorophyll molecules (P700) that absorbs 700-nm red light maximally; light of this wavelength can excite electrons derived from plastocyanin to an energy level that allows them to reduce ferredoxin, from which the electrons are then used to reduce $NADP^+$ to NADPH. (p. 301)
- photosystem II (PSII):** photosystem containing a pair of chlorophyll molecules (P680) that absorb 680-nm red light maximally; light of this wavelength can excite electrons donated by water to an energy level that allows them to reduce plastoquinone. (p. 301)
- photosystem complex:** a photosystem plus its associated light-harvesting complexes. (p. 301)
- phototroph:** organism that is capable of utilizing the radiant energy of the sun to satisfy its energy requirements. (pp. 109, 293)
- phragmoplast:** parallel array of microtubules that guides vesicles containing polysaccharides and glycoproteins toward the spindle equator during cell wall formation in dividing plant cells. (p. 579)
- phycoobilin:** accessory pigment found in red algae and cyanobacteria that absorbs visible light in the green-to-orange range of the spectrum, giving these cells their characteristic colors. (p. 300)
- phycoobilosome:** light-harvesting complex found in red algae and cyanobacteria that contains phycoobilins rather than chlorophyll and carotenoids. (p. 301)
- phytosterol:** any of several sterols that are found uniquely, or primarily, in the membranes of plant cells; examples include campesterol, sitosterol, and stigmasterol. (p. 165)
- PI 3-kinase (PI3K):** enzyme that adds a phosphate group to PIP_2 (phosphatidylinositol-4,5-bisphosphate), thereby converting it to PIP_3 (phosphatidylinositol-3,4,5-trisphosphate); key component of the PI3K-Akt pathway, which is activated in response to the binding of certain growth factors to their receptors. (p. 417)
- PI3K:** see *PI 3-kinase*.
- pigment:** light-absorbing molecule responsible for the color of a substance. (p. 297)
- pilus:** see *sex pilus*.
- PKA:** see *protein kinase A*.
- PKC:** see *protein kinase C*.
- plakin:** family of proteins involved in linking the integrin molecules of a hemidesmosome to intermediate filaments of the cytoskeleton. (p. 495)
- plaque:** dense layer of fibrous material located on the cytoplasmic side of adhesive junctions such as desmosomes, hemidesmosomes, and adherens junctions; composed of intracellular attachment proteins that link the junction to the appropriate type of cytoskeletal filament. (p. 495) The same term can also refer to the clear zone produced when bacterial cells in a small region of a culture dish are destroyed by infection with a bacteriophage. (p. 632)
- plasma membrane:** bilayer of lipids and proteins that defines the boundary of the cell and regulates the flow of materials into and out of the cell; also called the cell membrane. (pp. 82, 156)
- plasmid:** small circular DNA molecule in bacteria that can replicate independent of chromosomal DNA; useful as cloning vectors. (p. 530)
- plasmodesma** (plural, **plasmodesmata**): cytoplasmic channel through pores in the cell walls of two adjacent plant cells, allowing fusion of the plasma membranes and chemical communication between the cells. (pp. 98, 500)
- plasmolysis:** outward movement of water that causes the plasma membrane to pull away from the cell wall in cells that have been exposed to a hypertonic solution. (p. 200)
- plastid:** any of several types of plant cytoplasmic organelles derived from proplastids, including chloroplasts, amyloplasts, chromoplasts, proteinoplasts, and elaioplasts. (pp. 88, 295)
- plastocyanin (PC):** copper-containing protein that donates electrons to chlorophyll P700 of photosystem I in the light-requiring reactions of photosynthesis. (p. 305)
- plastoquinol:** fully reduced form of plastoquinone, involved in the light-requiring reactions of photosynthesis; present in the lipid phase of the photosynthetic membrane, where it transfers electrons to the cytochrome b_6/f complex. (p. 305)
- plastoquinone:** nonprotein (quinone) molecule associated with photosystem II, where it receives electrons from a modified type of chlorophyll called pheophytin during the light-requiring reactions of photosynthesis. (p. 304)
- platelet-derived growth factor (PDGF):** protein produced by blood platelets that stimulates the proliferation of connective tissue and smooth muscle cells. (p. 589)
- plus end (of microtubule):** rapidly growing end of a microtubule. (p. 427)
- plus-end tubulin interacting proteins (+-TIP proteins):** proteins that stabilize the plus ends of microtubules, decreasing the likelihood that microtubules will undergo catastrophic subunit loss. (p. 433)
- pmf:** see *proton motive force*.
- polar body:** tiny haploid cell produced during the meiotic divisions that create egg cells. Polar bodies receive a disproportionately small amount of cytoplasm and usually degenerate. (p. 611)
- polar microtubule:** spindle microtubule that interacts with spindle microtubules from the opposite spindle pole. (p. 573)
- polarity:** property of a molecule that results from part of the molecule having a partial positive charge and another part having a partial negative charge, usually because one region of the molecule possesses one or more electronegative atoms that draw electrons toward that region. (p. 23)
- polarized secretion:** fusion of secretory vesicles with the plasma membrane and expulsion of their contents to the cell exterior specifically localized at one end of a cell. (p. 342)

- poly(A) tail:** stretch of about 50–250 adenine nucleotides added to the 3' end of most eukaryotic mRNAs after transcription is completed. (p. 668)
- polycistronic mRNA:** an mRNA molecule that codes for more than one polypeptide. (p. 712)
- polymerase chain reaction (PCR):** reaction in which a specific segment of DNA is amplified by repeated cycles of (1) heat treatment to separate the two strands of the DNA double helix, (2) incubation with primers that are complementary to sequences located at the two ends of the DNA segment being amplified, and (3) incubation with DNA polymerase to synthesize DNA using the primers as starting points. (p. 560)
- polynucleotide:** linear chain of nucleotides linked by phosphodiester bonds. (p. 58)
- polypeptide:** linear chain of amino acids linked by peptide bonds. (pp. 32, 44)
- polyribosome:** cluster of two or more ribosomes simultaneously translating a single mRNA molecule. (p. 691)
- polysaccharide:** polymer consisting of sugars and sugar derivatives linked together by glycosidic bonds. (p. 60)
- polytene chromosome:** giant chromosome containing multiple copies of the same DNA molecule generated by successive rounds of DNA replication in the absence of cell division. (p. 728)
- porin:** transmembrane protein that forms pores for the facilitated diffusion of small hydrophilic molecules; found in the outer membranes of mitochondria, chloroplasts, and many bacteria. (pp. 205, 255, 297)
- postsynaptic neuron:** a neuron that receives a signal from another neuron through a synapse. (p. 380)
- posttranslational control:** mechanisms of gene regulation involving selective alterations in polypeptides that have already been synthesized; includes covalent modifications, proteolytic cleavage, protein folding and assembly, import into organelles, and protein degradation. (p. 751)
- posttranslational import:** uptake by organelles of completed polypeptide chains after they have been synthesized, mediated by specific targeting signals within the polypeptide. (p. 696)
- posttranslational modifications:** alterations in polypeptides that have already been synthesized; includes covalent modifications such as glycosylation, phosphorylation, or ubiquitylation, as well as proteolytic cleavage and folding. (p. 695)
- precarcinogen:** substance capable of causing cancer only after it has been metabolically activated by enzymes in the liver. (p. 767)
- pre-mRNA:** primary transcript whose processing yields a mature mRNA. (p. 668)
- pre-replication complex:** group of proteins that bind to eukaryotic DNA and license it for replication; includes the Origin Recognition Complex, MCM complex, and helicase loaders. (p. 554)
- pre-rRNA:** primary transcript whose processing yields mature rRNAs. (p. 665)
- presynaptic neuron:** a neuron that transmits a signal to another neuron through a synapse. (p. 380)
- pre-tRNA:** primary transcript whose processing yields a mature tRNA. (p. 666)
- primary cell wall:** flexible portion of the plant cell wall that develops beneath the middle lamella while cell growth is still occurring; contains a loosely organized network of cellulose microfibrils. (p. 499)
- primary structure:** sequence of amino acids in a polypeptide chain. (p. 47)
- primary transcript:** any RNA molecule newly produced by transcription, before any processing has occurred. (p. 665)
- primase:** enzyme that uses a single DNA strand as a template to guide the synthesis of the RNA primers that are required for initiation of replication of both the lagging and leading strands of a DNA double helix. (p. 561)
- primosome:** complex of proteins in bacterial cells that includes primase plus six other proteins involved in unwinding DNA and recognizing base sequences where replication is to be initiated. (p. 561)
- prion:** infectious, protein-containing particle responsible for neurological diseases such as scrapie in sheep and goats, kuru in humans, and mad cow disease in cattle—and its human form, vCJD. (pp. 101, 692)
- probe (nucleic acid):** single-stranded nucleic acid that is used in hybridization experiments to identify nucleic acids containing sequences that are complementary to the probe. (pp. 517, 633)
- procaspase:** an inactive precursor form of a caspase. (p. 593)
- procollagen:** a precursor molecule that is converted to collagen by proteolytic cleavage of sequences at both the N- and C-terminal ends. (p. 490)
- progression:** see *tumor progression*.
- projector lens:** electromagnetic lens located between the intermediate lens and the viewing screen in a transmission electron microscope. (p. A-19)
- prokaryote:** category of organisms characterized by the absence of a true nucleus and other membrane-bound organelles; includes bacteria and archaea. (p. 75)
- prometaphase:** stage of mitosis characterized by nuclear envelope breakdown and attachment of chromosomes to spindle microtubules; also called late prophase. (p. 572)
- promoter (site):** base sequence in DNA to which RNA polymerase binds when initiating transcription [PPA6]. (pp. 657, 712)
- promotion (stage of carcinogenesis):** gradual process by which cells previously exposed to an initiating carcinogen are subsequently converted into cancer cells by agents that stimulate cell proliferation. (p. 769)
- proofreading:** removal of mismatched base pairs during DNA replication by the exonuclease activity of DNA polymerase. (p. 559)
- propagation:** movement of an action potential along a membrane away from the site of origin. (p. 375)
- prophase:** initial phase of mitosis, characterized by chromosome condensation and the beginning of spindle assembly. Prophase I of meiosis is more complex, consisting of stages called leptotene, zygotene, pachytene, diplotene, and diakinesis. (p. 572)
- proplastid:** small, double-membrane-enclosed, plant cytoplasmic organelle that can develop into several kinds of plastids, including chloroplasts. (p. 295)
- prosthetic group:** small organic molecule or metal ion component of an enzyme that plays an indispensable role in the catalytic activity of the enzyme. (p. 132)
- proteasome:** multiprotein complex that catalyzes the ATP-dependent degradation of proteins linked to ubiquitin. (p. 751)
- protein:** macromolecule that consists of one or more polypeptides folded into a conformation specified by the linear sequence of amino acids. Proteins play important roles as enzymes, structural proteins, motility proteins, and regulatory proteins. (p. 41)
- protein disulfide isomerase:** enzyme in the ER lumen that catalyzes the formation and breakage of disulfide bonds between cysteine residues in polypeptide chains. (p. 699)
- protein kinase:** any of numerous enzymes that catalyze the phosphorylation of protein molecules. (p. 148)
- protein kinase A (PKA):** a protein kinase, activated by the second messenger cyclic AMP, that catalyzes the phosphorylation of serine or threonine residues in target proteins. (p. 396)
- protein kinase C (PKC):** enzyme that phosphorylates serine and threonine groups in a variety of target proteins when activated by diacylglycerol. (p. 401)
- protein phosphatase:** any of numerous enzymes that catalyze the dephosphorylation, or removal by hydrolysis, of phosphate groups from a variety of target proteins. (p. 148)
- proteoglycan:** complex between proteins and glycosaminoglycans found in the extracellular matrix. (p. 491)
- proteolysis:** degradation of proteins by hydrolysis of the peptide bonds between amino acids. (p. 266)
- proteolytic cleavage:** removal of a portion of a polypeptide chain, or cutting a polypeptide chain into two fragments, by an enzyme that cleaves peptide bonds. (p. 149)
- proteome:** the structure and properties of all the proteins produced by a genome. (p. 524)
- protoeukaryote:** hypothetical evolutionary ancestor of present-day eukaryotic cells whose ability to carry out phagocytosis allowed it to engulf and establish an endosymbiotic relationship with primitive bacteria. (p. 299)
- protofilament:** linear polymer of tubulin subunits; usually arranged in groups of 13 to form the wall of a microtubule. (p. 426)
- proton motive force (pmf):** force across a membrane exerted by an electrochemical proton gradient that tends to drive protons back down their concentration gradient. (p. 279)
- proton translocator:** channel through which protons flow across a membrane driven by an electrochemical gradient; examples include CF_o in thylakoid membranes and F_o in mitochondrial inner membranes. (pp. 280, 307)
- proto-oncogene:** normal cellular gene that can be converted into an oncogene by point mutation, gene amplification, chromosomal translocation, local DNA rearrangement, or insertional mutagenesis. (p. 772)
- provacuole:** vesicle in plant cells comparable to an endosome in animal cells; arises either from the Golgi complex or by autophagy. (p. 355)
- proximal control element:** DNA regulatory sequence located upstream of the core promoter but within about 100–200 base pairs of it. (p. 734)
- PSA test:** screening technique for early detection of prostate cancer that measures how much prostate-specific antigen (PSA) is present in the blood. (p. 787)
- pseudopodium (plural, pseudopodia):** large, blunt-ended cytoplasmic protrusion involved in cell crawling by amoebas, slime molds, and leukocytes. (p. 473)
- PSI:** see *photosystem I*.
- PSII:** see *photosystem II*.
- PTEN:** phosphatase that removes a phosphate group from PIP₃ (phosphatidylinositol-3,4,5-trisphosphate), thereby converting it to PIP₂ (phosphatidylinositol-4,5-bisphosphate); component of the PI3K-Akt pathway. (p. 417)

P-type ATPase: type of transport ATPase that is reversibly phosphorylated by ATP as part of the transport mechanism. (p. 210)

Puma (p53 upregulated modulator of apoptosis): protein that triggers apoptosis by binding to and inactivating Bcl-2, an inhibitor of apoptosis. (p. 588)

purine: two-ringed nitrogen-containing molecule; parent compound of the bases adenine and guanine. (p. 55)

pyrimidine: single-ringed nitrogen-containing molecule; parent compound of the bases cytosine, thymine, and uracil. (p. 55)

Q

Q cycle: proposed pathway for recycling electrons during mitochondrial or chloroplast electron transport to allow additional proton pumping across the membrane containing the electron carriers. (pp. 275, 305)

quantum: indivisible packet of energy carried by a photon of light. (p. 297)

quaternary structure: level of protein structure involving interactions between two or more polypeptide chains to form a single multimeric protein. (p. 54)

R

Rab GTPase: GTP-hydrolyzing protein involved in locking v-SNAREs and t-SNAREs together during the binding of a transport vesicle to an appropriate target membrane. (p. 351)

Rac: member of a family of monomeric G proteins, which also includes Rho and Cdc42, that stimulate formation of various actin-containing structures within cells. (p. 440)

radial spokes: inward projections from each of the nine outer doublets to the center pair of microtubules in the axoneme of a eukaryotic cilium or flagellum, believed to be important in converting the sliding of the doublets into a bending of the axoneme. (p. 456)

Ras (protein): a small, monomeric G protein bound to the inner surface of the plasma membrane; Ras is a key intermediate in transmitting signals from receptor tyrosine kinases to the cell interior. (p. 408)

rate-zonal centrifugation: see *density gradient centrifugation*.

RB gene: tumor suppressor gene coding for the Rb protein. (p. 778)

Rb protein: protein whose phosphorylation controls passage through the restriction point of the cell cycle. (p. 587)

reaction center: portion of a photosystem containing the two chlorophyll molecules that initiate electron transfer, utilizing the energy gathered by other chlorophyll molecules and accessory pigments. (p. 301) Also see *P680* and *P700*.

reactive oxygen species: highly reactive oxygen-containing compounds such as H_2O_2 , superoxide anion, and hydroxyl radical that are formed in the presence of molecular oxygen and can damage cells by oxidizing cellular components (p. 358)

receptor: a protein that contains a binding site for a specific signaling molecule. (p. 392)

receptor affinity: a measure of the chemical attraction between a receptor and its ligand. (p. 394)

receptor tyrosine kinase (RTK): a receptor whose activation causes it to catalyze the phosphorylation of tyrosine residues in proteins, thereby triggering a chain of signal transduction events inside cells that can lead to cell growth, proliferation, and differentiation. (p. 407)

receptor-mediated (clathrin-dependent) endocytosis: type of endocytosis initiated at coated pits and resulting in coated vesicles; believed to be a major mechanism for selective uptake of macromolecules and peptide hormones. (p. 343)

recessive (allele): allele that is present in the genome but is phenotypically expressed only in the homozygous form; masked by a dominant allele when heterozygous. (p. 601)

recombinant DNA molecule: DNA molecule containing DNA sequences derived from two different sources. (p. 629)

recombinant DNA technology: group of laboratory techniques for joining DNA fragments derived from two or more sources. (pp. 10, 628)

redox pair: two molecules or ions that are interconvertible by the loss or gain of electrons; also called a reduction-oxidation pair. (p. 272)

reduction: chemical reaction involving the addition of electrons; reduction of organic molecules frequently involves the addition of both electrons and hydrogen ions (protons) and is therefore also called a hydrogenation reaction. (p. 229)

reduction-oxidation pair: see *redox pair*.

refractive index: measure of the change in the velocity of light as it passes from one medium to another. (p. A-3)

regulated secretion: fusion of secretory vesicles with the plasma membrane and expulsion of their contents to the cell exterior in response to specific extracellular signals. (p. 341)

regulators of G protein signaling (RGS) proteins: group of proteins that stimulate GTP hydrolysis by the G_a subunit of G proteins. (p. 397)

regulatory light chain: type of myosin light chain that is phosphorylated by myosin light-chain kinase in smooth muscle cells, thereby enabling myosin to interact with actin filaments and triggering muscle contraction. (p. 470)

regulatory site: see *allosteric site*.

regulatory subunit: a subunit of a multisubunit enzyme that contains an allosteric site. (p. 147)

regulatory transcription factor: protein that controls the rate at which one or more specific genes are transcribed by binding to DNA control elements located outside the core promoter. (p. 734)

relative refractory period: time during the hyperpolarization phase of an action potential when the sodium channels of a nerve cell are capable of opening again, but it is difficult to trigger an action potential because Na^+ currents are opposed by larger K^+ currents. (p. 377)

release factors: group of proteins that terminate translation by triggering the release of a completed polypeptide chain from peptidyl tRNA bound to a ribosome's P site. (p. 690)

renaturation: return of a protein from a denatured state to the native conformation determined by its amino acid sequence, usually accompanied by restoration of physiological function. (p. 32) Also see *DNA renaturation*.

repeated DNA: DNA sequences present in multiple copies within an organism's genome. (p. 525)

replication fork: Y-shaped structure that represents the site at which replication of a DNA double helix is occurring. (p. 553)

replicon: total length of DNA replicated from a single origin of replication. (p. 554)

replicosome: large complex of proteins that work together to carry out DNA replication at the

replication fork; about the size of a ribosome. (p. 564)

repressible operon: group of adjoining genes that are normally transcribed, but whose transcription is inhibited in the presence of a corepressor. (p. 717)

repressor protein (eukaryotic): regulatory transcription factor whose binding to DNA control elements leads to a reduction in the transcription rate of nearby genes. (p. 736)

repressor protein (bacterial): protein that binds to the operator site of an operon and prevents transcription of adjacent structural genes. (p. 712)

residual body: mature lysosome in which digestion has ceased and only indigestible material remains. (p. 354)

resolution: minimum distance that can separate two points that still remain identifiable as separate points when viewed through a microscope. (p. A-3)

resolving power: ability of a microscope to distinguish adjacent objects as separate entities. (p. 6)

resonance energy transfer: mechanism whereby the excitation energy of a photoexcited molecule is transferred to an electron in an adjacent molecule, exciting that electron to a high-energy orbital; important means of passing energy from one pigment molecule to another in photosynthetic energy transduction. (p. 298)

resonance hybrid: the actual structure of functional groups such as carboxylate or phosphate groups that are written formally as two or more structures with one double bond and one or more single bonds to oxygen when the unshared electron pair is, in fact, delocalized over all of the possible bonds to oxygen; written as single bonds to all possible oxygen atoms and dashed lines indicating delocalization of one electron pair. (p. 226)

resonance stabilization: achievement of the most stable configuration of a molecule by maximal delocalization of an unshared electron pair over all possible bonds. (p. 226)

respirasome: group of respiratory complexes associated together in defined ratios. (p. 276)

respiratory complex: subset of carriers of the electron transport system consisting of a distinctive assembly of polypeptides and prosthetic groups, organized together to play a specific role in the electron transport process. (p. 274)

respiratory control: regulation of oxidative phosphorylation and electron transport by the availability of ADP. (p. 276)

response element: DNA base sequence located adjacent to physically separate genes whose expression can then be coordinated by binding a regulatory transcription factor to the response element wherever it occurs. (p. 741)

resting membrane potential (V_m): electrical potential (voltage) across the plasma membrane of an unstimulated nerve cell. (p. 367)

restriction endonuclease: any of a large family of enzymes isolated from bacteria that cut foreign DNA molecules at or near a palindromic recognition sequence that is usually 4 or 6 (but may be 8 or more) base pairs long; used in recombinant DNA technology to cleave DNA molecules at specific sites. (p. 518)

restriction fragment length polymorphism (RFLP): difference in restriction maps between individuals caused by small differences in the base sequences of their DNA. (p. 528)

- restriction map:** map of a DNA molecule indicating the location of cleavage sites for various restriction endonucleases. (p. 520)
- restriction/methylation system:** pathway in bacterial cells by which foreign DNA is cleaved by restriction endonucleases while the bacterial genome is protected from cleavage by prior methylation. (p. 520)
- restriction point:** control point near the end of G1 phase of the cell cycle where the cycle can be halted until conditions are suitable for progression into S phase; regulated to a large extent by the presence or absence of extracellular growth factors; called *Start* in yeast. (p. 581)
- restriction site:** DNA base sequence, usually 4 or 6 (but may be 8 or more) base pairs long, that is cleaved by a specific restriction endonuclease. (p. 518)
- retrograde flow (of F-actin):** bulk movement of actin microfilaments toward the rear of a cell protrusion (e.g., lamellipodium) as the protrusion extends. (p. 471)
- retrograde transport:** movement of vesicles from Golgi cisternae back toward the endoplasmic reticulum. (p. 334)
- retrotransposon:** type of transposable element that moves from one chromosomal site to another by a process in which the retrotransposon DNA is first transcribed into RNA, and reverse transcriptase then uses the RNA as a template to make a DNA copy that is integrated into the chromosomal DNA at another site. (p. 649)
- retrovirus:** any RNA virus that uses reverse transcriptase to make a DNA copy of its RNA. (p. 648)
- reverse transcriptase:** enzyme that uses an RNA template to synthesize a complementary molecule of double-stranded DNA. (p. 648)
- reversible inhibitor:** molecule that causes a reversible loss of catalytic activity when bound to an enzyme; upon dissociation of the inhibitor, the enzyme regains biological function. (p. 145)
- RFLP:** see *restriction fragment length polymorphism*.
- RGS proteins:** see *regulators of G protein signaling proteins*.
- Rho GTPases:** a family of monomeric G proteins, which includes Rho, Rac and Cdc42, that stimulate formation of various actin-containing structures within cells. (p. 440)
- Rho:** member of a family of monomeric G proteins, which also includes Rac and Cdc42, that stimulate formation of various actin-containing structures within cells. (p. 440)
- rho (ρ) factor:** bacterial protein that binds to the 3' end of newly forming RNA molecules, triggering the termination of transcription. (p. 659)
- ribonucleic acid:** see *RNA*.
- ribose:** five-carbon sugar present in RNA and in important nucleoside triphosphates such as ATP and GTP. (p. 54)
- ribosomal RNA (rRNA):** any of several types of RNA molecules used in the construction of ribosomes. (p. 645)
- ribosome:** small particle composed of rRNA and protein that functions as the site of protein synthesis in the cytoplasm of prokaryotes and in the cytoplasm, mitochondria, and chloroplasts of eukaryotes; composed of large and small subunits. (pp. 94, 679)
- riboswitch:** site in mRNA to which a small molecule can bind, triggering changes in mRNA conformation that impact either transcription or translation. (p. 721)
- ribozyme:** an RNA molecule with catalytic activity. (p. 150)
- ribulose-1,5-bisphosphate carboxylase/oxygenase:** see *rubisco*.
- RISC:** complex between either siRNA or microRNA and several proteins that together silence the expression of messenger RNAs or genes containing sequences complementary to those of these RNAs; abbreviation for RNA-induced silencing complex. (p. 749) Also see *miRISC* and *siRISC*.
- RNA (ribonucleic acid):** nucleic acid that plays several different roles in the expression of genetic information; constructed from nucleotides consisting of ribose phosphate linked to adenine, uracil, cytosine, or guanine. (p. 54) Also see *messenger RNA*, *ribosomal RNA*, *transfer RNA*, *microRNA*, *snRNA*, and *snoRNA*.
- RNA editing:** altering the base sequence of an mRNA molecule by the insertion, removal, or modification of nucleotides. (p. 674)
- RNA interference (RNAi):** ability of short RNA molecules (siRNAs or microRNAs) to inhibit gene expression by triggering the degradation or inhibiting the translation of specific mRNAs, or inhibiting transcription of the gene coding for a particular mRNA. (p. 748)
- RNA polymerase:** any of a group of enzymes that catalyze the synthesis of RNA using DNA as a template; function by adding successive nucleotides to the 3' end of the growing RNA strand. (p. 656)
- RNA polymerase I:** type of eukaryotic RNA polymerase present in the nucleolus that synthesizes an RNA precursor for three of the four types of rRNA. (p. 661)
- RNA polymerase II:** type of eukaryotic RNA polymerase present in the nucleoplasm that synthesizes pre-mRNA, microRNA, and most of the snRNAs. (p. 661)
- RNA polymerase III:** type of eukaryotic RNA polymerase present in the nucleoplasm that synthesizes a variety of small RNAs, including pre-tRNAs and 5S rRNA. (p. 661)
- RNA primer:** short RNA fragment, synthesized by DNA primase, that serves as an initiation site for DNA synthesis. (p. 561)
- RNA processing:** conversion of an initial RNA transcript into a final RNA product by the removal, addition, and/or chemical modification of nucleotide sequences. (p. 665)
- RNA splicing:** excision of introns from a primary RNA transcript to generate the mature, functional form of the RNA molecule. (p. 670)
- RNAi:** see *RNA interference*.
- rotation (of lipid molecules):** turning of a molecule about its long axis; occurs freely and rapidly in membrane phospholipids. (p. 167)
- rough endoplasmic reticulum (rough ER):** endoplasmic reticulum that is studded with ribosomes on its cytosolic side because of its involvement in protein synthesis. (pp. 90, 325)
- rough ER:** see *rough endoplasmic reticulum*.
- rRNA:** see *ribosomal RNA*.
- RTK:** see *receptor tyrosine kinase*.
- rubisco (ribulose-1,5-bisphosphate carboxylase/oxygenase):** enzyme that catalyzes the CO₂-capturing step of the Calvin cycle; joins CO₂ to ribulose-1,5-bisphosphate, forming two molecules of 3-phosphoglycerate. (p. 311)
- rubisco activase:** protein that stimulates photosynthetic carbon fixation by rubisco by removing inhibitory sugar phosphates from the rubisco active site. (p. 313)
- S**
- S:** see *entropy*.
- S:** see *substrate concentration* and *Svedberg unit*.
- S phase:** stage of the eukaryotic cell cycle in which DNA is synthesized. (p. 550)
- S1:** see *myosin subfragment 1*.
- sarcoma:** any cancer arising from a supporting tissue, such as bone, cartilage, fat, connective tissue, and muscle. (p. 758)
- sarcomere:** fundamental contractile unit of striated muscle myofibrils that extends from one Z line to the next and that consists of two sets of thin (actin) and one set of thick (myosin) filaments. (p. 461)
- sarcoplasmic reticulum (SR):** endoplasmic reticulum of a muscle cell, specialized for accumulating, storing, and releasing calcium ions. (p. 467)
- saturated fatty acid:** fatty acid without double or triple bonds such that every carbon atom in the chain has the maximum number of hydrogen atoms bonded to it. (p. 68)
- saturation:** inability of higher substrate concentrations to increase the velocity of an enzyme-catalyzed reaction beyond a fixed upper limit determined by the finite number of enzyme molecules available. (p. 139)
- scanning electron microscope (SEM):** microscope in which an electron beam scans across the surface of a specimen and forms an image from electrons that are deflected from the outer surface of the specimen. (pp. 8, A-20)
- scanning probe microscope:** instrument that visualizes the surface features of individual molecules by using a tiny probe that moves over the surface of a specimen. (p. A-26)
- Schwann cell:** cell type in the peripheral nervous system that forms the myelin sheath around nerve axons. (p. 379)
- second law of thermodynamics:** the law of thermodynamic spontaneity; principle stating that all physical and chemical changes proceed in a manner such that the entropy of the universe increases. (p. 114)
- second messenger:** any of several substances, including cyclic AMP, calcium ion, inositol triphosphate, and diacylglycerol, that transmit signals from extracellular signaling ligands to the cell interior. (p. 393)
- secondary cell wall:** rigid portion of the plant cell wall that develops beneath the primary cell wall after cell growth has ceased; contains densely packed, highly organized bundles of cellulose microfibrils. (p. 499)
- secondary structure:** level of protein structure involving hydrogen bonding between atoms in the peptide bonds along the polypeptide backbone, creating two main patterns called the α helix and β sheet conformations. (p. 48)
- secretory granule:** a large, dense secretory vesicle. (p. 339)
- secretory pathway:** pathway by which newly synthesized proteins move from the ER through the Golgi complex to secretory vesicles and secretory granules, which then discharge their contents to the exterior of the cell. (p. 339)
- secretory vesicle:** membrane-bounded compartment of a eukaryotic cell that carries secretory proteins from the Golgi complex to the plasma membrane for exocytosis and that may serve as a storage compartment for such proteins before they are released; large, dense vesicles are sometimes referred to as secretory granules. (pp. 90, 339)
- securin:** protein that prevents sister chromatid separation by inhibiting separase, the enzyme

- that would otherwise degrade the cohesins that hold sister chromatids together. (p. 585)
- sedimentation coefficient:** a measure of the rate at which a particle or macromolecule moves in a centrifugal force field; expressed in Svedberg units. (pp. 95, 327)
- sedimentation rate:** rate of movement of a molecule or particle through a solution when subjected to a centrifugal force. (p. 327)
- selectable marker:** gene whose expression allows cells to grow under specific conditions that prevent the growth of cells lacking this gene. (p. 632)
- selectin:** plasma membrane glycoprotein that mediates cell-cell adhesion by binding to specific carbohydrate groups located on the surface of target cells. (p. 480)
- self-assembly:** principle that the information required to specify the folding of macromolecules and their interactions to form more complicated structures with specific biological functions is inherent in the polymers themselves. (p. 32)
- SEM:** see *scanning electron microscope*.
- semiautonomous organelle:** organelle, either a mitochondrion or a chloroplast, that contains DNA and is therefore able to encode some of its polypeptides, although it is dependent on the nuclear genome to encode most of them. (p. 298)
- semiconservative replication:** mode of DNA replication in which each newly formed DNA molecule consists of one old strand and one newly synthesized strand. (p. 551)
- separate:** protease that initiates anaphase by degrading the cohesins that hold sister chromatids together. (p. 586)
- serine-threonine kinase receptor:** a receptor that, upon activation, catalyzes the phosphorylation of serine and threonine residues in target protein molecules. (p. 413)
- 70S initiation complex:** complex formed by the association of a 30S initiation complex with a 50S ribosomal subunit; contains an initiator aminoacyl tRNA at the P site and is ready to commence mRNA translation. (p. 686)
- sex chromosome:** chromosome involved in determining whether an individual is male or female. (p. 601)
- sex pilus (plural, pili):** projection emerging from the surface of a bacterial donor cell that binds to the surface of a recipient cell, leading to the formation of a transient cytoplasmic mating bridge through which DNA is transferred from donor cell to recipient cell during bacterial conjugation. (p. 622)
- sexual reproduction:** form of reproduction in which two parent organisms each contribute genetic information to the new organism; reproduction by the fusion of gametes. (p. 600)
- SH2 domain:** a region of a protein molecule that recognizes and binds to phosphorylated tyrosines in another protein. (p. 408)
- shadowing:** deposition of a thin layer of an electron-dense metal on a biological specimen from a heated electrode, such that surfaces facing toward the electrode are coated while surfaces facing away are not. (p. A-23)
- sheet (β sheet):** see *beta sheet*.
- short interfering RNA:** see *siRNA*.
- short tandem repeat (STR):** short repeated DNA sequences whose variation in length between individuals forms the basis for DNA fingerprinting. (p. 529)
- sidearm:** structure composed of axonemal dynein that projects out from each of the A tubules of the nine outer doublets in the axoneme of a eukaryotic cilium or flagellum. (p. 456)
- sigma (s) factor:** subunit of bacterial RNA polymerase that ensures the initiation of RNA synthesis at the correct site on the DNA strand. (p. 656)
- signal recognition particle (SRP):** cytoplasmic RNA-protein complex that binds to the ER signal sequence located at the N-terminus of a newly forming polypeptide chain and directs the ribosome-mRNA-polypeptide complex to the surface of the ER membrane. (p. 699)
- signal transduction:** mechanisms by which signals detected at the cell surface are transmitted into the cell's interior, resulting in changes in cell behavior and/or gene expression. (p. 393)
- silencer:** DNA sequence containing a binding site for transcription factors that inhibit transcription and whose position and orientation relative to the promoter can vary significantly without interfering with the ability to regulate transcription. (p. 734)
- simple diffusion:** unassisted net movement of a solute from a region where its concentration is higher to a region where its concentration is lower. (p. 197)
- SINEs (short interspersed nuclear elements):** class of interspersed, repeated DNA sequences less than 500 base pairs in length that function as transposable elements, relying on enzymes made by other mobile elements for their movement; include *Alu* sequences, the most prevalent SINE in humans. (p. 527)
- single bond:** chemical bond formed between two atoms as a result of sharing a pair of electrons. (p. 19)
- single nucleotide polymorphisms (SNPs):** variations in DNA base sequence involving single base changes that occur among individuals of the same species. (p. 524)
- single-stranded DNA binding protein (SSB):** protein that binds to single strands of DNA at the replication fork to keep the DNA unwound and therefore accessible to the DNA replication machinery. (p. 562)
- siRISC:** complex between siRNA and several proteins that together silence the expression of messenger RNAs or genes containing sequences complementary to those of the siRNA. (p. 749) Also see *miRISC* and *RISC*.
- siRNA:** class of double-stranded RNAs about 21–22 nucleotides in length that silence gene expression; act by either promoting the degradation of mRNAs with precisely complementary sequences or by inhibiting the transcription of genes containing precisely complementary sequences. (p. 749)
- sister chromatids:** the two replicated copies of each chromosome that remain attached to each other prior to anaphase of mitosis. (p. 549)
- site-specific mutagenesis:** technique for altering the DNA base sequence at a particular location in the genome, thereby creating a specific mutation whose effects can be studied. (p. 182)
- skeletal muscle:** type of muscle, striated in microscopic appearance, that is responsible for voluntary movements. (p. 460)
- Slicer:** ribonuclease present in RISC that cleaves mRNA at the site where the RISC has become bound. (p. 749)
- sliding-filament model:** model stating that muscle contraction is caused by thin actin filaments sliding past thick myosin filaments, with no change in the length of either type of filament. (p. 463)
- sliding-microtubule model:** model of motility in eukaryotic cilia and flagella which proposes that microtubule length remains unchanged but adjacent outer doublets slide past each other, thereby causing a localized bending because lateral connections between adjacent doublets and radial links to the center pair prevent free sliding of the microtubules past each other. (p. 457)
- Smad (protein):** class of proteins involved in the signaling pathway triggered by transforming growth factor β ; upon activation, Smads enter the nucleus and regulate gene expression. (p. 413)
- small ribosomal subunit:** component of a ribosome with a sedimentation coefficient of 40S in eukaryotes and 30S in prokaryotes; associates with a large ribosomal subunit to form a functional ribosome. (p. 95)
- smooth endoplasmic reticulum (smooth ER):** endoplasmic reticulum that has no attached ribosomes and plays no direct role in protein synthesis; involved in packaging of secretory proteins and synthesis of lipids. (pp. 90, 325)
- smooth ER:** see *smooth endoplasmic reticulum*.
- smooth muscle:** muscle lacking striations that is responsible for involuntary contractions such as those of the stomach, intestines, uterus, and blood vessels. (p. 469)
- SNAP:** see *soluble NSF attachment protein*.
- SNAP receptor protein:** see *SNARE protein*.
- SNARE (SNAP receptor) protein:** two families of proteins involved in targeting and sorting membrane vesicles; include the v-SNARES found on transport vesicles and the t-SNARES found on target membranes. (p. 351)
- SNARE hypothesis:** model explaining how membrane vesicles fuse with the proper target membrane; based on specific interactions between v-SNAREs (vesicle-SNAP receptors) and t-SNAREs (target-SNAP receptors). (p. 351)
- snoRNA:** group of small nucleolar RNAs that bind to complementary regions of pre-rRNA and target specific sites for methylation or cleavage. (p. 665)
- SNPs:** see *single nucleotide polymorphisms*.
- snRNA:** a small nuclear RNA molecule that binds to specific proteins to form a snRNP, which in turn assembles with other snRNPs to form a spliceosome. (p. 671)
- snRNP:** RNA-protein complex that assembles with other snRNPs to form a spliceosome; pronounced "snurp." (p. 671)
- sodium/potassium pump:** see Na^+/K^+ pump.
- soluble NSF attachment protein (SNAP):** soluble cytoplasmic protein that acts in conjunction with NSF (N-ethylmaleimide-sensitive factor) to mediate the fusion of membranes brought together by interactions between v-SNAREs and t-SNAREs. (p. 351)
- solute:** substance that is dissolved in a solvent, forming a solution. (p. 24)
- solvent:** substance, usually liquid, in which other substances are dissolved, forming a solution. (p. 24)
- Sos (protein):** a guanine-nucleotide exchange factor that activates Ras by triggering the release of GDP, thereby permitting Ras to acquire a molecule of GTP. The Sos protein is activated by interacting with a GRB2 protein molecule that has become bound to phosphorylated tyrosines in an activated tyrosine kinase receptor. (p. 408)
- Southern blotting:** technique in which DNA fragments separated by gel electrophoresis are transferred to a special type of "blotter" paper

- (nitrocellulose or nylon), which is then hybridized with a radioactive DNA probe. (p. 529)
- special pair:** two chlorophyll *a* molecules, located in the reaction center of a photosystem, that catalyze the conversion of solar energy into chemical energy. (p. 301)
- specific heat:** amount of heat needed to raise the temperature of 1 gram of a substance 1°C. (p. 23)
- sperm:** haploid male gamete, usually flagellated. (p. 602)
- sphingolipid:** class of lipids containing the amine alcohol sphingosine as a backbone. (pp. 69, 163)
- sphingosine:** amine alcohol that serves as the backbone for sphingolipids; contains an amino group that can form an amide bond with a long-chain fatty acid; also contains a hydroxyl group that can attach to a phosphate group. (p. 69)
- spliceosome:** protein-RNA complex that catalyzes the removal of introns from pre-mRNA. (p. 671)
- spore:** see *haploid spore*.
- sporophyte:** diploid generation in the life cycle of an organism that alternates between haploid and diploid forms; form that produces spores by meiosis. (p. 603)
- sputter coating:** vacuum evaporation process used to coat the surface of a specimen with a layer of gold or a mixture of gold and palladium prior to examining the specimen by scanning electron microscopy. (p. A-26)
- squid giant axon:** an exceptionally large axon emerging from certain squid nerve cells; its wide diameter (0.5–1.0 mm) makes it relatively easy to insert microelectrodes that can measure and control electrical potentials and ionic currents. (p. 367)
- SR:** see *sarcoplasmic reticulum*.
- SRP:** see *signal recognition particle*.
- SSB:** see *single-stranded DNA binding protein*.
- stage:** platform on which the specimen is placed in a microscope. (p. A-5)
- staining:** incubation of tissue specimens in a solution of dye, heavy metal, or other substance that binds specifically to selected cellular constituents, thereby giving those constituents a distinctive color or electron density. (p. A-18)
- standard free energy change (ΔG°):** free energy change accompanying the conversion of 1 mole of reactants to 1 mole of products, with the temperature, pressure, pH, and concentration of all relevant species maintained at standard values. (p. 122)
- standard reduction potential (E'_0):** convention used to quantify the electron transport potential of oxidation-reduction couples relative to the H^+/H_2 redox pair, which is assigned an E'_0 value of 0.0 V at pH 7.0. (p. 271)
- standard state:** set of arbitrary conditions defined for convenience in reporting free energy changes in chemical reactions. For systems consisting of dilute aqueous solutions, these conditions are usually a temperature of 25°C (298 K), a pressure of 1 atmosphere, and reactants other than water present at a concentration of 1 M. (p. 121)
- starch:** storage polysaccharide in plants consisting of repeating glucose subunits linked together by $\alpha(1 \rightarrow 4)$ bonds and, in some cases, $\alpha(1 \rightarrow 6)$ bonds. The two main forms of starch are the unbranched polysaccharide, amylose, and the branched polysaccharide, amylopectin. (p. 63)
- Start:** control point near the end of G1 phase of the yeast cell cycle where the cycle can be halted until conditions are suitable for progression into S phase; known as the *restriction point* in other eukaryotes. (p. 581)
- start codon:** the codon AUG in mRNA when it functions as the starting point for protein synthesis. (pp. 654, 684)
- start-transfer sequence:** amino acid sequence in a newly forming polypeptide that acts as both an ER signal sequence that directs the ribosome-mRNA-polypeptide complex to the ER membrane and as a membrane anchor that permanently attaches the polypeptide to the lipid bilayer. (p. 701)
- STAT:** type of transcription factor activated by phosphorylation in the cytoplasm catalyzed by Janus activated kinase, followed by migration of the activated STAT molecules to the nucleus. (p. 742)
- state:** condition of a system defined by various properties, such as temperature, pressure, and volume. (p. 111)
- stationary cisternae model:** model postulating that each compartment of the Golgi stack is a stable structure, and that traffic between successive cisternae is mediated by shuttle vesicles that bud from one cisterna and fuse with another. (p. 333)
- steady state:** nonequilibrium condition of an open system through which matter is flowing, such that all components of the system are present at constant, nonequilibrium concentrations. (p. 124)
- stem cell:** a cell capable of unlimited division that can differentiate into a variety of other cell types. (p. 725)
- stereo electron microscopy:** microscopic technique for obtaining a three-dimensional view of a specimen by photographing it at two slightly different angles. (p. A-25)
- stereoisomers:** two molecules that have the same structural formula but are not superimposable; stereoisomers are mirror images of each other. (p. 21)
- steroid:** any of numerous lipid molecules that are derived from a four-membered ring compound called phenanthrene. (p. 70)
- steroid hormone:** any of several steroids derived from cholesterol that function as signaling molecules, moving via the circulatory system to target tissues, where they cross the plasma membrane and interact with intracellular receptors to form hormone-receptor complexes that are capable of activating (or inhibiting) the transcription of specific genes. (p. 70)
- steroid receptor:** protein that functions as a transcription factor after binding to a specific steroid hormone. (p. 417)
- sterol:** any of numerous compounds consisting of a 17-carbon four-ring system with at least one hydroxyl group and a variety of other possible side groups; includes cholesterol and a variety of other biologically important compounds, such as the male and female sex hormones, that are related to cholesterol. (p. 165)
- sticky end:** single-stranded end of a DNA fragment generated by cleavage with a restriction endonuclease that tends to reassociate with another fragment generated by the same restriction endonuclease because of base complementarity. (p. 521)
- stomata (singular, stoma):** pores on the surface of a plant leaf that can be opened or closed to control gas and water exchange between the atmosphere and the interior of the leaf. (p. 309)
- stop codon:** sequence of three bases in mRNA that instructs the ribosome to terminate protein synthesis. UAG, UAA, and UGA generally function as stop codons. (pp. 654, 684)
- stop-transfer sequence:** hydrophobic amino acid sequence in a newly forming polypeptide that halts translocation of the chain through the ER membrane, thereby anchoring the polypeptide within the membrane. (p. 701)
- storage macromolecule:** polymer that consists of one or a few kinds of subunits in no specific order and that serves as a storage form of monosaccharides; examples include starch and glycogen. (p. 30)
- STR:** see *short tandem repeat*.
- striated muscle:** muscle whose myofibrils exhibit a pattern of alternating dark and light bands when viewed microscopically; includes both skeletal and cardiac muscle. (p. 461)
- stroma:** unstructured semifluid matrix that fills the interior of the chloroplast. (pp. 88, 297)
- stroma thylakoid:** membrane that interconnects stacks of grana thylakoids with each other. (pp. 87, 297)
- structural macromolecule:** polymer that consists of one or a few kinds of subunits in no specific order and that provides structure and mechanical strength to the cell; examples include cellulose and pectin. (p. 30)
- subcellular fractionation:** technique for isolating organelles from cell homogenates using various types of centrifugation. (pp. 9, 327)
- substrate activation:** role of an enzyme's active site in making a substrate molecule maximally reactive by subjecting it to the appropriate chemical environment for catalysis. (p. 137)
- substrate concentration (S):** amount of substrate present per unit volume at the beginning of a chemical reaction. (p. 139)
- substrate induction:** regulatory mechanism for catabolic pathways in which the synthesis of enzymes involved in the pathway is stimulated in the presence of the substrate and inhibited in the absence of the substrate. (p. 711)
- substrate specificity:** ability of an enzyme to discriminate between very similar molecules. (p. 133)
- substrate-level phosphorylation:** formation of ATP by direct transfer to ADP of a high-energy phosphate group derived from a phosphorylated substrate. (p. 235)
- substrate-level regulation:** enzyme regulation that depends directly on the interactions of substrates and products with the enzyme. (p. 146)
- succinate-coenzyme Q oxidoreductase:** see *complex II*.
- supercoiled DNA:** twisting of a DNA double helix upon itself, either in a circular DNA molecule or in a DNA loop anchored at both ends. (p. 514)
- supernatant:** material that remains in solution after particles of a given size and density are removed as a pellet during centrifugation. (p. 328)
- superresolution microscopy:** a set of related techniques, including stimulated emission depletion (STED) microscopy, photoactivated localization microscopy (PALM) and stochastic optical reconstruction microscopy (STORM), that allows objects to be visualized in the light microscope at a resolution greater than the theoretical limit predicted due to diffraction by the Abbé equation (p. A-16)
- suppressor tRNA:** mutant tRNA molecule that inserts an amino acid where a stop codon generated by another mutation would otherwise have caused premature termination of protein synthesis. (p. 693)

surface area/volume ratio: mathematical ratio of the surface area of a cell to its volume; decreases with increasing linear dimension of the cell (length or radius), thereby increasing the difficulty of maintaining adequate surface area for import of nutrients and export of waste products as cell size increases. (p. 76)

surroundings: the remainder of the universe when one is studying the distribution of energy within a given system. (p. 111)

survival factor: a secreted molecule whose presence prevents a cell from undergoing apoptosis. (p. 593)

Svedberg unit (S): unit for expressing the sedimentation coefficient of biological macromolecules: One Svedberg unit ($S = 10^{-13}$ second). In general, the greater the mass of a particle, the greater the sedimentation rate, though the relationship is not linear. (p. 327)

SWI/SNF: family of chromatin-remodeling proteins. (p. 732)

synaptic boutons: regions near the end of an axon where neurotransmitter molecules are stored for use in transmitting signals across the synapse. (p. 366)

symbiotic relationship: a mutually beneficial association between cells (or organisms) of two different species. (p. 298)

symport: coupled transport of two solutes across a membrane in the same direction. (p. 203)

synapse: tiny gap between a neuron and another cell (neuron, muscle fiber, or gland cell), across which the nerve impulse is transferred by direct electrical connection or by chemicals called neurotransmitters. (p. 366)

synapsis: close pairing between homologous chromosomes during the zygotene phase of prophase I of meiosis. (p. 604)

synaptic bouton: region near the end of an axon where neurotransmitter molecules are stored for use in transmitting signals across the synapse. (p. 366)

synaptic cleft: gap between the presynaptic and postsynaptic membranes at the junction between two nerve cells. (p. 381)

synaptonemal complex: zipperlike, protein-containing structure that joins homologous chromosomes together during prophase I of meiosis. (p. 605)

system: the restricted portion of the universe that one decides to study at any given time when investigating the principles that govern the distribution of energy. (p. 111)

T

T: see thymine.

T tubule system: see transverse tubule system.

tandemly repeated DNA: repeated DNA sequences whose multiple copies are adjacent to one another. (p. 526)

target-SNAP receptor: see t-SNARE.

TATA box: part of the core promoter for many eukaryotic genes transcribed by RNA polymerase II; consists of a consensus sequence of TATA followed by two or three more A's, located about 25 nucleotides upstream from the transcriptional startpoint. (p. 661)

TATA-binding protein (TBP): component of transcription factor TFIID that confers the ability to recognize and bind the TATA box sequence in DNA; also involved in regulating transcription initiation at promoters lacking a TATA box. (p. 664)

taxol: drug that binds tightly to microtubules and stabilizes them, causing much of the free

tubulin in the cell to assemble into microtubules. (p. 428)

TBP: see TATA-binding protein.

TCA cycle: see tricarboxylic acid cycle.

TE: see transitional element.

telomerase: special type of DNA polymerase that catalyzes the formation of additional copies of a telomeric repeat sequence. (p. 565)

telomere: DNA sequence located at either end of a linear chromosome; contains simple-sequence, tandemly repeated DNA. (pp. 526, 565)

telophase: final stage of mitosis or meiosis, when daughter chromosomes arrive at the poles of the spindle accompanied by reappearance of the nuclear envelope. (p. 574)

TEM: see transmission electron microscope.

temperature-sensitive mutant: cell that produces a protein that functions properly at normal temperatures but becomes seriously impaired when the temperature is altered slightly. (p. 556)

template: a nucleic acid whose base sequence serves as a pattern for the synthesis of another (complementary) nucleic acid. (p. 58)

template strand: the strand of a DNA double helix that serves as the template for RNA synthesis via complementary base pairing. (p. 652)

terminal bulb: see synaptic bouton.

terminal glycosylation: modification of glycoproteins in the Golgi complex involving removal and/or addition of sugars to the carbohydrate side chains formed by prior core glycosylation in the endoplasmic reticulum. (p. 335)

terminal oxidase: electron transfer complex that is capable of transferring electrons directly to oxygen. Complex IV (cytochrome *c* oxidase) of the mitochondrial electron transport system is an example. (p. 275)

terminal web: dense meshwork of spectrin and myosin molecules located at the base of a microvillus; the bundle of actin microfilaments that make up the core of the microvillus is anchored to the terminal web. (p. 438)

termination signal: DNA sequence located near the end of a gene that triggers the termination of transcription. (p. 659)

terpene: a lipid constructed from the five-carbon compound isoprene and its derivatives, joined together in various combinations. (p. 70)

tertiary structure: level of protein structure involving interactions between amino acid side chains of a polypeptide, regardless of where along the primary sequence they happen to be located; results in three-dimensional folding of a polypeptide chain. (p. 50)

tethering protein: a coiled-coil protein or a multisubunit protein complex that recognizes and binds vesicles to their target membranes. (p. 351)

tetrahedral (carbon atom): an atom of carbon from which four single bonds extend to other atoms, each bond equidistant from all other bonds, causing the atom to resemble a tetrahedron with its four equal faces. (p. 21)

TFIIB recognition element: see BRE.

TGF β : see transforming growth factor β .

TGN: see trans-Golgi network.

theory: a hypothesis that has been tested critically under many different conditions—usually by many different investigators using a variety of approaches—and is consistently supported by the evidence. (p. 13)

thermodynamic spontaneity: a measure of whether a reaction can occur, but it says nothing about whether the reaction actually will occur. Reactions with a negative free energy change are thermodynamically spontaneous. (p. 113)

thermodynamics: area of science that deals with the laws governing the energy transactions that accompany all physical processes and chemical reactions. (p. 111)

thick filament: myosin-containing filament, found in the myofibrils of striated muscle cells, in which individual myosin molecules are arranged in a staggered array with the heads of the myosin molecules projecting out in a repeating pattern. (p. 461)

thin filament: actin-containing filament, found in the myofibrils of striated muscle cells, in which two F-actin molecules are arranged in a helix associated with tropomyosin and troponin. (p. 461)

thin-layer chromatography (TLC): procedure for separating compounds by chromatography in a medium, such as silicic acid, that is bound as a thin layer to a glass or metal surface. (p. 166)

30-nm chromatin fiber: fiber formed by packing together the nucleosomes of a 10-nm chromatin fiber. (p. 533)

30S initiation complex: complex formed by the association of mRNA, the 30S ribosomal subunit, an initiator aminoacyl tRNA molecule, and initiation factor IF2. (p. 686)

three-dimensional (3-D) electron tomography: computer-based method for making three-dimensional reconstructions of structures visualized in serial thin sections by transmission electron microscopy. (p. A-25)

threshold potential: value of the membrane potential that must be reached before an action potential is triggered. (p. 375)

thylakoid: flattened membrane sac suspended in the chloroplast stroma, usually arranged in stacks called grana; contains the pigments, enzymes, and electron carriers involved in the light-requiring reactions of photosynthesis. (pp. 87, 297)

thylakoid lumen: compartment enclosed by an interconnected network of grana and stroma thylakoids. (p. 297)

thymine (T): nitrogen-containing aromatic base, chemically designated as a pyrimidine, which serves as an informational monomeric unit when present in DNA with other bases in a specific sequence; forms a complementary base pair with adenine (A) by hydrogen bonding. (p. 55)

Ti plasmid: DNA molecule that causes crown gall tumors when transferred into plants by bacteria; used as a cloning vector for introducing foreign genes into plant cells. (p. 636)

TIC: translocase of the inner chloroplast membrane, a transport complex involved in the uptake of specific polypeptides into the chloroplast. (p. 703)

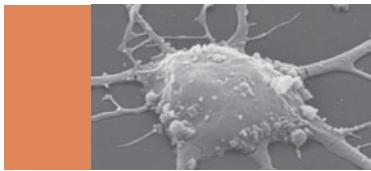

tight junction: type of cell junction in which the adjacent plasma membranes of neighboring animal cells are tightly sealed, thereby preventing molecules from diffusing from one side of an epithelial cell layer to the other by passing through the spaces between adjoining cells. (p. 484)

TIM: translocase of the inner mitochondrial membrane, a transport complex involved in the uptake of specific polypeptides into the mitochondrion. (p. 703)

+TIP proteins: see plus-end tubulin interacting proteins.

- TIRF:** see *total internal reflection fluorescence microscopy*.
- TLC:** see *thin-layer chromatography*.
- T_m:** see *transition temperature* or *DNA melting temperature*.
- TOC:** translocase of the outer chloroplast membrane, a transport complex involved in the uptake of specific polypeptides into the chloroplast. (p. 703)
- TOM:** translocase of the outer mitochondrial membrane, a transport complex involved in the uptake of specific polypeptides into the mitochondrion. (p. 703)
- topoisomerase:** enzyme that catalyzes the interconversion of the relaxed and supercoiled forms of DNA by making transient breaks in one or both DNA strands. (pp. 515, 562)
- total internal reflection fluorescence (TIRF) microscopy:** technique in which a light beam strikes the interface of two media of different indices of refraction at an angle beyond the critical angle, causing all the light to be reflected back into the incident medium; an “evanescent field” that develops at the interface allows selective excitation of fluorescent molecules located within \sim 100 nm of the interface. (p. A-15)
- trans-acting factor:** regulatory protein that exerts its function by binding to specific DNA sequences. (p. 715)
- transcription:** process by which RNA polymerase utilizes one DNA strand as a template for guiding the synthesis of a complementary RNA molecule. (p. 645)
- transcription factor:** protein required for the binding of RNA polymerase to a promoter and for the optimal initiation of transcription. (p. 587) Also see *general transcription factor* and *regulatory transcription factor*.
- transcription regulation domain:** region of a transcription factor, distinct from the DNA-binding domain, that is responsible for regulating transcription. (p. 738)
- transcription unit:** segment of DNA whose transcription gives rise to a single, continuous RNA molecule. (p. 656)
- transcriptional control:** group of regulatory mechanisms involved in controlling the rates at which specific genes are transcribed. (p. 732)
- transcriptome:** the entire set of RNA molecules produced by a genome. (p. 524)
- transcytosis:** endocytosis of material into vesicles that move to the opposite side of the cell and fuse with the plasma membrane, releasing the material into the extracellular space. (p. 347)
- transduction:** transfer of bacterial DNA sequences from one bacterium to another by a bacteriophage. (p. 621)
- transfection:** introduction of foreign DNA into cells under artificial conditions. (p. 772)
- transfer RNA (tRNA):** family of small RNA molecules, each binding a specific amino acid and possessing an anticodon that recognizes a specific codon in mRNA. (pp. 645, 681)
- transformation:** change in the hereditary properties of a cell brought about by the uptake of foreign DNA (pp. 507, 621)
- transforming growth factor β (TGF β):** family of growth factors that can exhibit either growth-stimulating or growth-inhibiting properties, depending on the target cell type; regulate a wide range of activities in both embryos and adult animals, including effects on cell growth, division, differentiation, and death. (pp. 413, 591)
- transgenic:** any organism whose genome contains a gene that has been experimentally introduced from another organism using the techniques of genetic engineering. (p. 636)
- trans-Golgi network (TGN):** region of the Golgi complex consisting of a network of membrane-bounded tubules that are located on the opposite side of the Golgi complex from the *cis*-Golgi network. (p. 332)
- transit sequence:** amino acid sequence that targets a completed polypeptide chain to either mitochondria or chloroplasts. (p. 703)
- transition state:** intermediate stage in a chemical reaction, of higher free energy than the initial state, through which reactants must pass before giving rise to products. (p. 130)
- transition temperature (T_m):** temperature at which a membrane will undergo a sharp decrease in fluidity (“freezing”) as the temperature is decreased and becomes more fluid again (“melts”) when it is then warmed; determined by the kinds of fatty acid side chains present in the membrane. (p. 169)
- transition vesicle:** membrane vesicle that shuttles lipids and proteins from the endoplasmic reticulum to the Golgi complex. (p. 325)
- transitional element (TE):** region of the endoplasmic reticulum that is involved in the formation of transition vesicles. (p. 325)
- translation:** process by which the base sequence of an mRNA molecule guides the sequence of amino acids incorporated into a polypeptide chain; occurs on ribosomes. (p. 645)
- translational control:** mechanisms that regulate the rate at which mRNA molecules are translated into their polypeptide products; includes control of translation rates by initiation factors, selective inhibition of specific mRNAs by translational repressor proteins or microRNAs, and control of mRNA degradation rates. (p. 746)
- translational repressor:** regulatory protein that selectively inhibits the translation of a particular mRNA. (p. 747)
- translesion synthesis:** DNA replication across regions where the DNA template is damaged. (p. 568)
- translocation:** movement of mRNA across a ribosome by a distance of three nucleotides, bringing the next codon into position for translation. (p. 688) (Note: The same term, *translocation*, which literally means “a change of location,” can also refer to the movement of a protein molecule through a membrane channel or to the transfer of a segment of one chromosome to another nonhomologous chromosome.)
- translocon:** structure in the ER membrane that carries out the translocation of newly forming polypeptides across (or into) the ER membrane. (p. 699)
- transmembrane protein:** an integral membrane protein possessing one or more hydrophobic regions that span the membrane plus hydrophilic regions that protrude from the membrane on both sides. (p. 177)
- transmembrane segment:** hydrophobic segment about 20–30 amino acids long that crosses the lipid bilayer in a transmembrane protein. (p. 177)
- transmission electron microscope (TEM):** type of electron microscope in which an image is formed by electrons that are transmitted through a specimen. (pp. 8, A-18)
- transport:** selective movement of substances across membranes, both into and out of cells and into and out of organelles. (p. 194)
- transport protein:** membrane protein that recognizes substances with great specificity and assists their movement across a membrane; includes both carrier proteins and channel proteins. (p. 202)
- transport vesicle:** vesicle that buds off from a membrane in one region of the cell and fuses with other membranes; includes vesicles that convey lipids and proteins from the ER to the Golgi complex, between the Golgi stack cisternae, and from the Golgi complex to various destinations in the cell, including secretory vesicles, endosomes, and lysosomes. (p. 332)
- transposable element (transposon):** DNA sequence that can move from one chromosomal location to another. (p. 527)
- transposon:** see *transposable element*.
- transverse diffusion:** movement of a lipid molecule from one monolayer of a membrane to the other, a thermodynamically unfavorable and therefore infrequent event; also called “flip-flop.” (p. 167)
- transverse (T) tubule system:** invaginations of the plasma membrane that penetrate into a muscle cell and conduct electrical impulses into the cell interior, where T tubules make close contact with the sarcoplasmic reticulum and trigger the release of calcium ions. (p. 467)
- triacylglycerol:** a glycerol molecule with three fatty acids linked to it; also called a triglyceride. (pp. 68, 265)
- triad:** region where a T tubule passes between the terminal cisternae of the sarcoplasmic reticulum in skeletal muscle. (p. 468)
- tricarboxylic acid cycle (TCA cycle):** cyclic metabolic pathway that oxidizes acetyl CoA to carbon dioxide in the presence of oxygen, generating ATP and the reduced coenzymes NADH and FADH₂; a component of aerobic respiration; also called the Krebs cycle. (p. 258)
- triglyceride:** see *triacylglycerol*.
- triple bond:** chemical bond formed between two atoms as a result of sharing three pairs of electrons. (p. 19)
- triplet code:** a coding system in which three units of information are read as a unit; a reference to the genetic code, which is read from mRNA in units of three bases called *codons*. (p. 650)
- triskelion:** structure formed by clathrin molecules consisting of three polypeptides radiating from a central vertex; the basic unit of assembly for clathrin coats. (p. 348)
- tRNA:** see *transfer RNA*.
- tropomyosin:** long, rodlike protein associated with the thin actin filaments of muscle cells, functioning as a component of the calcium-sensitive switch that activates muscle contraction; blocks the interaction between actin and myosin in the absence of calcium ions. (p. 462)
- troponin:** complex of three polypeptides (TnT, TnC, and TnI) that functions as a component of the calcium-sensitive switch that activates muscle contraction; displaces tropomyosin in the presence of calcium ions, thereby activating contraction. (p. 462)
- trp operon:** group of adjoining bacterial genes that code for enzymes involved in tryptophan biosynthesis and whose transcription is selectively inhibited in the presence of tryptophan. (p. 717)
- true-breeding (plant strain):** organism that, upon self-fertilization, produces only offspring of the same kind for a given genetic trait. (p. 612)
- t-SNARE (target-SNAP receptor):** protein associated with the outer surface of a target membrane that binds to a v-SNARE protein associated with the outer surface of an appropriate transport vesicle. (p. 351)
- tubulin:** family of related proteins that form the main building block of microtubules. (p. 426)

- Also see** *alpha tubulin, beta tubulin, gamma tubulin, and gamma tubulin ring complexes.*
- tumor:** growing mass of cells caused by uncontrolled cell proliferation. (p. 758) Also see *benign tumor* and *malignant tumor*.
- tumor grading:** assignment of numerical grades to tumors based on differences in their microscopic appearance; higher-grade cancers tend to grow and spread more aggressively, and to be less responsive to therapy, than lower-grade cancers. (p. 786)
- tumor progression:** gradual changes in tumor properties observed over time as cancer cells acquire more aberrant traits and become increasingly aggressive. (p. 769)
- tumor suppressor gene:** gene whose loss or inactivation by deletion or mutation can lead to cancer. (p. 777) Also see *gatekeeper gene* and *caretaker gene*.
- γ TuRCs: see *gamma tubulin ring complexes*.
- turgor pressure:** pressure that builds up in a cell due to the inward movement of water that occurs because of a higher solute concentration inside the cell than outside; accounts for the firmness, or turgidity, of fully hydrated cells or tissues of plants and other organisms. (p. 200)
- turnover number (k_{cat}):** rate at which substrate molecules are converted to product by a single enzyme molecule when the enzyme is operating at its maximum velocity. (p. 142)
- type II myosin:** form of myosin composed of four light chains and two heavy chains, each having a globular myosin head, a hinge region, and a long rodlike tail; found in skeletal, cardiac, and smooth muscle cells, as well as in nonmuscle cells. (p. 459)
- U**
- U: see *uracil*.
- ubiquitin:** small protein that is linked to other proteins as a way of marking the targeted protein for degradation by proteasomes. (p. 751)
- ultracentrifuge:** instrument capable of generating centrifugal forces that are large enough to separate subcellular structures and macromolecules on the basis of size, shape, and density. (pp. 9, 327)
- ultramicrotome:** instrument used to slice an embedded biological specimen into ultrathin sections for electron microscopy. (p. A-21)
- ultraviolet radiation (UV):** mutagenic type of radiation present in sunlight that triggers the formation of pyrimidine dimers in DNA. (p. 770)
- undershoot:** see *hyperpolarization*.
- unfolded protein response (UPR):** quality control mechanism in which sensor molecules in the ER membrane detect misfolded proteins and trigger a response that inhibits the synthesis of most proteins while enhancing the production of those required for protein folding and degradation. (p. 699)
- unidirectional pumping of protons:** the active and directional transport of protons across a membrane such that they accumulate preferentially on one side of the membrane, establishing an electrochemical proton gradient across the membrane; a central component of electron transport and ATP generation in both respiration and photosynthesis. (p. 278)
- uniport:** membrane protein that transports a single solute from one side of a membrane to the other. (p. 203)
- unsaturated fatty acid:** fatty acid molecule containing one or more double bonds. (p. 68)
- UPR:** see *unfolded protein response*.
- upstream:** located toward the 5' end of the DNA coding strand. (p. 657)
- uracil (U):** nitrogen-containing aromatic base, chemically designated as a pyrimidine, that serves as an informational monomeric unit when present in RNA with other bases in a specific sequence; forms a complementary base pair with adenine (A) by hydrogen bonding. (p. 55)
- useful magnification:** measurement of how much an image can be enlarged before additional enlargement provides no additional information. (p. A-4)
- UV:** see *ultraviolet radiation*.
- V**
- v: see *initial reaction velocity*.
- vacuole:** membrane-bound organelle in the cytoplasm of a cell, used for temporary storage or transport; acidic membrane-enclosed compartment in plant cells. (pp. 93, 355)
- vacuum evaporator:** bell jar containing a metal electrode and a carbon electrode in which a vacuum can be created; used in preparing metal replicas of the surfaces of biological specimens. (p. A-23)
- van der Waals interaction:** weak attractive interaction between two atoms caused by transient asymmetries in the distribution of charge in each atom. (p. 46)
- vesicle-SNAP receptor:** see *v-SNARE*.
- viroid:** small, circular RNA molecule that can infect and replicate in host cells even though it does not code for any protein. (p. 101)
- virus:** subcellular parasite composed of a protein coat and DNA or RNA, incapable of independent existence; invades and infects cells and redirects the host cell's synthetic machinery toward the production of more virus. (p. 99)
- V_m :** see *resting membrane potential*.
- V_{max} :** see *maximum velocity*.
- voltage:** see *electrical potential*.
- voltage sensor:** amino acid segment of a voltage-gated ion channel that makes the channel responsive to changes in membrane potential. (p. 374)
- voltage-gated calcium channel:** an integral membrane protein in the terminal bulb of presynaptic neurons that forms a calcium ion-conducting pore whose permeability is regulated by the membrane potential; action potentials cause the calcium channel to open and calcium ions rush into the cell, stimulating the release of neurotransmitters. (p. 384)
- voltage-gated ion channel:** an integral membrane protein that forms an ion-conducting pore whose permeability is regulated by changes in the membrane potential. (p. 372)
- v-SNARE (vesicle-SNAP receptor):** protein associated with the outer surface of a transport vesicle that binds to a t-SNARE protein associated with the outer surface of the appropriate target membrane. (p. 351)
- V-type ATPase:** type of transport ATPase that pumps protons into such organelles as vesicles, vacuoles, lysosomes, endosomes, and the Golgi complex. (p. 211)
- W**
- wavelength:** distance between the crests of two successive waves. (p. A-1)
- Western blotting:** technique in which polypeptides separated by gel electrophoresis are transferred to a special type of "blotter" paper (nitrocellulose or nylon), which is then reacted with labeled antibodies that are known to bind to specific polypeptides. (p. 180)
- wild type:** normal, nonmutant form of an organism, usually the form found in nature. (p. 619)
- Wnt pathway:** signaling pathway that plays a prominent role in controlling cell proliferation and differentiation during embryonic development; abnormalities in this pathway occur in some cancers. (p. 780)
- wobble hypothesis:** flexibility in base pairing between the third base of a codon and the corresponding base in its anticodon. (p. 681)
- work:** transfer of energy from one place or form to another place or form by any process other than heat flow. (p. 112)
- X**
- xenobiotic:** chemical compound that is foreign to biological organisms. (p. 358)
- xeroderma pigmentosum:** inherited susceptibility to cancer (mainly skin cancer) caused by defects in DNA excision repair or translesion synthesis of DNA. (p. 783)
- X-ray crystallography:** technique for determining the three-dimensional structure of macromolecules based on the pattern produced when a beam of X-rays is passed through a sample, usually a crystal or fiber. (pp. 180, A-27)
- Y**
- YAC:** see *yeast artificial chromosome*.
- yeast artificial chromosome (YAC):** yeast cloning vector consisting of a "minimalist" chromosome that contains all the DNA sequences needed for normal chromosome replication and segregation to daughter cells, and very little else. (p. 634)
- yeast two-hybrid system:** Technique for determining whether two proteins interact by introducing DNA encoding one protein fused to DNA encoding the DNA binding domain of a transcription factor (bait), and another DNA encoding the second protein plus sequence encoding the activation domain of the transcription factor (prey), followed by assessing expression of a reporter. (p. 740)
- Z**
- Z line:** dark line in the middle of the I band of a striated muscle myofibril; defines the boundary of a sarcomere. (p. 461)
- zinc finger:** DNA-binding motif found in some transcription factors; consists of an α helix and a two-segment β sheet held in place by the interaction of precisely positioned cysteine or histidine residues with a zinc atom. (p. 738)
- zygote:** diploid cell formed by the union of two haploid gametes. (p. 602)
- zygotene:** stage during prophase I of meiosis when homologous chromosomes become closely paired by the process of synapsis. (p. 605)

Guide to Techniques and Methods

The following techniques are important to cell biologists. Each technique is described in the text at the indicated location.

CELL CYCLE

Cell fusion: Chapter 19 (pp. 582–83; Fig. 19–33); Chapter 24 (pp. 777–78; Fig. 24–16)

Flow cytometry: Chapter 19 (p. 551)

Micropipetting: Chapter 19 (Fig. 19–34 on p. 584, cytoplasm transfer); Chapter 23 (Box 23A on p. 724, nuclear transfer)

Temperature-sensitive mutants: Chapter 19 (p. 556)

CELL SIGNALING

Antagonists and agonists for studying receptor-ligand interactions: Chapter 14 (p. 394)

Calcium indicators (to measure cytosolic calcium concentrations): Chapter 14 (pp. 402–03; Fig. 14–11)

Calcium ionophores (to induce ion movement): Chapter 14 (p. 402)

Dominant negative mutations (to study growth factor receptor function): Chapter 14 (p. 412; Fig. 14–19)

Fluorescence resonance energy transfer (FRET) for studying Ras: Appendix (Fig. A-22c)

Using genetic analysis to identify components of signaling pathways: Chapter 14 (Box 14B on pp. 410–11)

CLINICAL TECHNIQUES

Administration of ethanol as an antidote for methanol poisoning: Chapter 9 (p. 249; Prob. 9–6)

CYTOSKELETON

Drugs and mutations as tools for studying cytoskeletal function: Chapter 15 (pp. 428–29 and 435–36; Table 15–3 on p. 425)

Myosin S1 decoration to determine actin polarity: Chapter 15 (pp. 434–35; Fig. 15–13)

Use of microscopy techniques in studying the cytoskeleton: Chapter 15 (Table 15–2 on p. 425)

ENERGETICS

Calculation of ΔE (change in internal energy) and ΔH (change in enthalpy): Chapter 5 (p. 113)

Calculation of $\Delta G'$ (free energy change) and $\Delta G^{\circ\prime}$ (standard free energy change) for chemical reactions: Chapter 5 (pp. 120–23; Table 5–1 on p. 119)

Calculation of $\Delta G'$ (free energy change) for transport of charged and uncharged solutes across membranes: Chapter 8 (p. 218; Table 8–3 on p. 218)

Calculation of pmf (proton motive force): Chapter 10 (p. 279)

Disruption and reconstitution of mitochondria (to demonstrate the presence of a mitochondrial ATP synthase): Chapter 10 (pp. 279–80; Fig. 10–18)

Use of uncoupling agents to study ATP synthesis (p. 279)

ENZYME KINETICS

Analysis of competitive and noncompetitive inhibition: Chapter 6 (p. 145; Fig. 6–14)

Determination of K_m (Michaelis constant) and V_{max} (maximum velocity): Chapter 6 (pp. 143–44; Figs. 6–12 and 6–13)

Use of the Lineweaver-Burk, Eadie-Hofstee, and Hanes-Woolf plots to linearize enzyme kinetics data: Chapter 6 (pp. 142–43; Figs. 6–10 and 6–11; Prob. 6–13)

GENETICS

Cis-trans test with partially diploid bacteria: Chapter 23 (pp. 715–16; Table 23–2)

Cotransductional mapping: Chapter 20 (p. 621)

Genetic analysis by Mendelian crosses: Chapter 20 (pp. 612–15; Figs. 20–10, 20–11, and 20–12)

Genetic analysis to identify components of signaling pathways: Chapter 14 (Box 14B on pp. 410–11)

Genetic mapping by recombinant frequencies: Chapter 20 (pp. 620–24)

Gene therapy: Chapter 8 (Box 8B on pp. 206–7); Chapter 20 (p. 640)

Knockout mice (for studying gene function): Chapter 20 (pp. 637–40; Fig. 20–32)

Temperature-sensitive mutants: Chapter 19 (pp. 556–58)

Transgenic animals: Chapter 20 (Box 20A on p. 639)

Transgenic plants: Chapter 20 (p. 636; Fig. 20–31)

LABELING AND STAINING

Affinity labeling of proteins: Chapter 7 (Box 7A on pp. 182–83)

Autoradiography: Chapter 12 (pp. 339–40; Fig. 12–10); Chapter 18 (p. 519); Appendix (p. A–18)

Cytochemical localization of enzyme activity: Chapter 4 (Fig. 4–18); Chapter 12 (p. 352; Fig. 12–20)

Electron-opaque tracers (to demonstrate that tight junctions create a permeability barrier): Chapter 17 (pp. 484–85; Fig. 17–10)

Fluorescent antibodies (to identify specific membrane proteins): Chapter 7 (pp. 187–88; Fig. 7–28); Appendix (pp. A–9–10; Fig. A–12)

Fluorescent dyes (to demonstrate gap junction permeability): Chapter 17 (p. 503; Prob. 17–9 and Fig. 17–27)

Green fluorescent protein (GFP): Appendix (p. A–10; Fig. A–14)

Immunochemical staining: Chapter 12 (p. 333; Fig. 12–5)

Pulse-chase experiments: Chapter 23 (p. 747)

Radioisotopes (to trace metabolic fates of atoms): Chapter 1 (p. 9); (to distinguish between proteins on the inner and outer surfaces of membranes): Chapter 7 (p. 184; Fig. 7–24; Probs. 7–11 and 7–12)

MEMBRANES AND MEMBRANE TRANSPORT

Affinity labeling of membrane proteins: Chapter 7 (Box 7A on pp. 182–83)

Antibodies against specific cell-surface molecules (to identify specific proteins involved in cell-cell adhesion): Chapter 17 (p. 478)

Cell fusion (to study mobility of membrane proteins): Chapter 7 (pp. 187–88; Fig. 7–28)

Differential scanning calorimetry (to determine transition temperatures of membranes): Chapter 7 (pp. 169–70; Fig. 7–12)

Experimental evidence that discredited Davson-Danielli model: Chapter 7 (pp. 160–61)

Fluorescence recovery after photobleaching (to study mobility of membrane lipids and proteins): Chapter 7 (p. 169; Fig. 7–11)

Fluorescence microscopy (to study passage of molecules from one cell to another via gap junctions): Chapter 17 (p. 503; Prob. 17–9)

Freeze-fracture microscopy (to study membrane proteins and their mobility and to visualize tight junctions): Chapter 7 (pp. 174–75; Figs. 7–16, 7–17, and 7–18; p. 188; Fig. 7–29); Chapter 17 (pp. 484–86; Fig. 17–9)

Hydropathic analysis of membrane proteins (to identify possible transmembrane segments): Chapter 7 (pp. 180–81 and 192; Figs. 7–23 and 7–30; Prob. 7–10)

Inverted membrane vesicles (to study membrane transport): Chapter 7 (pp. 192–93; Prob. 7–12); Chapter 8 (p. 223; Prob. 8–11)

Liposomes (to study membrane proteins and membrane permeability): Chapter 8 (p. 199)

Patch clamping: Chapter 13 (pp. 372–73; Fig. 13–7)

Radioisotope labeling procedures (to distinguish between proteins exposed on the inner and outer surfaces of membranes): Chapter 7 (p. 184; Fig. 7–24; pp. 192–93; Probs. 7–11 and 7–12)

SDS-polyacrylamide gel electrophoresis, including two-dimensional (to separate proteins): Chapter 7 (pp. 178–80; Fig. 7–22)

Site-specific mutagenesis (to modify membrane proteins genetically): Chapter 7 (Box 7A on pp. 182–83; Fig. 7A–1)

Thin-layer chromatography (TLC) for analysis of membrane lipids: Chapter 7 (pp. 166–67; Fig. 7–9)

Tonicity changes (effects of hypertonicity and hypotonicity on osmotic movement of water in cells): Chapter 8 (Box 8A on pp. 200–1; Fig. 8A–1)

Voltage recording: Chapter 13 (p. 367; Fig. 13–3)

ELECTRON AND ATOMIC MICROSCOPY

Electron microscopy: Chapter 1 (p. 8); Appendix (pp. A–18–26)

Autoradiography: Chapter 12 (pp. 339–40; Fig. 12–10); Appendix (pp. A–18 and A–22)

CryoEM: Appendix (pp. A–28–29)

Earliest use by biologists: Chapter 1 (p. 6)
Electron tomography (3-D): Appendix (pp. A-25–26; Fig. A-36b,c)
Freeze etching: Appendix (pp. A-24–25)
Freeze fracturing: Chapter 1 (p. 8); Chapter 7 (pp. 174–75; Figs. 7-16, 7-17, and 7-18; p. 188; Fig. 7-29): Appendix (pp. A-24–25; Figs. A-34 and A-35)
High-voltage electron microscopy: Appendix (p. A-19)
Immunoelectron microscopy (immunoEM): Appendix (p. A-22; Fig. A-30)
Negative staining: Chapter 1 (p. 8); Chapter 10 (pp. 257; Fig. 10-5); Appendix (p. A-22; Fig. A-31)
Sample preparation techniques for electron microscopy: Appendix (pp. A-20–26)
Sectioning: Appendix (pp. A-17 and A-20–22; Figs. A-24 and A-28)
Shadowing: Appendix (pp. A-23–24; Figs. A-32 and A-33)
Staining: Appendix (p. A-18)
Scanning electron microscopy: Chapter 1 (p. 8; Fig. 1-4); Appendix (pp. A-19–20; Figs. A-27b and A-28)
Stereo electron microscopy: Chapter 1 (p. 8); Appendix (pp. A-25–26; Fig. A-36a)
Transmission electron microscopy: Chapter 1 (p. 8); Appendix (pp. A-19–20; Figs. A-26 and A-27a)
Scanning probe microscopy: Appendix (pp. A-26–27)
Atomic force microscope: Appendix (p. A-27)
Scanning tunneling microscope: Appendix (p. A-26; Fig. A-37)

LIGHT MICROSCOPY

Light microscopy: Chapter 1 (pp. 6–7; Table 1-1); Appendix (pp. A-5–18; Fig. A-5)
Autoradiography: Appendix (p. A-18)
Brightfield microscopy: Chapter 1 (p. 6; Table 1-1); Appendix (p. A-6)
Confocal microscopy: Chapter 1 (p. 7; Table 1-1); Appendix (pp. A-10–13; Figs. A-15 and A-17)
Digital deconvolution microscopy: Chapter 1 (p. 7); Appendix (p. A-13; Fig. A-19)
Digital microscopy: Chapter 1 (p. 7); Appendix (pp. A-13–14; Fig. A-20)
Differential interference contrast (DIC) microscopy: Chapter 1 (p. 7; Table 1-1); Appendix (pp. A-6–7; Figs. A-8 and A-9)
Earliest use by biologists: Chapter 1 (pp. 1–3)
Fixation: Appendix (p. A-17)
Fluorescence microscopy: Chapter 1 (p. 7; Table 1-1); Appendix (pp. A-8–10; Figs. A-10–15)
Fluorescence recovery after photobleaching (FRAP): Chapter 7 (p. 169; Fig. 7-11); Appendix (p. A-15; Fig. A-21a)
Fluorescence resonance energy transfer (FRET): Appendix (p. A-16, Fig. A-22)
Fluorescent probes: Appendix (pp. A-9–10)
Green fluorescent protein (GFP): Appendix (p. A-10; Fig. A-14)
Immunofluorescence microscopy: Appendix (p. A-9; Fig. A-12)
Multiphoton excitation microscopy: Appendix (p. A-12–13; Fig. A-18)
Optical “tweezers”: Appendix (p. A-16; Fig. A-23)
Phase-contrast microscopy: Chapter 1 (p. 7; Table 1-1); Appendix (p. A-6; Figs. A-6, A-7)
Photoactivation/photoconversion/photoswitching: Appendix (p. A-15; Fig. A-21b)
Sectioning: Appendix (pp. A-17–18; Fig. A-25)
Staining: Appendix (p. A-18)
Superresolution microscopy: Appendix (p. A-16; Fig. A-24)
Total internal reflection fluorescence microscopy: Appendix (p. A-15; Fig. A-21c)
Optical principles of microscopy: Appendix (pp. A-1–5; Fig. A-1)

MODEL ORGANISMS

Use of model organisms in cell biology: Chapter 1 (Box 1B on p. 12)

NUCLEIC ACIDS AND RECOMBINANT DNA

Bacterial artificial chromosomes (BACs): Chapter 20 (p. 634)
BLAST searching: Chapter 18 (p. 524)
Cloning of genes: Chapter 20 (pp. 628–35; Figs. 20-25, 20-26, 20-27, 20-30)
Chromatin immunoprecipitation (ChIP) assay: Chapter 21 (Box 21B on p. 658)
Cloning of organisms: Chapter 23 (Box 23A on p. 724)
Colony hybridization with nucleic acid probe: Chapter 20 (p. 633; Fig. 20-29)
cDNA molecules for transcription studies: Chapter 23 (p. 733; Fig. 23-19)
cDNA preparation (reverse transcription): Chapter 20 (p. 633; Fig. 20-28)
DNA denaturation and renaturation: Chapter 18 (pp. 515–17; Fig. 18-10)
DNA fingerprinting: Chapter 18 (Box 18C on pp. 528–29)
DNA microarrays: Chapter 23 (p. 733, Fig. 23-19)
DNA sequencing: Chapter 18 (pp. 520–22; Fig. 18-14)
DNase sensitivity of active genes in chromatin: Chapter 23 (pp. 728–29; Fig. 23-14)
Electrophoresis of DNA: Chapter 18 (pp. 518–19; Fig. 18-12)
Equilibrium density centrifugation of DNA: Chapter 19 (pp. 551–52; Fig. 19-3)
Footprinting technique for detecting protein-binding sites on DNA: Chapter 21 (Box 21B on p. 658)
Hybridization of nucleic acids: Chapter 18 (pp. 516–17)
Northern blotting: Chapter 23 (p. 733)
Nuclease digestion of chromatin (to isolate nucleosomes): Chapter 18 (pp. 531–32; Fig. 18-20)
Polymerase chain reaction (PCR): Chapter 19 (Box 19A on pp. 560–61); use in gene cloning and gene modification by epitope or polyhistidine tagging: Chapter 20 (p. 635)
Restriction enzymes: Chapter 18 (Box 18B on pp. 520–21)
Restriction mapping of DNA: Chapter 18 (pp. 519–20; Fig. 18-13)
RNA interference (for silencing genes to study gene function or treat diseases): Chapter 23 (p. 748)
Run-on transcription assay: Chapter 23 (pp. 732–33; Fig. 23-18)
Southern blotting: Chapter 18 (p. 529)
Yeast artificial chromosomes (YACs): Chapter 20 (p. 634; Fig. 20-30)
X-ray crystallography: Appendix (pp. A-27–28; Fig. A-39)

PROTEINS

Affinity labeling of proteins: Chapter 7 (Box 7A on pp. 182–83)
BLAST searching: Chapter 18 (p. 524)
Hydropathic analysis of proteins (to identify possible transmembrane segments): Chapter 7 (pp. 180 and 192; Figs. 7-23 and 7-30; Prob. 7-10)
Monoclonal antibodies: Chapter 24 (Box 24B on p. 789)
Protein denaturation and renaturation: Chapter 2 (pp. 32–33; Fig. 2-18a)
Protein sequencing: Chapter 3 (pp. 47–48)
SDS-polyacrylamide gel electrophoresis, including two-dimensional: Chapter 7 (pp. 178–80; Fig. 7-22)
Western blotting: Chapter 7 (p. 180)
X-ray crystallography: Chapter 6 (p. 136; Fig. 6-5); Chapter 7 (p. 180); Chapter 11 (p. 302; Fig. 11B-1); Appendix (pp. A-27–28; Fig. A-39)
Yeast two-hybrid system: Chapter 23 (p. 740; Fig. 23-B1)

SEPARATION OF CELLS, ORGANELLES, AND MOLECULES

Density gradient centrifugation: Chapter 12 (pp. 328–29; Fig. 12A-4)
Differential centrifugation: Chapter 12 (pp. 327–28; Figs. 12A-1 and 12A-3); used to isolate lysosomes: Chapter 4 (Box 4B on pp. 92–93)
Equilibrium density centrifugation: Chapter 12 (pp. 329 and 356–57); Chapter 19 (pp. 551–52; Fig. 19-3)
Gel electrophoresis of DNA: Chapter 18 (pp. 518–19; Fig. 18-12)
SDS-polyacrylamide gel electrophoresis as a means of separating proteins: Chapter 7 (pp. 178–80; Fig. 7-22)
Subcellular fractionation: Chapter 12 (Box 12A on pp. 327–29)
Thin-layer chromatography (TLC) for analysis of membrane lipids: Chapter 7 (pp. 166–67; Fig. 7-9)
Ultracentrifugation, earliest use by biologists: Chapter 1 (p. 9); used to achieve high g forces: Chapter 12 (p. 327)
