ABOUT THE AUTHORS

JEFF HARDIN is Professor and Chair of the Zoology Department at the University of Wisconsin-Madison. He is also faculty director of the Biology Core Curriculum, a four-semester honors biology sequence for undergraduates. His research interests center on how cells migrate and adhere to one another to change the shape of animal embryos. Dr. Hardin's teaching is enhanced by his extensive use of digital microscopy and his web-based teaching materials, which are used on many campuses in the United States and other countries. As part of his interest in teaching biology, Dr. Hardin was a founding member of the University of Wisconsin Teaching Academy. His teaching awards include a Lily Teaching Fellowship and a National Science Foundation Young Investigator Award. He is also on the editorial board of *CBE: Life Sciences Education*, and is a curator of WormClassroom, a digital initiative that promotes the use of *C. elegans* in college classrooms and laboratories.

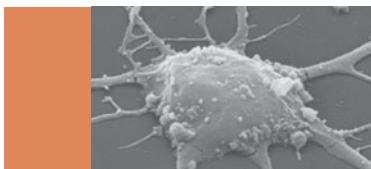

GREGORY BERTONI has been active in teaching, research, and scientific writing for over 25 years. He earned a Ph.D. in Cellular and Molecular Biology from the University of Wisconsin-Madison, where he taught students in introductory and graduate-level biochemistry, sophomore cell biology, and plant physiology. He helped to develop a new course entitled "Ways of Knowing" designed to introduce entering freshmen to a variety of academic fields as well as to the learning process itself. His published research includes studies in bacterial pathogenesis, plant-microbe interactions, and plant gene expression. Dr. Bertoni is a science editor for *The Plant Cell*, a leading international research journal in plant cell and molecular biology. He is also responsible for updating the journal's Teaching Tools in Plant Biology, an online resource for biology instructors. He has been teaching biology and medical microbiology at Columbus State Community College in Columbus, Ohio for most of the past 10 years. In addition, Dr. Bertoni is a freelance scientific writer who contributes to text- and web-based projects in biology, physics, and microbiology and assists authors in preparing manuscripts for publication.

LEWIS J. KLEINSMITH is an Arthur F. Thurnau Professor Emeritus of Molecular, Cellular, and Developmental Biology at the University of Michigan, where he has served on the faculty since receiving his Ph.D. from Rockefeller University in 1968. His teaching experiences have involved courses in introductory biology, cell biology, and cancer biology, and his research interests have included studies of growth control in cancer cells, the role of protein phosphorylation in eukaryotic gene regulation, and the control of gene expression during development. Among his numerous publications, he is the author of *Principles of Cancer Biology* as well as several award-winning educational software programs. His honors include a Guggenheim Fellowship, the Henry Russell Award, a Michigan Distinguished Service Award, citations for outstanding teaching from the Michigan Students Association, an NIH Plain Language Award, and a Best Curriculum Innovation Award from the EDUCOM Higher Education Software Awards Competition.

WAYNE M. BECKER taught cell biology at the University of Wisconsin-Madison for 30 years until his retirement. His interest in textbook writing grew out of notes, outlines, and problem sets that he assembled for his students, culminating in *Energy and the Living Cell*, a paperback text on bioenergetics published in 1977, and *The World of the Cell*, the first edition of which appeared in 1986. He earned all his degrees at the University of Wisconsin-Madison. All three degrees are in biochemistry, an orientation that is readily discernible in his textbooks. His research interests were in plant molecular biology, focused specifically on the regulation of the expression of genes that encode enzymes of the photorespiratory pathway. His honors include a Chancellor's Award for Distinguished Teaching, Guggenheim and Fulbright Fellowships, and a Visiting Scholar Award from the Royal Society of London. This text builds on his foundation, and is inspired by his legacy.

PREFACE

Because we enjoy interacting with biology undergrads and think that they should have biology textbooks that are clearly written, make the subject matter relevant to the reader, and help them appreciate not only how much we already know about biology—cell biology, in our case—but also how much more remains to be investigated and discovered? That's how any of the authors of this text would likely respond if asked why we've invested so much time in writing and revising *The World of the Cell*. Each of us has an extensive history of teaching undergraduate courses in cell biology and related areas, and each of us treasures our contact with students as one of the most rewarding aspects of being a faculty member.

As we reflect on the changes we've seen in our courses over the years, we realize that the past several decades have seen an explosive growth in our understanding of the properties and functions of living cells. This enormous profusion of information presents us with a daunting challenge as we confront the task of keeping *Becker's World of the Cell* up to date while simultaneously ensuring that it remains both manageable in length and readily comprehensible to students encountering the field of cell and molecular biology for the first time. This eighth edition represents our most recent attempt to rise to that challenge. As with the previous editions, each of us has brought our own teaching and writing experience to the venture in ways that we have found mutually beneficial—a view that we hope our readers will share.

One major objective for this edition has been to update the content of the text, especially in areas where the pace of research is especially brisk and recent findings are particularly significant. At the same time, we have remained committed to the three central goals that have characterized each preceding edition. As always, our primary goal is to introduce students to the fundamental principles that guide cellular organization and function. Second, we think it is important for students to understand some of the critical scientific evidence that has led to the formulation of these central concepts. And finally, we have sought to accomplish these goals in a book of manageable length that can be easily read and understood by beginning cell biology students—and that still fits in their backpacks! To accomplish this third goal, we have necessarily been selective both in the types of examples chosen to illustrate key concepts and in the quantity of scientific evidence included. We have, in other words, attempted to remain faithful to the overall purpose of each previous edition: to present the essential principles, processes, and methodol-

ogy of molecular and cell biology as lucidly as possible. We have also given careful attention to accuracy, consistency, vocabulary, and readability to minimize confusion and maximize understanding for our readers.

What's New in This Edition

The eighth edition retains the clear writing style from previous editions, and adds new emphasis on modern genetic/genomic/proteomic approaches to cell biology:

- **New, up-to-date information has been added** on the tools that modern cell biologists use, including model organisms, bioinformatics, and genomics/proteomics. This discussion in Chapter 1 better establishes the modern, 21st century approach to cell biology while retaining the classical emphasis from previous editions.
- **Major reorganization of the cell cycle and apoptosis material**, including moving apoptosis from Chapter 14 to Chapter 19 to better match conventional course syllabi.
- **New discussions of modern genetic and molecular technologies**, such as nanotechnology, bioluminescence, X-ray crystallographic data, and genetic engineering of animals and transgenic plants.
- **Content updates** have been added throughout the book highlighting the most recent advances in the understanding of cell biology (see Content Highlights of the Eighth Edition).
- **New, In-text media callouts** that link chapter content to multimedia resources, such as learning activities, 3D molecular structure tutorials, videos, and animations, that are available on www.thecellplace.com
 **VIDEOS** www.thecellplace.com Spindle formation during mitosis
- **New online videos, 3D structure tutorials, animations, and activities** have been added to The Cell Place (www.thecellplace.com) to enhance student learning through dynamic visualization.
- **New Pearson E-text** and Pearson Custom Library options are available.
- **New PowerPoint Lecture Tools**, including pre-made lecture outlines containing all of the figures and photos and embedded animations, and 5–10 personal response system (PRS) clicker questions per chapter.

Content Highlights of the Eighth Edition

Updated material and new information has been added throughout the book. Topics that have been altered, updated, or added include the following:

CHAPTER 1: Added a new box essay and figure describing the use of model organisms in cell biology research. Updated discussions of nanotechnology, new types of light and electron microscopes, advances in gene and genome sequencing, new “-omics” fields, and bioinformatic tools at NCBI (PubMed, GenBank, OMIM). Introduced “*in silico*” research as an extension of traditional *in vivo* and *in vitro* research.

CHAPTER 2: Described how viral self-assembly can be used in nanotechnology and biomedicine; described electronegativity in relation to polarity and solubility of biomolecules; and introduced soaps and detergents as amphipathic molecules.

CHAPTER 3: Streamlined discussion of protein function; improved discussion of peptide bond geometry; introduced CASP—the worldwide test of protein structure modeling programs; added miRNA and siRNA to the discussion of RNA; introduced lipid rafts earlier.

CHAPTER 4: Added discussions of the important functions of what had been called “junk” DNA, how mitochondrial DNA analysis is used to trace genetic lineages and the origin of modern humans, construction of an artificial ribosome *in vitro*, and how prions cause chronic wasting disease in deer and elk. Presented new results of X-ALD gene therapy clinical trial.

CHAPTER 5: Discussion of bioluminescence now includes luciferase, GFP, and YFP as tools for cell biologists; new figure added to show localization of YFP protein fusion by fluorescence microscopy. Strengths in discussions of bioenergetics and thermodynamics have been retained.

CHAPTER 6: Updated discussion on induced fit; added new figures showing formation of lysozyme active site after protein folding and the changes in the active site of carboxypeptidase following substrate binding; added description of aspirin as an irreversible inhibitor of cyclooxygenase; described cryophilic microorganisms such as *Listeria*.

CHAPTER 7: Added a new paragraph and figure describing the common glycolipids MGDG and DGDG; included a more extensive description of lipid raft composition, formation, and proteomics; added descriptions of how antimicrobial peptides disrupt cell membranes, described membrane receptors for nutrients and for the gaseous hormone ethylene; updated roles of caveolae in human physiology and disease.

CHAPTER 8: Added description of aquaporin discovery by Agre and colleagues; added new figure showing structures of bacterial porin and human aquaporin. Updated discussion of all five subclasses of P-type ATPases; added discussion of how the $\text{Na}^+/\text{glucose}$ symporter can affect the treatment of cholera; introduced additional members of the human glucose transporter family; described use of bacteriorhodopsin in biomolecular electronics.

CHAPTER 9: Added new discussion clarifying resonance stabilization and electron delocalization; expanded discussion of anaerobic respiration; described role of unusual microorganisms in geochemical cycling of nutrients and global biomass production; noted how oxidative stress and free radicals can damage cells.

CHAPTER 10: Included more emphasis on cellular locations of biochemical processes and on similarities between bacterial and eukaryotic respiration; clarified difference between internal and external electron acceptors; introduced pyruvate symporter. In response to reviewer requests, added figure and extensive description of β -oxidation of fatty acids.

CHAPTER 11: Added new paragraph describing newly discovered quantum effects during photosynthetic light harvesting; emphasized similarities between mitochondrial and chloroplast electron transport; introduced pioneering work of van Niel in the 1930s using photosynthetic bacteria. Added an analogy for a potential energy barrier by comparing the thylakoid membrane to a hydroelectric dam, clarified nomenclature of photosystems I and II.

CHAPTER 12: Added new paragraph describing mechanism of action and clinical uses of botulinum toxin. Added new material on N-glycosylation and secretion involving interleukin-31 and p53 and new micrographs showing exocytosis and phagocytosis. Added new paragraph describing reactive oxygen species and their detoxification in the peroxisome; included a more detailed description of the reaction mechanism of P-450 monooxygenases.

CHAPTER 13: Reorganized discussion of squid giant axon and the basic membrane potential measuring technique: how membrane potential is measured in neurons is now discussed prior to what contributes to the membrane potential. Updated depiction of voltage-gated channels to reflect X-ray crystallographic data. Changed terminology from “terminal bulb” to “synaptic bouton,” which is more common among neurobiologists. Updated the discussion of neurotransmitters to include endocannabinoids, and created a new table showing chemical structure of selected neurotransmitters. Now mention “kiss-and-run” exocytosis as an additional mechanism of neurotransmitter release.

CHAPTER 14: Added a discussion of co-receptors, a section on how Wnts and Hedgehogs feed into G protein signaling, a new table on hormones, a section on nuclear hormone receptors, and added PTEN to the discussion of insulin signaling. Reorganized content between Chapter 14 and Chapter 19 to streamline discussion: apoptosis and discussion of *C. elegans* has been moved out of this chapter.

CHAPTER 15: Katanins are now discussed in the microtubule section. Added significant new information on formins in the actin section, and much more coverage of Rho GTPases, including RhoGEFs, GAPs, and GDIs.

CHAPTER 16: Added new information and a new part of a figure on hair cells, as well as significant new text on intraflagellar transport (IFT) and ciliopathies to Box 16A. Updated the figure on focal contacts and the leading edge to provide an integrated view of actin polymerization at the leading edge.

CHAPTER 17: Added further description of apical-basal polarity in epithelia, and the epithelial-mesenchymal transition (EMT), and there is now more emphasis on the dynamic nature of cell adhesion. Added new information on the Par3/Par6/aPKC polarity complex and on the dystrophin/dystroglycan complex. Also updated discussion of claudins to include paracellular transport and human diseases associated with claudins. Added text about kindlins to the focal adhesion discussion and updated treatment of integrin-linked kinase (ILK).

CHAPTER 18: Added new information on NTF2 in the Ran/importin/exportin section. Updated section on nuclear bodies to be more explicit about types and functions of nuclear bodies (Cajal, GEMs, speckles, etc.). Added a new figure describing the percentage of various types of DNA in the human genome.

CHAPTER 19: Added new information on spindle midzones, as well as new material and a new figure on myosin and Rho during cytokinesis. Added new material on ATR and checkpoint kinases in the cell cycle control section. Reorganized content between Chapter 14 and Chapter 19 to streamline discussion: much of the Ras discussion and Akt/PI3K has been moved out of this chapter. Apoptosis was removed from Chapter 14, and is now in Chapter 19. In addition, the apoptosis figure was redrawn to show a more accurate depiction of the apoptosome based on cryoEM data.

CHAPTER 20: Added substantially more discussion and a new figure on knockout mice. The section on genetic engineering has been reworked, and there is now better balance between genetic engineering of animals and transgenic plants. A new figure showing pronuclear injection in mice was added. Updated the section on screening of bacterial clones to reflect the “modern” way of doing this by restriction digests and

sequencing. The section on gene conversion was shortened to accommodate more modern material.

CHAPTER 21: Added information on regulatory role of the C terminus of RNA pol II. Added a discussion of electrophoretic mobility shift assays (EMSA) as a technique, while the historical method of R loop detection was streamlined and supplemented with an improved schematic diagram.

CHAPTER 22: Added a new figure showing the results of experiments with microsomes, demonstrating that cotranslational import is required for cleavage of the signal sequence. Added a brief discussion of operons in eukaryotes.

CHAPTER 23: Added further discussion and a new figure regarding the Dolly cloning method. Substantially increased the discussion of embryonic stem (ES) cells and induced pluripotent stem cells (iPS cells), including a new figure. Added two new figures on methylation of DNA and chromatin/histone remodeling, increased coverage of epigenetics, and added discussion of Prader-Willi and Angelman syndromes. Added a box on the yeast two-hybrid system, updated the discussion of the structure of the *lac* repressor/operon to reflect crystallographic data. Revised and expanded the discussion of *Hox* genes (including a new figure). Added discussion of SUMOylation in the post-translational control section.

CHAPTER 24: Added discussion on how cancers evade destruction by the immune system, and how the tumor microenvironment influences tumor growth, invasion, and metastasis. More discussion of the ability of cancer cells to evade apoptosis and of the Rho family in triggering the enhanced cell motility that leads to invasion and metastasis. Added more discussion on how polycyclic aromatic hydrocarbons in tobacco cause unique mutations in the *p53* gene, and added information about the typical mutation patterns in cancer cells obtained from genome sequencing studies. Added information about the role of microRNAs and histone methylation in cancer epigenetics, and more information about cancer vaccines.

APPENDIX: Added mention of photoconvertible and photoswitchable fluorophores. Added a section on various techniques for superresolution microscopy. Streamlined discussion of correlative microscopy. Updated figure on the fluorescence microscope to more accurately reflect modern epifluorescence systems.

Techniques and Methods

Throughout the text, we have tried to explain not only *what* we know about cells but also *how* we know what we know. Toward that end, we have included descriptions of experimental techniques and findings in every chapter, almost always in the context of the questions they address and in anticipation of the answers they provide. For example, polyacrylamide gel electrophoresis is introduced not

in a chapter that simply catalogues a variety of methods for studying cells but in Chapter 7, where it becomes important to our understanding of how membrane proteins can be separated from one another. Similarly, equilibrium density centrifugation is described in Chapter 12, where it is essential to our understanding of how lysosomes were originally distinguished from mitochondria and subsequently from peroxisomes as well.

To help readers locate techniques out of context, an alphabetical Guide to Techniques and Methods appears on the inside of the front cover, with references to chapters, pages, tables, figures, and boxed essays, as appropriate. To enhance its usefulness, the Guide to Techniques and Methods includes references not just to laboratory techniques but also to the mathematical determination of values such as ΔG (free energy change) and $\Delta E_0'$ (standard reduction potential), bioinformatics techniques such as BLAST searching, and even to clinical procedures such as the treatment of methanol poisoning.

Microscopy is the only exception to our general approach of introducing techniques in context. The techniques of light and electron microscopy are so pervasively relevant to contemporary cell biology that they warrant special consideration as a self-contained unit, which is included as an Appendix entitled *Visualizing Cells and Molecules*. This Appendix gives students ready access to detailed information on a variety of microscopy techniques, including cutting-edge uses of light microscopy for imaging and manipulating molecular processes.

Building on the Strengths of Previous Editions

We have retained and built upon the strengths of prior editions in four key areas:

1. The chapter organization focuses on main concepts.

- Each chapter is divided into sections that begin with a *concept statement heading*, which summarizes the material and helps students focus on the main points to study and review.
- Chapters are written and organized in ways that allow instructors to assign the chapters and chapter sections in different sequences to make the book adaptable to a wide variety of course plans.
- Each chapter culminates with a bulleted *Summary of Key Points* that briefly describes the main points covered in each section of the chapter.
- Each *Summary of Key Points* is followed by a *Making Connections* paragraph that highlights some of the interrelationships that connect the content of the current chapter to topics covered elsewhere in the book.

2. The illustrations teach concepts at an appropriate level of detail.

- Many of the more complex figures incorporate *minicaptions* to help students grasp concepts more quickly by drawing their focus into the body of an illustration rather than depending solely on a separate figure legend to describe what is taking place.
- *Overview figures* outline complicated structures or processes in broad strokes and are followed by text and figures that present supporting details.
- Carefully selected micrographs are usually accompanied by scale bars to indicate magnification.

3. Important terminology is highlighted and defined in several ways.

- **Boldface type** is used to highlight the most important terms in each chapter, all of which are defined in the Glossary.
- *Italics* are employed to identify additional technical terms that are less important than boldfaced terms but significant in their own right. Occasionally, italics are also used to highlight important phrases or sentences.
- The Glossary includes definitions and page references for all bold-faced key terms and acronyms in every chapter—more than 1500 terms in all, a veritable “dictionary of cell biology” in its own right.

4. Each chapter helps students learn the process of science, not just facts.

- Text discussions emphasize the experimental evidence that underlies our understanding of cell structure and function, to remind readers that advances in cell biology, as in all branches of science, come not from lecturers in their classrooms or textbook authors at their computers but from researchers in their laboratories.
- The inclusion of a *Problem Set* at the end of each chapter reflects our conviction that we learn science not just by reading or hearing about it, but by working with it. The problems are designed to emphasize understanding and application, rather than rote recall. Many of the problems are class-tested, having been selected from problem sets and exams we have used in our own courses.
- To maximize the usefulness of the problem sets, detailed answers for all problems are available for students in a *Solutions Manual* that is available for purchase separately.
- Each chapter contains one or more *Boxed Essays* to aid students in their understanding of particularly important or intriguing aspects of cell biology.

Some of the essays provide *Deeper Insights* into potentially difficult principles, such as the essay that uses the analogy of monkeys shelling peanuts to explain enzyme kinetics (Box 6A). Other essays describe *Tools of Discovery*, some of the important experimental techniques used by cell biologists, as exemplified by the description of DNA fingerprinting in Box 18C. And yet another role of the boxed essays is to describe *Human Applications* of research findings in cell biology, as illustrated by the discussion of cystic fibrosis and the prospects for gene therapy in Box 8B.

- A *Suggested Reading* list is included at the end of each chapter, with an emphasis on review articles and carefully selected research publications that motivated students are likely to understand. We have tried to avoid overwhelming readers with lengthy bibliographies of the original literature but have referenced articles that are especially relevant to the topics of the chapter. In most chapters, we have included a few citations of especially important historical publications, which are marked with blue dots to alert the reader to their historical significance.

Supplementary Learning Aids

For Instructors

Instructor Resource DVD-ROM for Becker's World of the Cell • 0-321-68959-3/978-0-321-68959-7

Available to adopters, this DVD-ROM includes:

- PowerPoint Lecture Tools, including pre-made lecture outlines containing all of the figures and photos and embedded animations, and 5–10 Personal Response System (PRS) clicker questions per chapter.
- JPEG images of all textbook figures and photos, including printer-ready transparency acetate masters.
- Videos and animations of key concepts, organized by chapter for ease of use in the classroom.
- The full test bank for *Becker's World of the Cell*.

Computerized Test Bank for Becker's World of the Cell • 0-321-68958-5/978-0-321-68958-0

The test bank provides over 1000 multiple-choice, short-answer, and inquiry/activity questions.

For Students

Solutions Manual for Becker's World of the Cell • 0-321-68961-5/978-0-321-68961-0

Written by the authors, this is a collection of complete, detailed answers for all of the end-of-chapter questions and problems.

The Cell Place for Becker's World of the Cell • 0-321-68960-7/978-0-321-68960-3

The book's companion website, www.thecellplace.com, helps students explore a variety of cell biology topics in depth, and includes interactive tutorials, simulations, animations, videos, molecular structure files, and step-by-step problems. Practice quizzes contain 20 multiple-choice questions for each chapter, with instant feedback for correct and incorrect answers.

We Welcome Your Comments and Suggestions

The ultimate test of any textbook is how effectively it helps instructors teach and students learn. We welcome feedback and suggestions from readers and will try to acknowledge all correspondence.

ACKNOWLEDGMENTS

We want to acknowledge the contributions of the numerous people who have made this book possible. We are indebted especially to the many students whose words of encouragement catalyzed the writing of these chapters and whose thoughtful comments and criticisms have contributed much to whatever level of reader-friendliness the text may be judged to have. Each of us owes a special debt of gratitude to our colleagues, from whose insights and suggestions we have benefited greatly and borrowed freely. We also acknowledge those who have contributed to previous editions of our textbooks, including David Deamer, Martin Poenie, Jane Reece, John Raasch, and Valerie Kish, as well as Peter Armstrong, John Carson, Ed Clark, Joel Goodman, David Gunn, Jeanette Natzle, Mary Jane Niles, Timothy Ryan, Beth Schaefer, Lisa Smit, David Spiegel, Akif Uzman, and Karen Valentine. Most importantly, we are grateful to Wayne Becker for his incisive writing and vision, which led to the creation of this book and featured so prominently in previous editions. We have tried to carry on his tradition of excellence. In addition, we want to express our appreciation to the many colleagues who graciously consented to contribute micrographs to this endeavor, as well as the authors and publishers who have kindly granted permission to reproduce copyrighted material.

The many reviewers listed below provided helpful criticisms and suggestions at various stages of manuscript development and revision. Their words of appraisal and counsel were gratefully received and greatly appreciated. Indeed, the extensive review process to which this and the prior editions of the book have been exposed should be considered a significant feature of the book. Nonetheless, the final responsibility for what you read here remains ours, and you may confidently attribute to us any errors of omission or commission encountered in these pages.

We are also deeply indebted to the many publishing professionals whose consistent encouragement, hard work, and careful attention to detail contributed much to the clarity of both the text and the art. Special recognition and sincere appreciation go to Anna Amato in her role as project editor, to Gary Carlson, Josh Frost, Lindsay White, Deborah Gale, Lori Newman, Laura Tommasi, Sonia DiVittorio, and Lee Ann Doctor at Benjamin Cummings, to Stephanie Davidson at Dartmouth Publishing, and to Crystal Clifton and her colleagues at Progressive Publishing Alternatives.

Finally, we are grateful beyond measure to our wives, families, graduate students, and postdoctoral associates, without whose patience, understanding, and forbearance this book could not have been written.

APPENDIX *Visualizing Cells and Molecules* *A-1*

Glossary *G-1*

Photo, Illustration, and Text Credits *C-1*

Index *I-1*

DETAILED CONTENTS

About the Authors *iii*

Preface *v*

Acknowledgments *x*

1 A Preview of the Cell *1*

The Cell Theory: A Brief History *1*

The Emergence of Modern Cell Biology *3*

- The Cytological Strand Deals with Cellular Structure *4*
- The Biochemical Strand Covers the Chemistry of Biological Structure and Function *8*
- The Genetic Strand Focuses on Information Flow *9*

“Facts” and the Scientific Method *11*

Summary of Key Points *14*

Making Connections *15*

Problem Set *15*

Suggested Reading *17*

BOX 1A Tools of Discovery: Units of Measurement in Cell Biology *2*

BOX 1B Tools of Discovery: Model Organisms in Cell Biology Research *12*

2 The Chemistry of the Cell *18*

The Importance of Carbon *18*

- Carbon-Containing Molecules Are Stable *19*
- Carbon-Containing Molecules Are Diverse *20*
- Carbon-Containing Molecules Can Form Stereoisomers *21*

The Importance of Water *22*

- Water Molecules Are Polar *23*
- Water Molecules Are Cohesive *23*
- Water Has a High Temperature-Stabilizing Capacity *23*
- Water Is an Excellent Solvent *24*

The Importance of Selectively Permeable Membranes *25*

- A Membrane Is a Lipid Bilayer with Proteins Embedded in It *26*
- Membranes Are Selectively Permeable *27*

The Importance of Synthesis by Polymerization *27*

- Macromolecules Are Responsible for Most of the Form and Function in Living Systems *27*
- Cells Contain Three Different Kinds of Macromolecules *29*
- Macromolecules Are Synthesized by Stepwise Polymerization of Monomers *30*

The Importance of Self-Assembly *32*

- Many Proteins Self-Assemble *32*
- Molecular Chaperones Assist the Assembly of Some Proteins *32*
- Noncovalent Bonds and Interactions Are Important in the Folding of Macromolecules *34*
- Self-Assembly Also Occurs in Other Cellular Structures *35*

The Tobacco Mosaic Virus Is a Case Study in Self-Assembly *35*

Self-Assembly Has Limits *36*

Hierarchical Assembly Provides Advantages for the Cell *36*

Summary of Key Points *38*

Making Connections *39*

Problem Set *39*

Suggested Reading *40*

BOX 2A Deeper Insights: Tempus Fugit and the Fine Art of Watchmaking *37*

3 The Macromolecules of the Cell *41*

Proteins *41*

- The Monomers Are Amino Acids *41*
- The Polymers Are Polypeptides and Proteins *44*
- Several Kinds of Bonds and Interactions Are Important in Protein Folding and Stability *44*
- Protein Structure Depends on Amino Acid Sequence and Interactions *47*

Nucleic Acids *54*

- The Monomers Are Nucleotides *54*
- The Polymers Are DNA and RNA *57*
- A DNA Molecule Is a Double-Stranded Helix *59*

Polysaccharides *60*

- The Monomers Are Monosaccharides *61*
- The Polymers Are Storage and Structural Polysaccharides *63*
- Polysaccharide Structure Depends on the Kinds of Glycosidic Bonds Involved *65*

Lipids *65*

- Fatty Acids Are the Building Blocks of Several Classes of Lipids *68*
- Triacylglycerols Are Storage Lipids *68*
- Phospholipids Are Important in Membrane Structure *69*
- Glycolipids Are Specialized Membrane Components *70*
- Steroids Are Lipids with a Variety of Functions *70*
- Terpenes Are Formed from Isoprene *70*

Summary of Key Points *71*

Making Connections *72*

Problem Set *72*

Suggested Reading *74*

BOX 3A Deeper Insights: On the Trail of the Double Helix *60*

4 Cells and Organelles *75*

Properties and Strategies of Cells *75*

- All Organisms Are Bacteria, Archaea, or Eukaryotes *75*
- Limitations on Cell Size *76*
- Eukaryotic Cells Use Organelles to Compartmentalize Cellular Function *78*

Bacteria, Archaea, and Eukaryotes Differ from Each Other in Many Ways 78
Cell Specialization Demonstrates the Unity and Diversity of Biology 81

The Eukaryotic Cell in Overview:

Pictures at an Exhibition 82

The Plasma Membrane Defines Cell Boundaries and Retains Contents 82
The Nucleus Is the Information Center of the Eukaryotic Cell 83
Intracellular Membranes and Organelles Define Compartments 84
The Cytosol of Eukaryotic Cells Contains the Cytosol and Cytoskeleton 95
The Extracellular Matrix and the Cell Wall Are “Outside” the Cell 98

Viruses, Viroids, and Prions:

Agents That Invade Cells 99

A Virus Consists of a DNA or RNA Core Surrounded by a Protein Coat 99
Viroids Are Small, Circular RNA Molecules 101
Prions Are “Proteinaceous Infective Particles” 101

Summary of Key Points 102

Making Connections 103

Problem Set 103

Suggested Reading 104

BOX 4A Human Applications: Organelles and Human Diseases 86

BOX 4B Deeper Insights: Discovering Organelles: The Importance of Centrifuges and Chance Observations 92

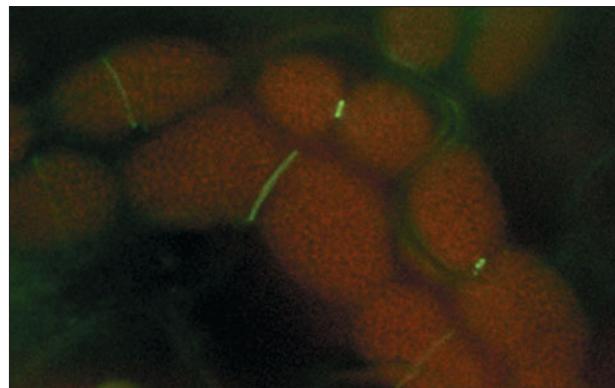

5 Bioenergetics: The Flow of Energy in the Cell 106

The Importance of Energy 106

Cells Need Energy to Drive Six Different Kinds of Changes 106
Organisms Obtain Energy Either from Sunlight or from the Oxidation of Chemical Compounds 108
Energy Flows Through the Biosphere Continuously 109
The Flow of Energy Through the Biosphere Is Accompanied by a Flow of Matter 110

Bioenergetics 111

To Understand Energy Flow, We Need to Understand Systems, Heat, and Work 111
The First Law of Thermodynamics Tells Us That Energy Is Conserved 112

The Second Law of Thermodynamics Tells Us That Reactions Have Directionality 113
Entropy and Free Energy Are Two Alternative Means of Assessing Thermodynamic Spontaneity 114

Understanding ΔG 119

The Equilibrium Constant Is a Measure of Directionality 119
ΔG Can Be Calculated Readily 120
The Standard Free Energy Change Is ΔG Measured Under Standard Conditions 121
Summing Up: The Meaning of ΔG' and ΔG° 122
Free Energy Change: Sample Calculations 123

Life and the Steady State:

Reactions That Move Toward Equilibrium Without Ever Getting There 124

Summary of Key Points 124

Making Connections 125

Problem Set 125

Suggested Reading 128

BOX 5A Deeper Insights: Jumping Beans and Free Energy 116

6 Enzymes: The Catalysts of Life 129

Activation Energy and the Metastable State 129

Before a Chemical Reaction Can Occur, the Activation Energy Barrier Must Be Overcome 130
The Metastable State Is a Result of the Activation Barrier 130
Catalysts Overcome the Activation Energy Barrier 131

Enzymes as Biological Catalysts 131

Most Enzymes Are Proteins 132
Substrate Binding, Activation, and Catalysis Occur at the Active Site 136

Enzyme Kinetics 138

Most Enzymes Display Michaelis–Menten Kinetics 139
What Is the Meaning of V_{max} and K_m ? 141
Why Are K_m and V_{max} Important to Cell Biologists? 141
The Double-Reciprocal Plot Is a Useful Means of Linearizing Kinetic Data 142
Determining K_m and V_{max} : An Example 143
Enzyme Inhibitors Act Either Irreversibly or Reversibly 144

Enzyme Regulation 146

Allosteric Enzymes Are Regulated by Molecules Other than Reactants and Products 146
Allosteric Enzymes Exhibit Cooperative Interactions Between Subunits 148
Enzymes Can Also Be Regulated by the Addition or Removal of Chemical Groups 148

RNA Molecules as Enzymes: Ribozymes 150

Summary of Key Points 151

Making Connections 152

Problem Set 152

Suggested Reading 155

BOX 6A Deeper Insights: Monkeys and Peanuts 140

7 Membranes: Their Structure, Function, and Chemistry 156

The Functions of Membranes 156

- Membranes Define Boundaries and Serve as Permeability Barriers 156
- Membranes Are Sites of Specific Proteins and Therefore of Specific Functions 156
- Membrane Proteins Regulate the Transport of Solutes 157
- Membrane Proteins Detect and Transmit Electrical and Chemical Signals 158
- Membrane Proteins Mediate Cell Adhesion and Cell-to-Cell Communication 158

Models of Membrane Structure: An Experimental Perspective 158

- Overton and Langmuir: Lipids Are Important Components of Membranes 159
- Gorter and Grendel: The Basis of Membrane Structure Is a Lipid Bilayer 159
- Davson and Danielli: Membranes Also Contain Proteins 160
- Robertson: All Membranes Share a Common Underlying Structure 160
- Further Research Revealed Major Shortcomings of the Davson–Danielli Model 160
- Singer and Nicolson: A Membrane Consists of a Mosaic of Proteins in a Fluid Lipid Bilayer 161
- Unwin and Henderson: Most Membrane Proteins Contain Transmembrane Segments 163
- Recent Findings Further Refine Our Understanding of Membrane Structure 163

Membrane Lipids: The “Fluid” Part of the Model 163

- Membranes Contain Several Major Classes of Lipids 163
- Thin-Layer Chromatography Is an Important Technique for Lipid Analysis 166
- Fatty Acids Are Essential to Membrane Structure and Function 167
- Membrane Asymmetry: Most Lipids Are Distributed Unequally Between the Two Monolayers 167
- The Lipid Bilayer Is Fluid 169
- Membranes Function Properly Only in the Fluid State 169
- Most Organisms Can Regulate Membrane Fluidity 172
- Lipid Rafts Are Localized Regions of Membrane Lipids That Are Involved in Cell Signaling 173

Membrane Proteins: The “Mosaic” Part of the Model 173

- The Membrane Consists of a Mosaic of Proteins: Evidence from Freeze-Fracture Microscopy 174
- Membranes Contain Integral, Peripheral, and Lipid-Anchored Proteins 175
- Proteins Can Be Separated by SDS–Polyacrylamide Gel Electrophoresis 178
- Determining the Three-Dimensional Structure of Membrane Proteins Is Becoming More Feasible 180
- Molecular Biology Has Contributed Greatly to Our Understanding of Membrane Proteins 181
- Membrane Proteins Have a Variety of Functions 181
- Membrane Proteins Are Oriented Asymmetrically Across the Lipid Bilayer 184

Many Membrane Proteins Are Glycosylated 185
Membrane Proteins Vary in Their Mobility 187

Summary of Key Points 189

Making Connections 190

Problem Set 190

Suggested Reading 193

BOX 7A Tools of Discovery: Revolutionizing the Study of Membrane Proteins: The Impact of Molecular Biology 182

8 Transport Across Membranes: Overcoming the Permeability Barrier 194

Cells and Transport Processes 194

- Solutes Cross Membranes by Simple Diffusion, Facilitated Diffusion, and Active Transport 194
- The Movement of a Solute Across a Membrane Is Determined by Its Concentration Gradient or Its Electrochemical Potential 196
- The Erythrocyte Plasma Membrane Provides Examples of Transport Mechanisms 196

Simple Diffusion: Unassisted Movement Down the Gradient 197

- Diffusion Always Moves Solutes Toward Equilibrium 197
- Osmosis Is the Diffusion of Water Across a Selectively Permeable Membrane 198
- Simple Diffusion Is Limited to Small, Nonpolar Molecules 199
- The Rate of Simple Diffusion Is Directly Proportional to the Concentration Gradient 201

Facilitated Diffusion: Protein-Mediated Movement Down the Gradient 201

- Carrier Proteins and Channel Proteins Facilitate Diffusion by Different Mechanisms 202
- Carrier Proteins Alternate Between Two Conformational States 202
- Carrier Proteins Are Analogous to Enzymes in Their Specificity and Kinetics 202
- Carrier Proteins Transport Either One or Two Solutes 203
- The Erythrocyte Glucose Transporter and Anion Exchange Protein Are Examples of Carrier Proteins 203
- Channel Proteins Facilitate Diffusion by Forming Hydrophilic Transmembrane Channels 205

Active Transport: Protein-Mediated Movement Up the Gradient 208

- The Coupling of Active Transport to an Energy Source May Be Direct or Indirect 209
- Direct Active Transport Depends on Four Types of Transport ATPases 209
- Indirect Active Transport Is Driven by Ion Gradients 212

Examples of Active Transport 212

- Direct Active Transport: The Na^+/K^+ Pump Maintains Electrochemical Ion Gradients 213
- Indirect Active Transport: Sodium Symport Drives the Uptake of Glucose 213
- The Bacteriorhodopsin Proton Pump Uses Light Energy to Transport Protons 215

The Energetics of Transport 216

For Uncharged Solutes, the ΔG of Transport Depends Only on the Concentration Gradient 216
For Charged Solutes, the ΔG of Transport Depends on the Electrochemical Potential 218

Summary of Key Points 219

Making Connections 220

Problem Set 221

Suggested Reading 223

BOX 8A **Deeper Insights:** Osmosis: The Diffusion of Water Across a Selectively Permeable Membrane 200

BOX 8B **Human Applications:** Membrane Transport, Cystic Fibrosis, and the Prospects for Gene Therapy 206

9 Chemotrophic Energy Metabolism: Glycolysis and Fermentation 224

Metabolic Pathways 224

ATP: The Universal Energy Coupler 225

ATP Contains Two Energy-Rich Phosphoanhydride Bonds 225
ATP Hydrolysis Is Highly Exergonic Because of Charge Repulsion and Resonance Stabilization 226
ATP Is an Important Intermediate in Cellular Energy Metabolism 227

Chemotrophic Energy Metabolism 229

Biological Oxidations Usually Involve the Removal of Both Electrons and Protons and Are Highly Exergonic 229
Coenzymes Such as NAD⁺ Serve as Electron Acceptors in Biological Oxidations 230
Most Chemotrophs Meet Their Energy Needs by Oxidizing Organic Food Molecules 230
Glucose Is One of the Most Important Oxidizable Substrates in Energy Metabolism 231
The Oxidation of Glucose Is Highly Exergonic 231
Glucose Catabolism Yields Much More Energy in the Presence of Oxygen than in Its Absence 231
Based on Their Need for Oxygen, Organisms Are Aerobic, Anaerobic, or Facultative 231

Glycolysis and Fermentation: ATP Generation Without the Involvement of Oxygen 232

Glycolysis Generates ATP by Catabolizing Glucose to Pyruvate 232
The Fate of Pyruvate Depends on Whether Oxygen Is Available 235
In the Absence of Oxygen, Pyruvate Undergoes Fermentation to Regenerate NAD⁺ 236
Fermentation Taps Only a Fraction of the Substrate's Free Energy but Conserves That Energy Efficiently as ATP 237

Alternative Substrates for Glycolysis 238

Other Sugars and Glycerol Are Also Catabolized by the Glycolytic Pathway 238
Polysaccharides Are Cleaved to Form Sugar Phosphates That Also Enter the Glycolytic Pathway 238

Gluconeogenesis 239

The Regulation of Glycolysis and Gluconeogenesis 241

Key Enzymes in the Glycolytic and Gluconeogenic Pathways Are Subject to Allosteric Regulation 241
Fructose-2,6-Bisphosphate Is an Important Regulator of Glycolysis and Gluconeogenesis 245

Novel Roles for Glycolytic Enzymes 245

Summary of Key Points 247

Making Connections 248

Problem Set 248

Suggested Reading 251

BOX 9A **Deeper Insights:** "What Happens to the Sugar?" 242

10 Chemotrophic Energy Metabolism: Aerobic Respiration 252

Cellular Respiration: Maximizing ATP Yields

Aerobic Respiration Yields Much More Energy than Fermentation Does 252
Respiration Includes Glycolysis, Pyruvate Oxidation, the TCA Cycle, Electron Transport, and ATP Synthesis 254

The Mitochondrion: Where the Action

Takes Place 254

Mitochondria Are Often Present Where the ATP Needs Are Greatest 254
Are Mitochondria Interconnected Networks Rather than Discrete Organelles? 255
The Outer and Inner Membranes Define Two Separate Compartments and Three Regions 255
Mitochondrial Functions Occur in or on Specific Membranes and Compartments 257
In Bacteria, Respiratory Functions Are Localized to the Plasma Membrane and the Cytoplasm 257

The Tricarboxylic Acid Cycle: Oxidation in the Round 258

Pyruvate Is Converted to Acetyl Coenzyme A by Oxidative Decarboxylation 259
The TCA Cycle Begins with the Entry of Acetate as Acetyl CoA 259
Two Oxidative Decarboxylations Then Form NADH and Release CO₂ 260
Direct Generation of GTP (or ATP) Occurs at One Step in the TCA Cycle 260
The Final Oxidative Reactions of the TCA Cycle Generate FADH₂ and NADH 260
Summing Up: The Products of the TCA Cycle Are CO₂, ATP, NADH, and FADH₂ 262
Several TCA Cycle Enzymes Are Subject to Allosteric Regulation 263
The TCA Cycle Also Plays a Central Role in the Catabolism of Fats and Proteins 263
The TCA Cycle Serves as a Source of Precursors for Anabolic Pathways 266
The Glyoxylate Cycle Converts Acetyl CoA to Carbohydrates 267

Electron Transport: Electron Flow from Coenzymes to Oxygen 267

The Electron Transport System Conveys Electrons from Reduced Coenzymes to Oxygen 267
The Electron Transport System Consists of Five Kinds of Carriers 270
The Electron Carriers Function in a Sequence Determined by Their Reduction Potentials 271
Most of the Carriers Are Organized into Four Large Respiratory Complexes 274
The Respiratory Complexes Move Freely Within the Inner Membrane 275

The Electrochemical Proton Gradient:

Key to Energy Coupling 276

- Electron Transport and ATP Synthesis Are Coupled Events 276
- Coenzyme Oxidation Pumps Enough Protons to Form 3 ATP per NADH and 2 ATP per FADH₂ 277
- The Chemiosmotic Model Is Affirmed by an Impressive Array of Evidence 277

ATP Synthesis: Putting It All Together 279

- F₁ Particles Have ATP Synthase Activity 279
- The F₀F₁ Complex: Proton Translocation Through F₀ Drives ATP Synthesis by F₁ 280
- ATP Synthesis by F₀F₁ Involves Physical Rotation of the Gamma Subunit 282
- The Chemiosmotic Model Involves Dynamic Transmembrane Proton Traffic 284

Aerobic Respiration: Summing It All Up 284

- The Maximum ATP Yield of Aerobic Respiration Is 38 ATPs per Glucose 284
- Aerobic Respiration Is a Highly Efficient Process 287

Summary of Key Points 288

Making Connections 289

Problem Set 289

Suggested Reading 292

BOX 10A **Deeper Insights:** The Glyoxylate Cycle, Glyoxosomes, and Seed Germination 268

11 Phototrophic Energy Metabolism: Photosynthesis 293

An Overview of Photosynthesis 293

- The Energy Transduction Reactions Convert Solar Energy to Chemical Energy 293
- The Carbon Assimilation Reactions Fix Carbon by Reducing Carbon Dioxide 295
- The Chloroplast Is the Photosynthetic Organelle in Eukaryotic Cells 295
- Chloroplasts Are Composed of Three Membrane Systems 295

Photosynthetic Energy Transduction I:

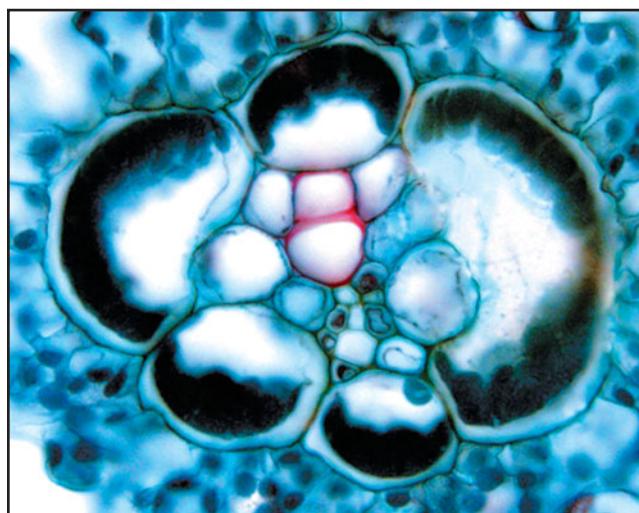

Light Harvesting 297

- Chlorophyll Is Life's Primary Link to Sunlight 298
- Accessory Pigments Further Expand Access to Solar Energy 300
- Light-Gathering Molecules Are Organized into Photosystems and Light-Harvesting Complexes 300
- Oxygenic Phototrophs Have Two Types of Photosystems 301

Photosynthetic Energy Transduction II:

NADPH Synthesis 302

- Photosystem II Transfers Electrons from Water to a Plastoquinone 303
- The Cytochrome b₆/f Complex Transfers Electrons from a Plastoquinol to Plastocyanin 305
- Photosystem I Transfers Electrons from Plastocyanin to Ferredoxin 306
- Ferredoxin-NADP⁺ Reductase Catalyzes the Reduction of NADP⁺ 306

Photosynthetic Energy Transduction III:

ATP Synthesis 307

- The ATP Synthase Complex Couples Transport of Protons Across the Thylakoid Membrane to ATP Synthesis 307
- Cyclic Photophosphorylation Allows a Photosynthetic Cell to Balance NADPH and ATP Synthesis 308
- A Summary of the Complete Energy Transduction System 308

Photosynthetic Carbon Assimilation I:

The Calvin Cycle 309

- Carbon Dioxide Enters the Calvin Cycle by Carboxylation of Ribulose-1,5-Bisphosphate 309
- 3-Phosphoglycerate Is Reduced to Form Glyceraldehyde-3-Phosphate 311
- Regeneration of Ribulose-1,5-Bisphosphate Allows Continuous Carbon Assimilation 311
- The Complete Calvin Cycle and Its Relation to Photosynthetic Energy Transduction 311

Regulation of the Calvin Cycle 312

- The Calvin Cycle Is Highly Regulated to Ensure Maximum Efficiency 312
- Rubisco Activase Regulates Carbon Fixation by Rubisco 313

Photosynthetic Carbon Assimilation II:

Carbohydrate Synthesis 313

- Glucose-1-Phosphate Is Synthesized from Triose Phosphates 313
- The Biosynthesis of Sucrose Occurs in the Cytosol 314
- The Biosynthesis of Starch Occurs in the Chloroplast Stroma 315
- Photosynthesis Also Produces Reduced Nitrogen and Sulfur Compounds 315

Rubisco's Oxygenase Activity Decreases Photosynthetic Efficiency 315

- The Glycolate Pathway Returns Reduced Carbon from Phosphoglycolate to the Calvin Cycle 316
- C₄ Plants Minimize Photorespiration by Confining Rubisco to Cells Containing High Concentrations of CO₂ 317
- CAM Plants Minimize Photorespiration and Water Loss by Opening Their Stomata Only at Night 320

Summary of Key Points 320

Making Connections 321

Problem Set 322

Suggested Reading 323

- BOX 11B** **Deeper Insights:** A Photosynthetic Reaction Center from a Purple Bacterium 302

12 The Endomembrane System and Peroxisomes 324

The Endoplasmic Reticulum 324

- The Two Basic Kinds of Endoplasmic Reticulum Differ in Structure and Function 325
- Rough ER Is Involved in the Biosynthesis and Processing of Proteins 326
- Smooth ER Is Involved in Drug Detoxification, Carbohydrate Metabolism, Calcium Storage, and Steroid Biosynthesis 330
- The ER Plays a Central Role in the Biosynthesis of Membranes 331

The Golgi Complex 332

- The Golgi Complex Consists of a Series of Membrane-Bounded Cisternae 332
- Two Models Depict the Flow of Lipids and Proteins Through the Golgi Complex 333

Roles of the ER and Golgi Complex in Protein Glycosylation 334

- Initial Glycosylation Occurs in the ER 334
- Further Glycosylation Occurs in the Golgi Complex 335

Roles of the ER and Golgi Complex in Protein Trafficking 335

- ER-Specific Proteins Contain Retention and Retrieval Tags 337
- Golgi Complex Proteins May Be Sorted According to the Lengths of Their Membrane-Spanning Domains 338
- Targeting of Soluble Lysosomal Proteins to Endosomes and Lysosomes Is a Model for Protein Sorting in the TGN 338
- Secretory Pathways Transport Molecules to the Exterior of the Cell 339

Exocytosis and Endocytosis: Transporting Material Across the Plasma Membrane 341

- Exocytosis Releases Intracellular Molecules Outside the Cell 341
- Endocytosis Imports Extracellular Molecules by Forming Vesicles from the Plasma Membrane 342

Coated Vesicles in Cellular Transport Processes 348

- Clathrin-Coated Vesicles Are Surrounded by Lattices Composed of Clathrin and Adaptor Protein 348
- The Assembly of Clathrin Coats Drives the Formation of Vesicles from the Plasma Membrane and TGN 349
- COPI- and COPII-Coated Vesicles Travel Between the ER and Golgi Complex Cisternae 350
- SNARE Proteins Mediate Fusion Between Vesicles and Target Membranes 350

Lysosomes and Cellular Digestion 352

- Lysosomes Isolate Digestive Enzymes from the Rest of the Cell 352
- Lysosomes Develop from Endosomes 353
- Lysosomal Enzymes Are Important for Several Different Digestive Processes 353
- Lysosomal Storage Diseases Are Usually Characterized by the Accumulation of Indigestible Material 355

The Plant Vacuole: A Multifunctional Organelle 355

Peroxisomes 356

- The Discovery of Peroxisomes Depended on Innovations in Equilibrium Density Centrifugation 356
- Most Peroxisomal Functions Are Linked to Hydrogen Peroxide Metabolism 357
- Plant Cells Contain Types of Peroxisomes Not Found in Animal Cells 358
- Peroxisome Biogenesis Occurs by Division of Preexisting Peroxisomes 359

Summary of Key Points 360

Making Connections 362

Problem Set 362

Suggested Reading 364

- BOX 12B** **Human Applications:** Cholesterol, the LDL Receptor, and Receptor-Mediated Endocytosis 346

13 Signal Transduction Mechanisms: I. Electrical and Synaptic Signaling in Neurons 365

Neurons 365

- Neurons Are Specially Adapted for the Transmission of Electrical Signals 366

Understanding Membrane Potential 367

- The Resting Membrane Potential Depends on Differing Concentrations of Ions Inside and Outside the Neuron and on the Selective Permeability of the Membrane 368
- The Nernst Equation Describes the Relationship Between Membrane Potential and Ion Concentration 369
- Steady-State Concentrations of Common Ions Affect Resting Membrane Potential 370
- The Goldman Equation Describes the Combined Effects of Ions on Membrane Potential 370

Electrical Excitability 372

- Ion Channels Act Like Gates for the Movement of Ions Through the Membrane 372
- Patch Clamping and Molecular Biological Techniques Allow the Activity of Single Ion Channels to Be Monitored 372
- Specific Domains of Voltage-Gated Channels Act as Sensors and Inactivators 373

The Action Potential 375

- Action Potentials Propagate Electrical Signals Along an Axon 375
- Action Potentials Involve Rapid Changes in the Membrane Potential of the Axon 375
- Action Potentials Result from the Rapid Movement of Ions Through Axonal Membrane Channels 377
- Action Potentials Are Propagated Along the Axon Without Losing Strength 378
- The Myelin Sheath Acts Like an Electrical Insulator Surrounding the Axon 379

Synaptic Transmission 380

- Neurotransmitters Relay Signals Across Nerve Synapses 381
- Elevated Calcium Levels Stimulate Secretion of Neurotransmitters from Presynaptic Neurons 384

Secretion of Neurotransmitters Involves the Docking and Fusion of Vesicles with the Plasma Membrane	385
Neurotransmitters Are Detected by Specific Receptors on Postsynaptic Neurons	386
Neurotransmitters Must Be Inactivated Shortly After Their Release	387
Integration and Processing of Nerve Signals	388
Neurons Can Integrate Signals from Other Neurons Through Both Temporal and Spatial Summation	388
Neurons Can Integrate Both Excitatory and Inhibitory Signals from Other Neurons	388
Summary of Key Points	389
Making Connections	389
Problem Set	390
Suggested Reading	391

BOX 13A Human Applications: Poisoned Arrows, Snake Bites, and Nerve Gases 387

14 Signal Transduction Mechanisms: II. Messengers and Receptors	392
Chemical Signals and Cellular Receptors	392
Different Types of Chemical Signals Can Be Received by Cells	392
Receptor Binding Involves Specific Interactions Between Ligands and Their Receptors	393
Receptor Binding Activates a Sequence of Signal Transduction Events Within the Cell	394
G Protein-Linked Receptors	396
Many Seven-Membrane Spanning Receptors Act via G Proteins	396
Cyclic AMP Is a Second Messenger Whose Production Is Regulated by Some G Proteins	398
Disruption of G Protein Signaling Causes Several Human Diseases	399
Many G Proteins Use Inositol Trisphosphate and Diacylglycerol as Second Messengers	401
The Release of Calcium Ions Is a Key Event in Many Signaling Processes	402
The $\beta\gamma$ Subunits of G Proteins Can Also Transduce Signals	405
Other Signaling Pathways Can Activate G Proteins	405
Protein Kinase-Associated Receptors	406
Growth Factors Often Bind Protein Kinase-Associated Receptors	407
Receptor Tyrosine Kinases Aggregate and Undergo Autophosphorylation	407
Receptor Tyrosine Kinases Initiate a Signal Transduction Cascade Involving Ras and MAP Kinase	408
Receptor Tyrosine Kinases Activate a Variety of Other Signaling Pathways	409
Scaffolding Complexes Can Facilitate Cell Signaling	410
Dominant Negative Mutant Receptors Are Important Tools for Studying Receptor Function	411
Other Growth Factors Transduce Their Signals via Receptor Serine-Threonine Kinases	413
Disruption of Growth Factor Signaling Can Lead to Cancer	413
Growth Factor Receptor Pathways Share Common Themes	414

Hormonal Signaling 414

Hormones Can Be Classified by the Distance They Travel and by Their Chemical Properties	415
Control of Glucose Metabolism Is a Good Example of Endocrine Regulation	415
Steroid Hormone Receptors Act Primarily in the Nucleus, not the Cell Surface	417

Summary of Key Points 419

Making Connections 419

Problem Set 420

Suggested Reading 421

15 Cytoskeletal Systems 422

Major Structural Elements of the Cytoskeleton 422

Eukaryotes Have Three Basic Types of Cytoskeletal Elements	422
Bacteria Have Cytoskeletal Systems That Are Structurally Similar to Those in Eukaryotes	422
The Cytoskeleton Is Dynamically Assembled and Disassembled	423
Microtubules	424
Two Types of Microtubules Are Responsible for Many Functions in the Cell	424
Tubulin Heterodimers Are the Protein Building Blocks of Microtubules	426
Microtubules Can Form as Singlets, Doublets, or Triplets	427
Microtubules Form by the Addition of Tubulin Dimers at Their Ends	427
Addition of Tubulin Dimers Occurs More Quickly at the Plus Ends of Microtubules	427
Drugs Can Affect the Assembly of Microtubules	428
GTP Hydrolysis Contributes to the Dynamic Instability of Microtubules	429
Microtubules Originate from Microtubule-Organizing Centers Within the Cell	430
MTOCs Organize and Polarize the Microtubules Within Cells	430
Microtubule Stability Is Tightly Regulated in Cells by a Variety of Microtubule-Binding Proteins	432

Microfilaments 433

- Actin Is the Protein Building Block of Microfilaments 434
- Different Types of Actin Are Found in Cells 434
- G-Actin Monomers Polymerize into F-Actin Microfilaments 434
- Specific Drugs Affect Polymerization of Microfilaments 435
- Cells Can Dynamically Assemble Actin into a Variety of Structures 436
- Actin-Binding Proteins Regulate the Polymerization, Length, and Organization of Microfilaments 437
- Cell Signaling Regulates Where and When Actin-Based Structures Assemble 439

Intermediate Filaments 442

- Intermediate Filament Proteins Are Tissue Specific 443
- Intermediate Filaments Assemble from Fibrous Subunits 443
- Intermediate Filaments Confer Mechanical Strength on Tissues 444
- The Cytoskeleton Is a Mechanically Integrated Structure 444

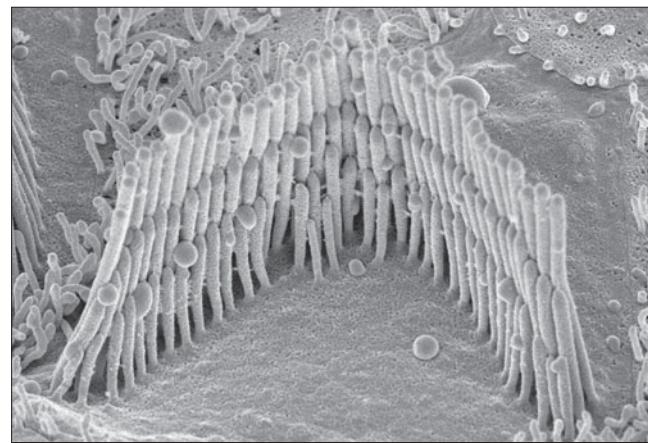

Summary of Key Points 445

BOX 15A *Human Applications: Infectious Microorganisms Can Move Within Cells Using Actin “Tails”* 441

16 Cellular Movement: Motility and Contractility 449

Motile Systems 449

Intracellular Microtubule-Based Movement:

Kinesin and Dynein 450

- MT Motor Proteins Move Organelles Along Microtubules During Axonal Transport 450
- Motor Proteins Move Along Microtubules by Hydrolyzing ATP 451
- Kinesins Are a Large Family of Proteins with Varying Structures and Functions 452
- Dyneins Can Be Grouped into Two Major Classes: Axonemal and Cytoplasmic Dyneins 452
- Microtubule Motors Are Involved in Shaping the Endomembrane System and Vesicle Transport 452

Microtubule-Based Motility: Cilia and Flagella 453

- Cilia and Flagella Are Common Motile Appendages of Eukaryotic Cells 453
- Cilia and Flagella Consist of an Axoneme Connected to a Basal Body 454
- Microtubule Sliding Within the Axoneme Causes Cilia and Flagella to Bend 457

Actin-Based Cell Movement: The Myosins 459

- Myosins Are a Large Family of Actin-Based Motors with Diverse Roles in Cell Motility 459
- Many Myosins Move Along Actin Filaments in Short Steps 459

Filament-Based Movement in Muscle 460

- Skeletal Muscle Cells Contain Thin and Thick Filaments 460
- Sarcomeres Contain Ordered Arrays of Actin, Myosin, and Accessory Proteins 461
- The Sliding-Filament Model Explains Muscle Contraction 463

Cross-Bridges Hold Filaments Together, and ATP Powers Their Movement 464

The Regulation of Muscle Contraction Depends on Calcium 466

The Coordinated Contraction of Cardiac Muscle Cells Involves Electrical Coupling 468

Smooth Muscle Is More Similar to Nonmuscle Cells than to Skeletal Muscle 469

Actin-Based Motility in Nonmuscle Cells 471

- Cell Migration via Lamellipodia Involves Cycles of Protrusion, Attachment, Translocation, and Detachment 471
- Chemotaxis Is a Directional Movement in Response to a Graded Chemical Stimulus 472
- Amoeboid Movement Involves Cycles of Gelation and Solation of the Actin Cytoskeleton 473

Unwinding the DNA Double Helix Requires DNA Helicases, Topoisomerases, and Single-Stranded DNA Binding Proteins	562		
Putting It All Together: DNA Replication in Summary	562		
Telomeres Solve the DNA End-Replication Problem	564		

DNA Damage and Repair 567

- DNA Damage Can Occur Spontaneously or in Response to Mutagens 567
- Translesion Synthesis and Excision Repair Correct Mutations Involving Abnormal Nucleotides 568
- Mismatch Repair Corrects Mutations That Involve Noncomplementary Base Pairs 569
- Damage Repair Helps Explain Why DNA Contains Thymine Instead of Uracil 569
- Double-Strand DNA Breaks Are Repaired by Nonhomologous End-Joining or Homologous Recombination 570

Nuclear and Cell Division 571

- Mitosis Is Subdivided into Prophase, Prometaphase, Metaphase, Anaphase, and Telophase 571
- The Mitotic Spindle Is Responsible for Chromosome Movements During Mitosis 574
- Cytokinesis Divides the Cytoplasm 578
- Cell Division Is Sometimes Asymmetric 580

Regulation of the Cell Cycle 580

- The Length of the Cell Cycle Varies Among Different Cell Types 580
- Progression Through the Cell Cycle Is Controlled at Several Key Transition Points 581
- Studies Involving Cell Fusion and Cell Cycle Mutants Led to the Identification of Molecules That Control the Cell Cycle 582
- Progression Through the Cell Cycle Is Controlled by Cyclin-Dependent Kinases (Cdks) 583
- Mitotic Cdk-Cyclin Drives Progression Through the G2-M Transition by Phosphorylating Key Proteins Involved in the Early Stages of Mitosis 583
- The Anaphase-Promoting Complex Coordinates Key Mitotic Events by Targeting Specific Proteins for Destruction 585
- G1 Cdk-Cyclin Regulates Progression Through the Restriction Point by Phosphorylating the Rb Protein 586
- Checkpoint Pathways Monitor for Chromosome-to-Spindle Attachments, Completion of DNA Replication, and DNA Damage 587
- Putting It All Together: The Cell Cycle Regulation Machine 588

Growth Factors and Cell Proliferation 589

- Stimulatory Growth Factors Activate the Ras Pathway 589
- Stimulatory Growth Factors Can Also Activate the PI3K-Akt Pathway 591

Inhibitory Growth Factors Act Through Cdk Inhibitors 591

Apoptosis 591

- Apoptosis Is Triggered by Death Signals or Withdrawal of Survival Factors 593

20 Sexual Reproduction, Meiosis, and Genetic Recombination 600

Sexual Reproduction 600

- Sexual Reproduction Produces Genetic Variety by Bringing Together Chromosomes from Two Different Parents 600
- Diploid Cells May Be Homozygous or Heterozygous for Each Gene 601
- Gametes Are Haploid Cells Specialized for Sexual Reproduction 602

Meiosis 602

- The Life Cycles of Sexual Organisms Have Diploid and Haploid Phases 603

Meiosis Converts One Diploid Cell into Four Haploid Cells 604

- Meiosis I Produces Two Haploid Cells That Have Chromosomes Composed of Sister Chromatids 605
- Meiosis II Resembles a Mitotic Division 607
- Sperm and Egg Cells Are Generated by Meiosis Accompanied by Cell Differentiation 611
- Meiosis Generates Genetic Diversity 612

Genetic Variability: Segregation and Assortment of Alleles 612

- Information Specifying Recessive Traits Can Be Present Without Being Displayed 613
- The Law of Segregation States That the Alleles of Each Gene Separate from Each Other During Gamete Formation 615
- The Law of Independent Assortment States That the Alleles of Each Gene Separate Independently of the Alleles of Other Genes 615
- Early Microscopic Evidence Suggested That Chromosomes Might Carry Genetic Information 615
- Chromosome Behavior Explains the Laws of Segregation and Independent Assortment 616
- The DNA Molecules of Homologous Chromosomes Have Similar Base Sequences 617

Genetic Variability: Recombination and Crossing Over 618

- Chromosomes Contain Groups of Linked Genes That Are Usually Inherited Together 619
- Homologous Chromosomes Exchange Segments During Crossing Over 619
- Gene Locations Can Be Mapped by Measuring Recombination Frequencies 620

Genetic Recombination in Bacteria and Viruses 620

- Co-infection of Bacterial Cells with Related Bacteriophages Can Lead to Genetic Recombination 620
- Transformation and Transduction Involve Recombination with Free DNA or RNA Brought into Bacterial Cells by Bacteriophages 621
- Conjugation Is a Modified Sexual Activity That Facilitates Genetic Recombination in Bacteria 621

Molecular Mechanism of Homologous Recombination

624

- DNA Breakage and Exchange Underlies Homologous Recombination 624
- Homologous Recombination Can Lead to Gene Conversion 625
- Homologous Recombination Is Initiated by Single-Strand DNA Exchanges (Holliday Junctions) 626
- The Synaptonemal Complex Facilitates Homologous Recombination During Meiosis 628

Recombinant DNA Technology and Gene Cloning

628

- The Discovery of Restriction Enzymes Paved the Way for Recombinant DNA Technology 628
- DNA Cloning Techniques Permit Individual Gene Sequences to Be Produced in Large Quantities 629
- Genomic and cDNA Libraries Are Both Useful for DNA Cloning 632
- Large DNA Segments Can Be Cloned in YACs and BACs 634
- PCR Is Widely Used to Clone Genes from Sequenced Genomes 635

Genetic Engineering

635

- Genetic Engineering Can Produce Valuable Proteins That Are Otherwise Difficult to Obtain 636
- The Ti Plasmid Is a Useful Vector for Introducing Foreign Genes into Plants 636
- Genetic Modification Can Improve the Traits of Food Crops 636
- Concerns Have Been Raised About the Safety and Environmental Risks of GM Crops 637
- Animals Can Be Genetically Modified by Adding or Knocking Out Specific Genetic Elements 637
- Gene Therapies Are Being Developed for the Treatment of Human Diseases 640

Summary of Key Points

644

BOX 20A Tools of Discovery: Making “Designer” Mice 639

21 Gene Expression: I. The Genetic Code and Transcription

645

The Directional Flow of Genetic Information

646

- Experiments on *Neurospora* Revealed That Genes Can Code for Enzymes 646
- Most Genes Code for the Amino Acid Sequences of Polypeptide Chains 647
- The Genetic Code Is a Triplet Code 648
- The Genetic Code Is Degenerate and Nonoverlapping 652
- Messenger RNA Guides the Synthesis of Polypeptide Chains 652
- The Codon Dictionary Was Established Using Synthetic RNA Polymers and Triplets 654
- Of the 64 Possible Codons in Messenger RNA, 61 Code for Amino Acids 654
- The Genetic Code Is (Nearly) Universal 655

Transcription in Bacterial Cells

656

- Transcription Is Catalyzed by RNA Polymerase, Which Synthesizes RNA Using DNA as a Template 656
- Transcription Involves Four Stages: Binding, Initiation, Elongation, and Termination 656

Transcription in Eukaryotic Cells

660

- RNA Polymerases I, II, and III Carry Out Transcription in the Eukaryotic Nucleus 660
- Three Classes of Promoters Are Found in Eukaryotic Nuclear Genes, One for Each Type of RNA Polymerase 661
- General Transcription Factors Are Involved in the Transcription of All Nuclear Genes 663
- Elongation, Termination, and RNA Cleavage Are Involved in Completing Eukaryotic RNA Synthesis 664

RNA Processing

665

- Ribosomal RNA Processing Involves Cleavage of Multiple rRNAs from a Common Precursor 665
- Transfer RNA Processing Involves Removal, Addition, and Chemical Modification of Nucleotides 666

A Preview of the Cell

The cell is the basic unit of biology. Every organism either consists of cells or is itself a single cell. Therefore, it is only by understanding the structure and function of cells that we can appreciate both the capabilities and the limitations of living organisms, whether they are animals, plants, fungi, or microorganisms.

We are in the midst of an exciting revolution in biology that has brought with it tremendous advances in our understanding of how cells are constructed and how they carry out all the intricate functions necessary for life. Particularly significant is the dynamic nature of the cell, which has the capacity to grow, reproduce, and become specialized and also the ability to respond to stimuli and adapt to changes in its environment. We hope that the static depictions of cells in printed texts do not give you the mistaken impression that cells themselves are static, so we encourage you to view videos and animations of “cells in action” on our website, *The Cell Place*.

The field of cell biology itself is rapidly changing as scientists from a variety of related disciplines work together to gain a better understanding of how cells work. The convergence of cytology, genetics, and biochemistry has made modern cell biology one of the most exciting and dynamic disciplines in all of biology. If this text helps you to appreciate the marvels and diversity of cellular functions and helps you to experience the excitement of discovery, then one of our main goals in writing this book for you will have been met.

In this introductory chapter, we will look briefly at the origin of cell biology as a discipline. Then we will consider the three main historical strands of cytology, genetics, and biochemistry that have formed our current understanding of what cells are and how they work. We will conclude with a brief discussion of the nature of knowledge itself by considering biological facts, the scientific method, and the use of some common model organisms in cell biology—how do we know what we know?

The Cell Theory: A Brief History

The story of cell biology started to unfold more than 300 years ago, as European scientists began to focus their crude microscopes on a variety of biological material ranging from tree bark to bacteria to human sperm. One such scientist was Robert Hooke, Curator of Instruments for the Royal Society of London. In 1665, Hooke built a microscope and examined thin slices of cork cut with a penknife. He saw a network of tiny boxlike compartments that reminded him of a honeycomb and called these little compartments *cells*, from the Latin word *cellula*, meaning “little room.”

We now know that what Hooke observed were not cells at all. Those boxlike compartments were formed by the empty cell walls of dead plant tissue, which is what cork really is. However, Hooke would not have thought of these cells as dead, because he did not understand that they could be alive! Although he noticed that cells in other plant tissues were filled with what he called “juices,” he preferred to concentrate on the more prominent cell walls of the dead cork cells that he had first encountered.

Hooke’s observations were limited by the *magnification power* of his microscope, which enlarged objects to only 30 times ($30\times$) their normal size. This made it difficult to learn much about the internal organization of cells. A few years later, Antonie van Leeuwenhoek, a Dutch textile merchant, produced small lenses that could magnify objects to almost 300 times ($300\times$) their size. Using these superior lenses, van Leeuwenhoek became the first to observe living cells, including blood cells, sperm cells, bacteria, and single-celled organisms (algae and protozoa) found in pond water. He reported his observations to the Royal Society of London in a series of letters during the late 1600s. His detailed reports attest to both the high quality of his lenses and his keen powers of observation.

Two factors restricted further understanding of the nature of cells. First, the microscopes of the day had limited *resolution (resolving power)*—the ability to see fine

Units of Measurement in Cell Biology

The challenge of understanding cellular structure and organization is complicated by the problem of size. Most cells and their organelles are too small to be seen by the unaided eye. In addition, the units used to measure them are unfamiliar to many students and therefore often difficult to appreciate. The problem can be

approached in two ways: by realizing that only two units are really necessary to express the dimensions of most structures of interest to us, and by considering a variety of structures that can be appropriately measured with each of these two units.

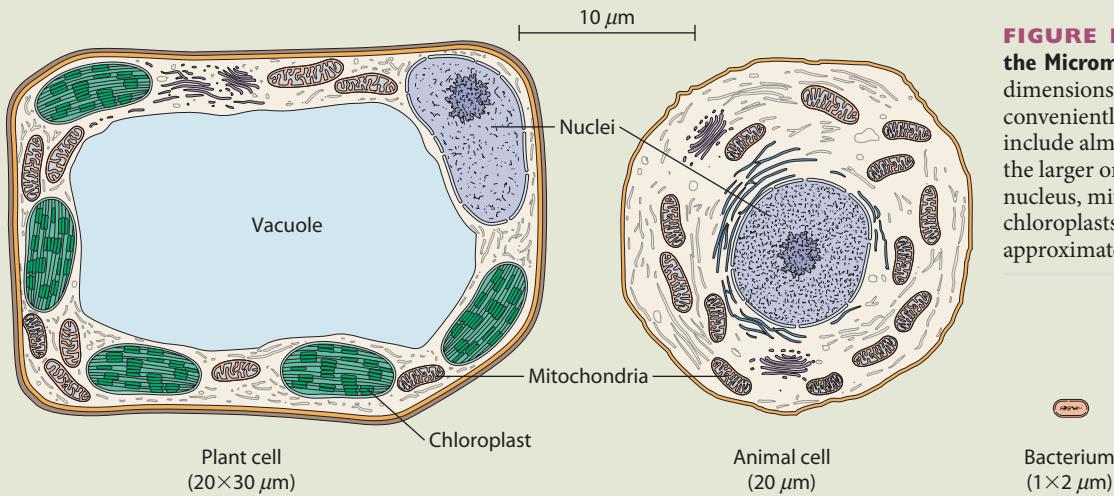

FIGURE 1A-1 The World of the Micrometer. Structures with dimensions that can be measured conveniently in micrometers include almost all cells and some of the larger organelles, such as the nucleus, mitochondria, and chloroplasts. One inch equals approximately 25,000 micrometers.

details of structure. Even van Leeuwenhoek's superior instruments could push this limit only so far. The second factor was the descriptive nature of seventeenth-century biology. It was an age of observation, with little thought given to explaining the intriguing architectural details being discovered in biological materials.

More than a century passed before the combination of improved microscopes and more experimentally minded microscopists resulted in a series of developments that led to an understanding of the importance of cells in biological organization. By the 1830s, important optical improvements were made in lens quality and in the *compound microscope*, in which one lens (the eyepiece) magnifies the image created by a second lens (the objective). This allowed both higher magnification and better resolution. Now, structures only 1 micrometer (μm) in size could be seen clearly. (See **Box IA** for a discussion of the units of measurement appropriate to cell biology.)

Aided by such improved lenses, the English botanist Robert Brown found that every plant cell he looked at contained a rounded structure, which he called a *nucleus*, a term derived from the Latin word for “kernel.” In 1838, his German colleague Matthias Schleiden came to the important conclusion that all plant tissues are composed of cells and that an embryonic plant always arises from a single cell. A year later, German cytologist Theodor Schwann reported similar conclusions concerning animal tissue, thereby discrediting earlier speculations that plants and animals do not resemble each other structurally. These speculations arose

because plant cell walls form conspicuous boundaries between cells that are readily visible even with a crude microscope, whereas individual animal cells, which lack cell walls, are much harder to distinguish in a tissue sample. However, when Schwann examined animal cartilage cells, he saw that they were unlike most other animal cells because they have boundaries that are well defined by thick deposits of collagen fibers. Thus, he became convinced of the fundamental similarity between plant and animal tissue. Based on his astute observations, Schwann developed a single unified theory of cellular organization, which has stood the test of time and continues to be the basis for our own understanding of the importance of cells and cell biology.

As originally postulated by Schwann in 1839, the **cell theory** had two basic principles:

1. All organisms consist of one or more cells.
2. The cell is the basic unit of structure for all organisms.

Less than 20 years later, a third principle was added. This grew out of Brown's original description of nuclei, extended by Swiss botanist Karl Nägeli to include observations on the nature of cell division. By 1855 Rudolf Virchow, a German physiologist, concluded that cells arose only by the division of other, preexisting cells. Virchow encapsulated this conclusion in the now-famous Latin phrase *omnis cellula e cellula*, which in translation becomes the third principle of the modern cell theory:

3. All cells arise only from preexisting cells.

The **micrometer (μm)** is the most useful unit for expressing the size of cells and organelles. A micrometer (sometimes also called a *micron*) is one-millionth of a meter (10^{-6} m). In general, bacterial cells are a few micrometers in diameter, and the cells of plants and animals are 10 to 20 times larger in any single dimension. Organelles such as mitochondria and chloroplasts tend to have diameters or lengths of a few micrometers and are thus comparable in size to whole bacterial cells. In general, if you can see it with a light microscope, you can express its dimensions conveniently in micrometers (**Figure 1A-1**).

The **nanometer (nm)**, on the other hand, is the unit of choice for molecules and subcellular structures that are too small to be seen with the light microscope. A nanometer is one-billionth of a meter (10^{-9} m), so it takes 1000 nanometers to equal 1 micrometer. A ribosome has a diameter of about 25 nm. Other structures that can be measured conveniently in nanometers are microtubules, microfilaments, membranes, and DNA molecules (**Figure 1A-2**). A slightly smaller unit, the angstrom (\AA), is occasionally used in cell biology when measuring dimensions within proteins and DNA molecules. An angstrom equals 0.1 nm, which is about the size of a hydrogen atom.

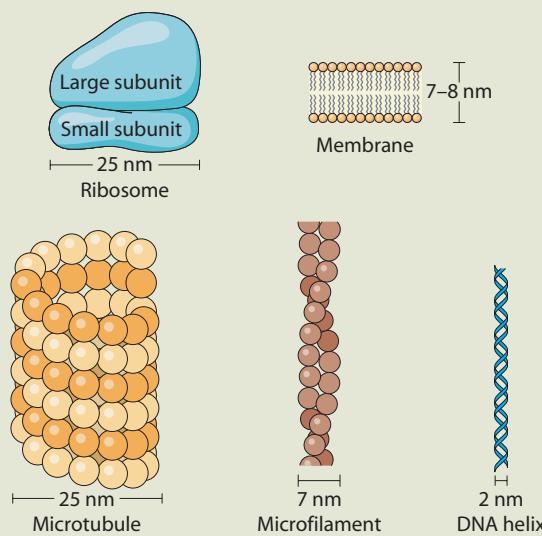

FIGURE 1A-2 The World of the Nanometer. Structures with dimensions that can be measured conveniently in nanometers include ribosomes, membranes, microtubules, microfilaments, and the DNA double helix. One nm equals 10 Å.

Thus, the cell is not only the basic unit of structure for all organisms but also the basic unit of reproduction. No wonder, then, that we must understand cells and their properties to appreciate all other aspects of biology. Because many of you have seen examples of “typical” cells in textbooks that may give the false impression that there are relatively few different types of cells, let’s take a look at a few examples of the diversity of cells that exist in our world (**Figure 1-1**).

Cells exist in a wide variety of shapes and sizes, from filamentous fungal cells to spiral-shaped *Treponema* bacteria to the differently-shaped cells of the human blood system (Figures 1-1a–c). Other cells have much more exotic shapes, such as the radiolarian and the protozoan shown in Figures 1-1d and 1-1e. Even the two human single-celled gametes, the egg and the sperm, differ greatly in size and shape (Figure 1-1f). Often, an appreciation of a cell’s shape and structure gives clues about its function. For example, the large surface area of the microvilli on our intestinal cells aids in maximizing nutrient absorption (Figure 1-1g), the spiral thickenings in the cell walls of plant xylem tissue give strength to these water-conducting vessels in wood (Figure 1-1h), and the highly branched cells of a human neuron allow it to interact with numerous other neurons (Figure 1-1i). In our studies throughout this textbook, we will see many other interesting examples of diversity in cell structure and function. First, though, let’s examine the historical roots leading to the development of contemporary cell biology.

The Emergence of Modern Cell Biology

Modern cell biology results from the weaving together of three different strands of biological inquiry—cytology, biochemistry, and genetics—into a single cord. As the timeline of **Figure 1-2** illustrates, each of the strands has had its own historical origins, and each one makes unique and significant contributions to modern cell biology. Contemporary cell biologists must be adequately informed about all three strands, regardless of their own immediate interests. In addition, they must understand how biological processes follow the laws of chemistry and physics.

Historically, the first of these strands to emerge is **cytology**, which is concerned primarily with cellular structure. In our studies, we will often encounter words containing the Greek prefix *cyto-* or the suffix *-cyte*, both of which mean “hollow vessel” and refer to cells. As we have already seen, cytology had its origins more than three centuries ago and depended heavily on the light microscope for its initial impetus. The advent of electron microscopy and other advanced optical techniques has dramatically increased our understanding of cell structure and function.

The second strand represents the contributions of **biochemistry** to our understanding of cellular structure and function. Most of the developments in this field have occurred over the past 75 years, though the roots go back at least a century earlier. Especially important has been the development of techniques such as ultracentrifugation,

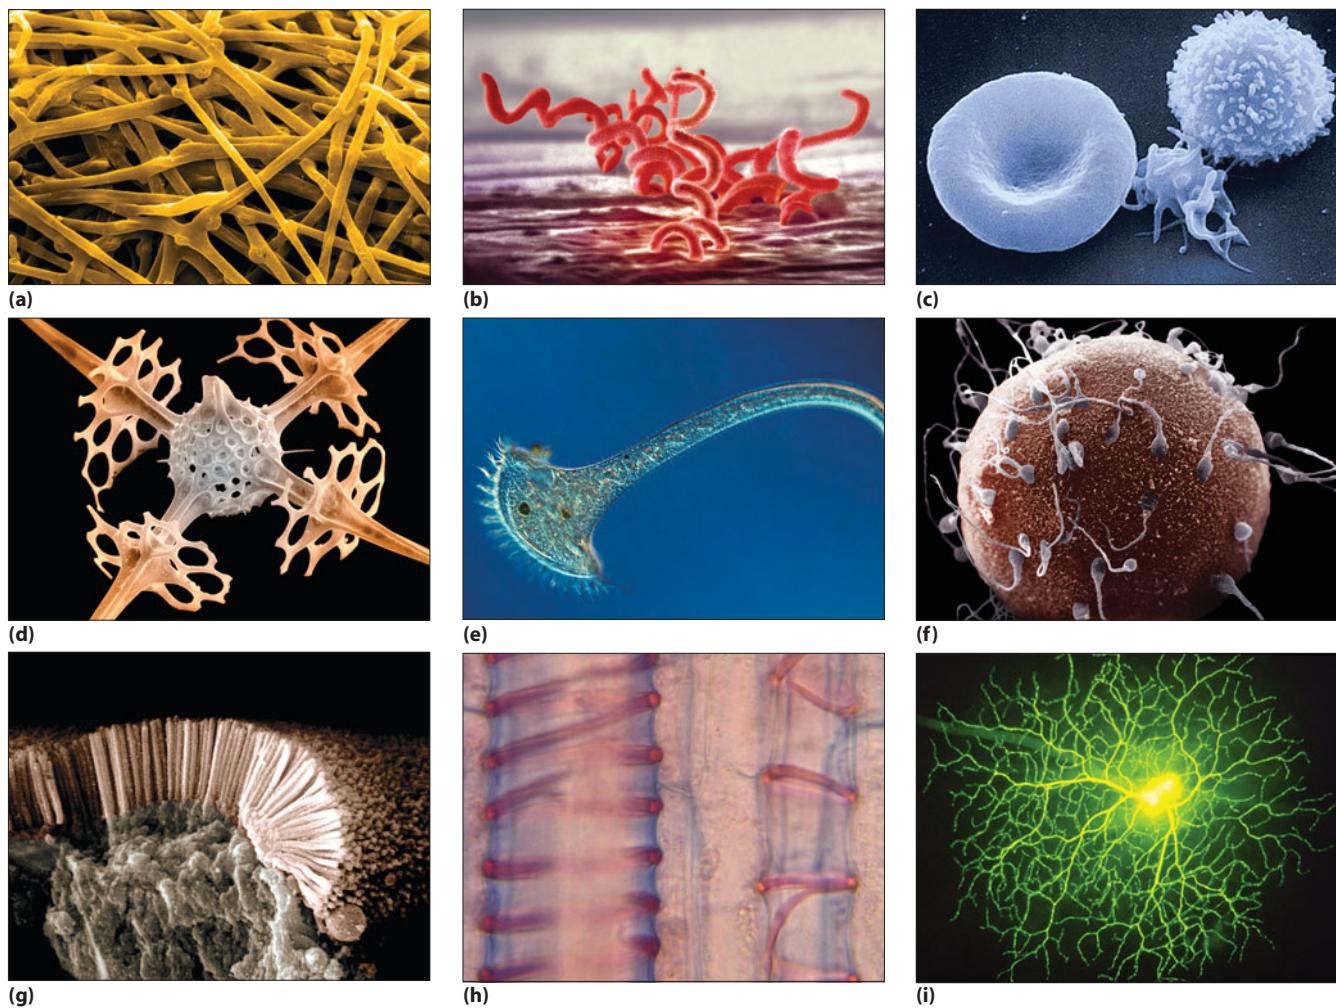

FIGURE I-1 The Cells of the World. The diversity of cell types existing all around us includes (a) filamentous fungal cells; (b) *Treponema* bacteria; (c) a human red blood cell, a platelet, and a white blood cell (left to right); (d) a radiolarian; (e) *Stentor* (a protozoan); (f) human egg and sperm cells; (g) intestinal cells; (h) plant xylem cells; and (i) a retinal neuron.

chromatography, radioactive labeling, electrophoresis, and mass spectrometry for separating and identifying cellular components. We will encounter these and other techniques later in our studies as we explore how specific details of cellular structure and function were discovered using these techniques. To locate discussions of specific techniques, see the Guide to Techniques and Methods inside the front cover.

The third strand contributing to the development of modern cell biology is **genetics**. Here, the timeline stretches back more than 150 years to Austrian monk and biologist Gregor Mendel. Again, however, we have gained much of our present understanding within the past 75 years. An especially important landmark on the genetic strand is the demonstration that, in all organisms, DNA (deoxyribonucleic acid) is the bearer of genetic information. It encodes the tremendous variety of proteins and RNA (ribonucleic acid) molecules responsible for most of the functional and structural features of cells. Recent accomplishments on the genetic strand include the sequencing of the entire *genomes* (all of the DNA) of humans and other species and

the *cloning* (production of genetically identical organisms) of mammals, including sheep, cattle, and cats.

Therefore, to understand present-day cell biology, we must appreciate its diverse roots and the important contributions made by each of its component strands to our current understanding of what a cell is and what it can do. Each of the three historical strands of cell biology is discussed briefly here; a deeper appreciation of each will come in later chapters as we explore cells in detail. Keep in mind also that in addition to developments in cytology, biochemistry, and genetics, the field of cell biology has benefited greatly from advancements in other fields of study such as chemistry, physics, computer science, and engineering.

The Cytological Strand Deals with Cellular Structure

Strictly speaking, cytology is the study of cells. Historically, however, cytology has dealt primarily with cellular structure, mainly through the use of optical techniques.

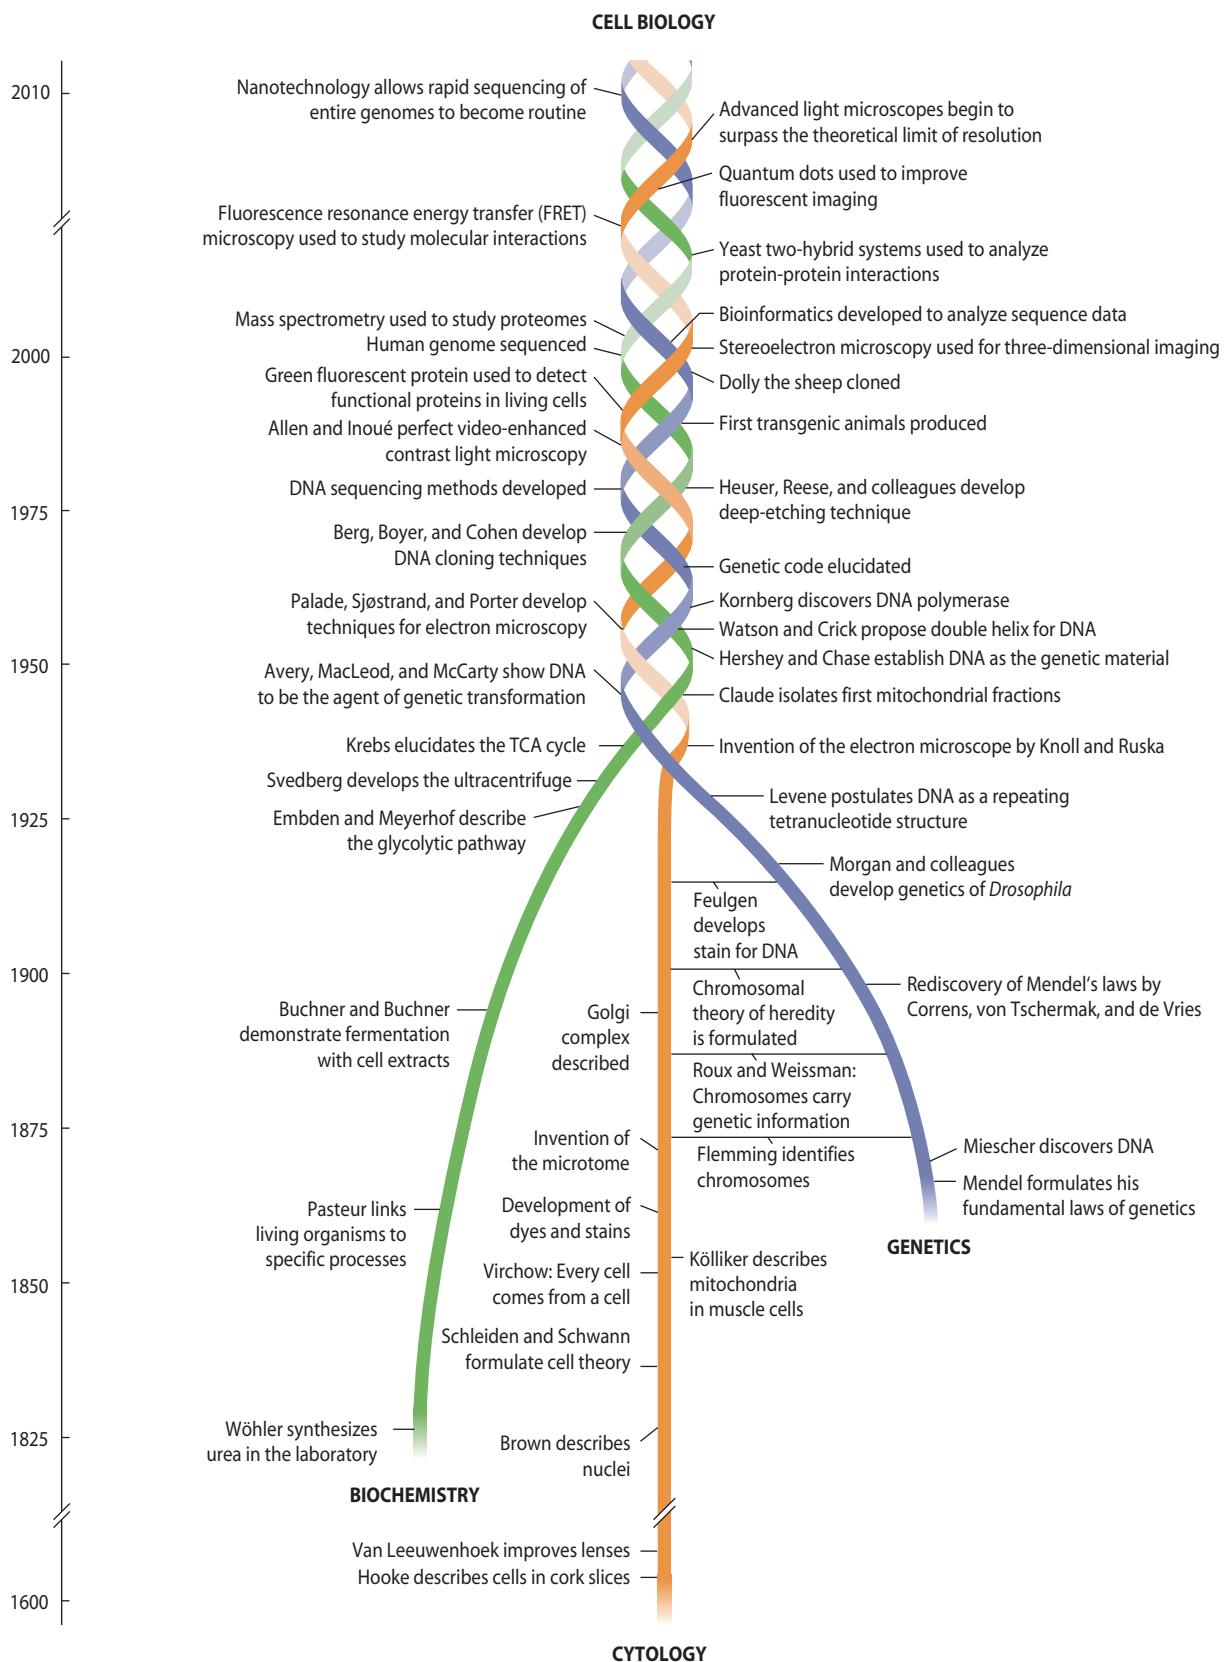

FIGURE I-2 The Cell Biology Time Line. Although cytology, biochemistry, and genetics began as separate disciplines, they have increasingly merged since about 1925.

Here we will describe briefly some of the microscopy that is important in cell biology. For a more detailed discussion of microscopic techniques, see the Appendix.

The Light Microscope. The **light microscope** was the earliest tool of the cytologists and continues to play an important role in our elucidation of cellular structure. Light microscopy allowed cytologists to identify membrane-bounded structures such as *nuclei*, *mitochondria*, and *chloroplasts* within a variety of cell types. Such structures are called *organelles* (“little organs”) and are prominent features of most plant and animal (but not bacterial) cells. Chapter 4 presents an overview of organelle types and, in later chapters, we will investigate their structure and function in more detail.

Other significant advancements include the development of the microtome in the mid-1800s and the availability of various dyes and stains at about the same time. A *microtome* is an instrument developed for rapid and efficient preparation of very thin (several μm) tissue slices of biological samples. Many of the dyes important for staining and identifying subcellular structures were developed in the latter half of the nineteenth century by German industrial chemists working with coal tar derivatives.

Together with improved optics and more sophisticated lenses, these developments extended light microscopy to the physical limits of resolution imposed by the size of the wavelengths of visible light. As used in microscopy, the **limit of resolution** refers to how far apart adjacent objects must be in order to be distinguished as separate entities. For example, if the limit of resolution of a microscope is 400 nanometers (nm), this means that objects must be at least 400 nm apart to be recognizable as separate entities. The smaller the limit of resolution, the greater the **resolving power**, or ability to see fine details of structure, of the microscope. Therefore, a better microscope might have a resolution of 200 nm, meaning that objects only 200 nm apart can be distinguished from each other. Because of the physical nature of light itself, the theoretical limit of resolution for the light microscope is approximately half of the size of the wavelength of light used for illumination, allowing maximum magnifications of about 1000–1500 \times . For visible light (wavelengths of 400–700 nm), the limit of resolution is about 200–350 nm. **Figure 1-3** illustrates the useful range of the light microscope and compares its resolving power with that of the human eye and the electron microscope, which we will discuss shortly.

Visualization of Cells. The type of microscopy described thus far is called *brightfield microscopy* because white light is passed directly through a specimen that is either stained or unstained and the background (the field) is illuminated. A significant limitation of this approach is that specimens often must be chemically fixed (preserved), dehydrated, embedded in paraffin or plastic for slicing into thin sections, and stained to highlight otherwise transparent features. Fixed and stained specimens are no longer alive, and therefore features observed by this

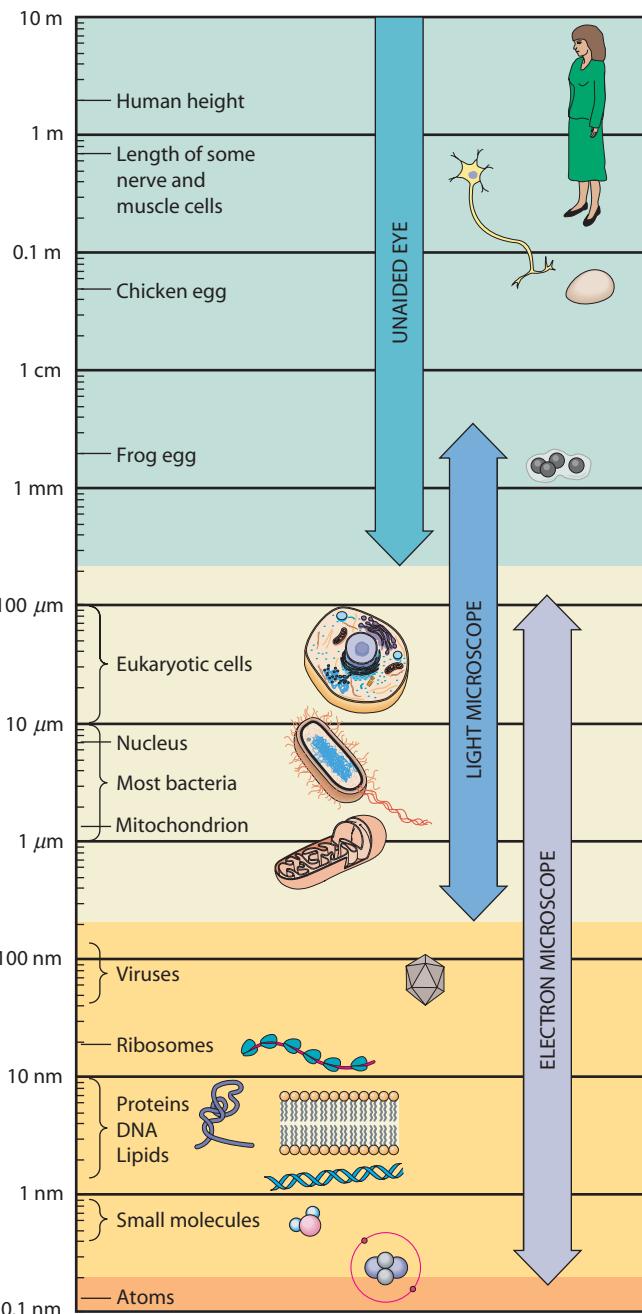

FIGURE 1-3 Relative Resolving Power of the Human Eye, the Light Microscope, and the Electron Microscope. Notice that the vertical axis is on a logarithmic scale to accommodate the wide range of sizes shown.

method could be distortions caused by slide preparation processes that are not typical of the living cells. To overcome this disadvantage, a variety of special optical techniques have been developed for observing living cells directly. These include phase-contrast microscopy, differential interference contrast microscopy, fluorescence microscopy, and confocal microscopy. In **Table 1-1**, you can see images taken using each of these techniques and compare them with the images seen with brightfield microscopy for both unstained and stained specimens. Because these

Table I-1 Different Types of Light Microscopy: A Comparison

Type of Microscopy	Light Micrographs of Human Cheek Epithelial Cells	Type of Microscopy
Brightfield (unstained specimen): Passes light directly through specimen; unless cell is naturally pigmented or artificially stained, image has little contrast.		Phase contrast: Enhances contrast in unstained cells by amplifying variations in refractive index within specimen; especially useful for examining living, unpigmented cells.
Brightfield (stained specimen): Staining with various dyes enhances contrast, but most staining procedures require that cells be fixed (preserved).		Differential interference contrast: Also uses optical modifications to exaggerate differences in refractive index.
Fluorescence: Shows the locations of specific molecules in the cell. Fluorescent substances absorb ultraviolet radiation and emit visible light. The fluorescing molecules may occur naturally in the specimen but more often are made by tagging the molecules of interest with fluorescent dyes or antibodies.		Confocal: Uses lasers and special optics to focus illuminating beam on a single plane within the specimen. Only those regions within a narrow depth of focus are imaged. Regions above and below the selected plane of view appear black rather than blurry.

20 μm

Source: Adapted from Campbell and Reece, *Biology*, 6th ed. (San Francisco: Benjamin Cummings, 2002), p. 110.

techniques are discussed in the Appendix in more detail, here we will content ourselves with brief descriptions.

Phase-contrast and *differential interference contrast microscopy* make it possible to see living cells clearly. Both techniques enhance and amplify slight changes in the phase of transmitted light as it passes through a structure having a different refractive index (based in part on density) than the surrounding medium. *Fluorescence microscopy* is a powerful method that enables researchers to detect specific proteins, DNA sequences, or other molecules that are made fluorescent by coupling them to a fluorescent dye or binding them to a fluorescently labeled antibody. By simultaneously using two or more such dyes or antibodies, each emitting light of a different color, researchers can follow the distributions of different kinds of molecules in the same cell. This method can also be used with fluorescently labeled DNA sequences to determine the presence and precise position of specific genes within a cell. In recent years, *green fluorescent protein (GFP)* from the bioluminescent jellyfish *Aequorea victoria* has become an invaluable tool for studying the temporal and spatial distribution of particular proteins in a cell. When a protein of interest is fused with GFP, its synthesis and movement can be followed in living cells. In 2008, the Nobel Prize in Chemistry was awarded to Martin Chalfie, Osamu Shimomura, and Roger Y. Tsien for the discovery and development of GFP.

An inherent limitation of fluorescence microscopy is that the viewer can focus on only a single plane of the

specimen at a time, yet fluorescent light is emitted throughout the specimen, blurring the image. This problem is largely overcome by *confocal scanning*, which uses a laser beam to illuminate just one plane of the specimen at a time. When used with thick specimens such as whole cells, this approach gives much better resolution. In the paired fluorescence and confocal images of cheek cells at the bottom of Table 1-1, the confocal image gives much better resolution, and even allows the small bacteria in the cheek cell sample to be seen easily.

Other recent developments in light microscopy are *digital video microscopy*, which uses video cameras to collect digital images for computer storage, and *deconvolution microscopy*, a computational technique that uses complex mathematical algorithms to increase the contrast and resolution of these digital images. By attaching a highly light-sensitive digital video camera to a light microscope, researchers can observe cells for extended periods of time using very low levels of light. This image intensification is particularly useful to visualize fluorescent molecules present at low levels in living cells and even to see and identify individual macromolecules. In fact, extremely powerful light microscopes are currently being developed that use imaging and computational methods so advanced that they can see beyond the theoretical limit of resolution, visualizing structures in the 100-nm range, which, until the past few years, were believed impossible to see with any light microscope.

The Electron Microscope. However, despite these significant advances, light microscopy is inevitably subject to the limit of resolution imposed by the wavelength of the light used to view the sample. Even the use of ultraviolet radiation, with shorter wavelengths than visible light, increases the resolution by only a factor of two.

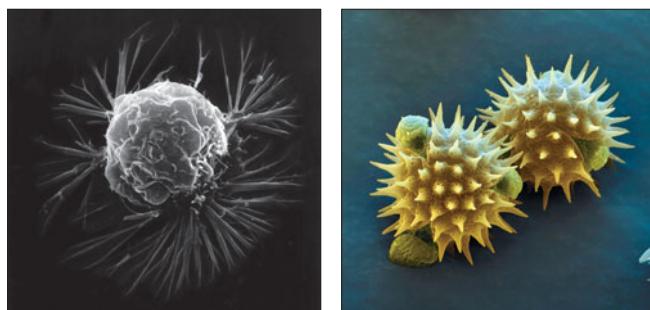

A major breakthrough in resolving power came with the development of the **electron microscope**, which was invented in Germany in 1931 by Max Knoll and Ernst Ruska. In place of visible light and optical lenses, the electron microscope uses a beam of electrons that is deflected and focused by an electromagnetic field. Because the wavelength of electrons is so much shorter than the wavelength of photons of visible light, the limit of resolution for the electron microscope is much better—about 0.1–0.2 nm. As a result, the useful magnification of the electron microscope is also much higher—up to 100,000 \times (see Figure 1-3).

Most electron microscopes have one of two basic designs: the **transmission electron microscope (TEM)** and the **scanning electron microscope (SEM)**. Both are described in detail in the Appendix and images from each are shown in Figure 1-4. Transmission and scanning electron microscopes are similar because each employs a beam of electrons, but they use quite different mechanisms to form the image. As the name implies, a TEM forms an image from electrons that are transmitted through the specimen. An SEM, on the other hand, scans the surface of the specimen and forms an image by detecting electrons that are deflected from the outer surface of the specimen. Scanning electron microscopy is an especially spectacular technique because of the sense of depth it gives to biological structures.

Several specialized techniques of electron microscopy are in use, including *negative staining*, *shadowing*, *freeze fracturing*, and *freeze etching*. Each of these techniques is a useful means of visualizing specimens in three dimensions. Also valuable for this purpose is a technique called *stereo electron microscopy*, in which the same sample is photographed at two slightly different angles to produce a three-dimensional image. *Scanning tunneling microscopy*, developed in the early 1980s, is so sensitive that it allows the visualization of individual atoms. These techniques are described in detail in the Appendix.

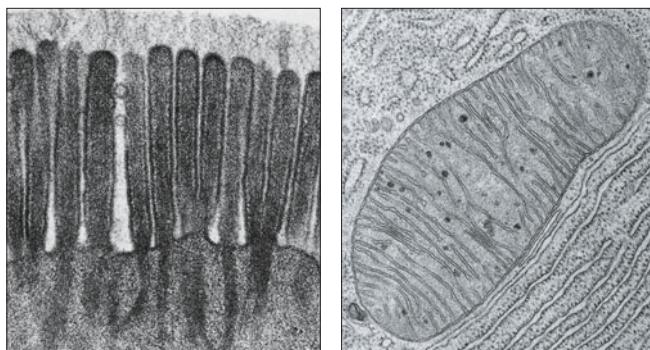

Microscopy techniques are constantly evolving. In 2009, a new type of electron microscope, the *scanning transmission electron microscope* was described. Rather than using a vacuum, as in conventional electron microscopy, this microscope allows the visualization of cells in liquid and can be used with whole cells. At about the same time, a *magnetic resonance force microscope* was developed that allows us to image viruses and large macromolecules.

Electron microscopy continues to revolutionize our understanding of cellular architecture by making detailed ultrastructural investigations possible. While organelles such as nuclei or mitochondria are large enough to be seen with a light microscope, they can be studied in much greater detail with an electron microscope. In addition, electron microscopy has revealed cellular structures that are too small to be seen with a light microscope. These

include ribosomes, membranes, microtubules, and microfilaments (see Figure 1A-2).

The Biochemical Strand Covers the Chemistry of Biological Structure and Function

At about the same time cytologists started exploring cellular structure with their microscopes, other scientists were making observations that began to explain and clarify cellular function. Much of what is now called biochemistry dates from a discovery reported in 1828 by the German chemist Friedrich Wöhler, a contemporary and fellow countryman of Schleiden and Schwann. He revolutionized our thinking about biology and chemistry by demonstrating that urea, an organic compound of biological origin, could be synthesized in the laboratory from an inorganic starting material, ammonium cyanate.

Until Wöhler reported his results, it had been widely held that living organisms were unique, not governed by the laws of chemistry and physics that apply to the nonliving world. By showing that a compound made by living organisms—a “bio-chemical”—could be synthesized in a laboratory just like any other chemical, Wöhler helped to break down the conceptual distinction between the living and nonliving worlds and dispelled the notion that biochemical processes were somehow exempt from the laws of chemistry and physics.

Another major advance came about 40 years later, when French chemist and biologist Louis Pasteur showed that living yeast cells were responsible for the fermentation of sugar into alcohol. In 1897, German bacteriologists Eduard and Hans Buchner found that fermentation could also take place with isolated extracts from yeast cells—that is, the intact cells themselves were not required. Gradually it became clear that the active agents in the extracts were specific biological catalysts that have since come to be called **enzymes**—from *zyme*, a Greek word meaning “yeast.”

Significant progress in our understanding of cellular function came in the 1920s and 1930s as individual steps in the biochemical pathways for fermentation and related cellular processes were elucidated. This was a period dominated by German biochemists such as Gustav Embden, Otto Meyerhof, Otto Warburg, and Hans Krebs. For example, the description of the enzymatic steps in the *Embden-Meyerhof pathway* for glycolysis was a major research triumph of the early 1930s. It was followed shortly by the elucidation of the *Krebs cycle* (also known as the TCA cycle). Both of these pathways are important because of their role in the process by which cells extract energy from glucose and other foodstuffs. We will study these biochemical pathways in detail in Chapters 9 and 10. At about the same time, Fritz Lipmann, an American biochemist, showed that the high-energy compound *adenosine triphosphate* (ATP) is the principal energy storage compound in most cells.

An important advance in the study of biochemical reactions and pathways came as radioactive isotopes such as ^3H , ^{14}C , and ^{32}P were first used to trace the metabolic fate of specific atoms and molecules. American chemist Melvin Calvin and his colleagues at the University of California, Berkeley, were pioneers in this field as they traced the fate of ^{14}C -labeled carbon dioxide ($^{14}\text{CO}_2$) in illuminated algal cells that were actively photosynthesizing. Their work, carried out in the late 1940s and early 1950s, led to the elucidation of the *Calvin cycle*—the most common pathway for photosynthetic carbon metabolism. The Calvin cycle was the first metabolic pathway to be elucidated using a radioisotope.

Biochemistry took another major step forward with the development of *centrifugation* as a means of separating and isolating subcellular structures and macromolecules based on their size, shape, and/or density—a process called **subcellular fractionation**. Centrifugation techniques used for this purpose include *differential centrifugation*, *density gradient centrifugation*, and *equilibrium density centrifugation*. These three techniques are described in detail in Box 12A (page 327). Especially useful for resolving small organelles and macromolecules is the **ultracentrifuge**, developed by Swedish chemist Theodor Svedberg in the late 1920s. An ultracentrifuge is capable of very high speeds—over 100,000 revolutions per minute—and can thereby subject samples to forces exceeding 500,000 times the force of gravity. In many ways, the ultracentrifuge is as significant to biochemistry as the electron microscope is to

cytology. In fact, both instruments were developed at about the same time, so the ability to see organelles and other subcellular structures coincided with the capability to isolate and purify them.

Other biochemical techniques that have proven useful for isolating and purifying subcellular components include chromatography and electrophoresis. **Chromatography** is a general term describing a variety of techniques by which a mixture of molecules in solution is progressively fractionated as the solution flows over a stationary absorbing phase, usually contained in a column. Chromatographic techniques separate molecules based on their size, charge, or affinity for specific molecules or functional groups. An example of a chromatographic technique is shown in Figure 7-9.

Electrophoresis refers to several related techniques that use an electrical field to separate molecules based on their mobility and is used extensively to determine the sizes of protein, DNA, and RNA molecules. The most common medium for electrophoretic separation of proteins and nucleic acids is a gel of either polyacrylamide or agarose. The use of polyacrylamide gel electrophoresis to resolve proteins is illustrated in Figure 7-22.

After proteins have been separated by electrophoresis, **mass spectrometry** is commonly used to determine the size and composition of individual proteins. This technique, which allows researchers to determine the identity and characteristics of individual proteins in a mix of thousands of different proteins in a cell, has led to significant advances. For example, in the emerging field of *proteomics*, researchers are attempting to understand the functions and interactions of all the proteins present in a particular cell. Mass spectrometry is described in more detail in Chapter 18.

To summarize, with the enhanced ability to see subcellular structures, to fractionate them, and to isolate them, cytologists and biochemists began to realize how well their respective observations on cellular structure and function could complement each other. These scientists were laying the foundations for modern cell biology.

The Genetic Strand Focuses on Information Flow

The third strand in the historical cord of cell biology is genetics. Like the other two, this strand has important roots in the nineteenth century. In this case, the strand begins with Gregor Mendel, whose studies with the pea plants he grew in a monastery garden must surely rank among the most famous experiments in all of biology. His findings were published in 1866, laying out the principles of segregation and independent assortment of the “hereditary factors” that we know today as **genes**. But Mendel was clearly a man ahead of his time. His work went almost unnoticed when it was first published and was not fully appreciated until its rediscovery nearly 35 years later. (It is interesting to note that over 2000 years ago, the Greek philosopher Aristotle referred to a physical entity he called the “germ.” He stated that it “springs forth from a definite parent and gives rise to

a predictable progeny,” and he called it “the ruling influence and fabricator of the offspring.”)

In the decade following Mendel’s work, the role of the nucleus in the genetic continuity of cells came to be appreciated. In 1880, German biologist Walther Flemming identified **chromosomes**, threadlike bodies seen in dividing cells. Flemming called the division process *mitosis*, from the Greek word for “thread.” Chromosome number soon came to be recognized as a distinctive characteristic of a species and was shown to remain constant from generation to generation. That the chromosomes themselves might be the actual bearers of genetic information was suggested by German anatomist Wilhelm Roux as early as 1883 and expressed more formally by his countryman, biologist August Weissman, shortly thereafter.

With the roles of the nucleus and chromosomes established and appreciated, the stage was set for the rediscovery of Mendel’s initial observations. This came in 1900, when his studies were cited almost simultaneously by three plant geneticists working independently: Carl Correns in Germany, Ernst von Tschermak in Austria, and Hugo de Vries in Holland. Within three years, the **chromosome theory of heredity** was formulated, following work by American physician Walter Sutton and German biologist Theodor Boveri. The chromosome theory of heredity proposed that the hereditary factors responsible for Mendelian inheritance are located on the chromosomes within the nucleus. This hypothesis received its strongest confirmation from the work of American biologist Thomas Hunt Morgan and his students, Calvin Bridges and Alfred Sturtevant, at Columbia University during the first two decades of the twentieth century. Using *Drosophila melanogaster*, the common fruit fly, as their experimental model organism, they identified a variety of morphological mutants of *Drosophila* and were able to link specific traits to specific chromosomes.

Meanwhile, the foundation for our understanding of the chemical basis of inheritance was slowly being laid. An important milestone was the discovery of DNA by Swiss biologist Johann Friedrich Miescher in 1869. Using such unlikely sources as salmon sperm and human pus from surgical bandages, Miescher isolated and described what he called “nuclein.” But, like Mendel, Miescher was ahead of his time. It was about 75 years before the role of his nuclein as the genetic information of the cell came to be fully appreciated.

As early as 1914, DNA was implicated as an important component of chromosomes by German chemist Robert Feulgen’s staining technique, a method that is still in use today. But it was considered quite unlikely that DNA could be the bearer of genetic information due to the apparently monotonous structure of DNA. By 1930, DNA was known to be composed of only four different nucleotides—and this did not seem to be enough variety to account for all the diversity seen in living organisms. Proteins, on the other hand, were much more diverse, being composed of 20 different amino acids. In fact, until the middle of the twentieth century, it was widely thought that proteins were the carriers of genetic information from generation to generation, since

they seemed to be the only nuclear components with enough variety to account for the obvious diversity of genes.

A landmark experiment clearly pointing to DNA as the genetic material was reported in 1944 by Oswald Avery, Colin MacLeod, and Maclyn McCarty. Their work, discussed in more detail in Chapter 18, showed that DNA could “transform” a nonpathogenic strain of bacteria into a pathogenic strain, causing a heritable genetic change. Eight years later, American biochemists Alfred Hershey and Martha Chase showed that DNA, and not protein, enters a bacterial cell when it is infected and genetically altered by a bacterial virus.

Meanwhile, American biologists George Beadle and Edward Tatum, working in the 1940s with the bread mold *Neurospora crassa*, formulated the “one gene–one enzyme” concept, asserting that each gene controls the production of a single, specific protein. Shortly thereafter, in 1953, the unlikely team of former ornithology student James Watson and physicist Francis Crick, with assistance from X-ray crystallographer Rosalind Franklin, proposed their now-famous *double helix model* for DNA structure, which immediately suggested how replication and genetic mutations could occur. Soon afterward, it was discovered how DNA specifies the order of amino acids in proteins and that several different kinds of RNA molecules serve as intermediates in protein synthesis.

The 1960s brought especially significant developments, including the discovery of the polymerase enzymes that synthesize DNA and RNA and the “cracking” of the genetic code, which specifies the relationship between the order of nucleotides in a DNA or RNA molecule and the order of amino acids in a protein. At about the same time, biochemist Jacques Monod and geneticist François Jacob of France deduced the mechanism responsible for the regulation of bacterial gene expression.

Important techniques along the genetic strand of Figure 1-2 include the separation of DNA molecules and fragments by ultracentrifugation and gel electrophoresis. Of equal, if not greater, importance is *nucleic acid hybridization*, which includes a variety of related techniques that depend on the ability of two single-stranded nucleic acid molecules with complementary base sequences to bind, or *hybridize*, to each other, thereby forming a double-stranded hybrid. These techniques can be applied to DNA-DNA, DNA-RNA, and even RNA-RNA interactions, and they are useful to isolate and identify specific DNA or RNA molecules.

Our current understanding of gene expression has relied heavily on the development of **recombinant DNA technology** since the 1970s. This technology was made possible by the discovery of *restriction enzymes*, which have the ability to cleave DNA molecules at specific sequences so that scientists can create *recombinant DNA molecules* containing DNA sequences from two different sources. This capability led quickly to the development of *gene cloning*, a process for generating many copies of specific DNA sequences for detailed study and further manipulation. These important techniques are explained and explored in detail in Chapters 18 and 20.

At about the same time, **DNA sequencing** methods were devised for rapidly determining the base sequences of DNA molecules. This technology is now routinely applied not just to individual genes but to entire *genomes* (i.e., the total DNA content of a cell). Initially, genome sequencing was applied mainly to bacterial genomes because they are relatively small—a few million bases, typically. But DNA sequencing has long since been successfully applied to much larger genomes, including those from species of yeast, roundworm, plants, and animals that are of special interest to researchers. A major triumph was the sequencing of the entire human genome, which contains about 3.2 billion bases. This feat was accomplished by the *Human Genome Project*, a cooperative international effort that began in 1990, involved hundreds of scientists, and established the complete sequence of the human genome by 2003.

The challenge of analyzing the vast amount of data generated by DNA sequencing has led to a new discipline, called **bioinformatics**, which merges computer science and biology as a means of making sense of sequence data. This approach has led to the recognition that the human genome contains approximately 25,000 protein-coding genes, about half of which were not characterized before genome sequencing. It is also enabling scientists to study the *proteome*, the total protein content of a cell, analyzing thousands of proteins simultaneously. Proteomic studies aim to understand the structure and properties of every protein produced by a genome and to learn how these proteins interact with each other to regulate cellular functions.

Numerous bioinformatic tools are publicly available through the National Center for Biotechnology Information (NCBI), which is operated by the U.S. National Institutes of Health (NIH). In addition to housing PubMed, a searchable archive of over 17 million citations from life science journals, NCBI maintains GenBank, a comprehensive database of all publicly available nucleotide and amino acid sequences (over 100 million as of early 2010). Also available are numerous tools to compare gene and protein sequences from all organisms and to analyze their structure and function. In addition, NCBI provides a wealth of biological information, such as the OMIM (Online Mendelian Inheritance in Man) database, which is an encyclopedic collection of information regarding human genetic disorders and mutations involving over 12,000 genes.

Using yeast as a model organism to isolate and characterize genetic mutants, scientists have learned much about how cells function by studying mutant yeast strains that are deficient in particular genes and their protein products. For example, cell cycle mutants of yeast that display abnormal cell division have been invaluable in helping us understand how normal cells divide. Recently, the use of the yeast *two-hybrid system*, which allows us to determine how specific proteins interact within a living cell, has contributed greatly to our understanding of the complex molecular interactions involved in cellular function.

In the last decade, we have seen major advances both in *nanotechnology*, the development of nanometer-sized machines, tools, and biosensors, and in computer-aided

analysis of experimental results. A generation ago, it took a week to sequence a single gene, but now thousands of genes can be sequenced in a few days. The ability to simultaneously analyze thousands of molecules on a global basis throughout the cell has led to a proliferation of “-omics” studies. We now have *transcriptomics*, the study of all transcribed genes in a particular cell, *metabolomics*, the analysis of all metabolic reactions happening at a given time in a cell, and even *lipidomics*, the study of all the lipids in a cell. Keep your eyes open in the next few years, as this explosion of biological information will likely lead to a host of new fields of “-omics” studies!

These and other techniques helped to launch an era of molecular genetics that continues to revolutionize biology. In the process, the historical strand of genetics that dates back to Mendel became intimately entwined with those of cytology and biochemistry, and the discipline of cell biology as we know it today came into being.

“Facts” and the Scientific Method

If asked what you expect to get out of a science textbook, you may reply that you intend to learn the facts about the particular scientific area that the textbook covers—cell biology, in the case of this text. If pressed to explain what a “fact” is, most people would probably reply that a fact is “something that we know to be true.” When we say, for example, that “all organisms consist of one or more cells” or that “DNA is the bearer of genetic information,” we recognize these statements as facts of cell biology. But we must also recognize that the first of these statements was initially regarded as part of a theory, and the second statement actually replaced an earlier misconception that genes were made of proteins.

Cell biology is rich with examples of facts that were once widely held but have since been altered or even discarded as cell biologists gained a better understanding of the phenomena those facts attempted to explain. As we saw earlier, the early nineteenth century “fact” that living matter consisted of substances quite different from those in nonliving matter, was discredited following work by Wöhler, who synthesized the biological compound urea from an inorganic compound, and Eduard and Hans Buchner, who showed that nonliving extracts from yeast cells could ferment sugar into ethanol. Thus, views held as fact by generations of scientists were eventually discarded and replaced by the new fact that living matter follows the same laws of chemistry and physics as do inorganic materials.

For a more contemporary example, until recently it was regarded as a fact that the sun is the ultimate source of all energy in the biosphere. Then came the discovery of *deep-sea thermal vents* and the thriving communities of organisms that live around them, none of which depends on solar energy. Instead, these organisms depend on energy derived from hydrogen sulfide (H_2S) by bacteria, which use this energy to synthesize organic compounds from carbon dioxide.

Although we have advanced microscopes and sophisticated methods to isolate and analyze individual cells and cellular components and have volumes of research data describing what we now know about cells, to fully understand how cells work, we need to test our hypotheses *in vivo* (in living organisms). Cell biologists rely heavily on a variety of *model organisms* representing the major kingdoms of life to help unlock the secrets of the cell.

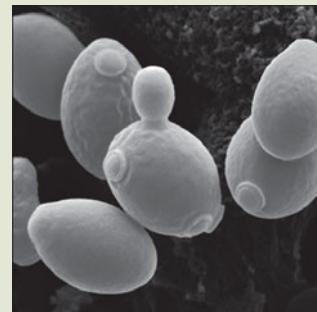

A **model organism** is a species that is widely studied, well-characterized, easy to manipulate, and has particular advantages making it useful for experimental studies. A few examples are the bacterium *Escherichia coli*, the yeast *Saccharomyces cerevisiae*, and the fruit fly *Drosophila melanogaster* (**Figure 1B-1**). Gregor Mendel, in his classic studies of gene inheritance and segregation, used garden pea plants as his model organism because they were easy to grow, could be used for manual genetic crosses, and displayed easily observable characteristics such as plant height, seed color and shape, etc.

A biochemistry professor once pointed out that his lecture on cellular DNA synthesis was primarily a lecture on *E. coli* DNA synthesis, since the majority of what we knew about this process at the time was based on studies using this single-celled model organism. *E. coli* is easy to grow in the lab, has a short generation time (20 minutes), and is easily mutagenized for studies of gene function. In 1997, it became the first bacterium to have its complete genome sequenced. Because it readily takes up DNA from virtually any organism, it has become the “workhorse” of cellular and molecular biology and is extensively used for the analysis and

FIGURE 1B-1 Common Model Organisms. Examples of some frequently-used model organisms are shown: (a) *Escherichia coli* colonies on blood agar, (b) *Saccharomyces cerevisiae* yeast cells (SEM), (c) a wild-type *Drosophila melanogaster* fly, (d) a *Caenorhabditis elegans* roundworm, (e) a laboratory mouse (*Mus musculus*), and (f) an *Arabidopsis thaliana* plant.

Thus, as you can see, a fact is really a much more tenuous piece of information than our everyday sense of the word might imply. Just like cells themselves, facts are dynamic and subject to change, sometimes abruptly. To a scientist, a fact is simply an attempt to state our best current understanding of the natural world around us, based on observations and experiments. A fact is valid only until it is revised or replaced by a better understanding based on more careful observations or more discriminating experiments.

How does new and better information become available? Scientists usually assess new information with a systematic approach called the *scientific method*. After making observations and consulting prior studies, the scientist formulates a *hypothesis*, a tentative explanation or model that can be tested experimentally. Next, the investigator designs a controlled experiment to test the

(a) *E. coli*(b) *S. cerevisiae*(c) *Drosophila*(d) *C. elegans*(e) *Mus musculus*(f) *Arabidopsis*

hypothesis by varying specific conditions while keeping other variables constant. The scientist then collects the data, interprets the results, and accepts or rejects the hypothesis, which must be consistent not only with the results of this particular experiment but also with prior knowledge. This often involves the use of *Occam's razor*, the principle stating that, when we try to understand nature, it is often the simplest explanation consistent with the observable facts that is the most likely to be correct.

Research experiments are often conducted in the laboratory using purified chemicals and cellular components. This type of experiment is described as *in vitro*, which literally means “in glass.” Experiments using live cells or organisms are referred to as *in vivo* (“in life”), often using one of a variety of popular *model organisms* (**Box 1B**). More recently, experiments using computers to test new hypotheses involv-

production of genes and proteins for research, industrial, and medical uses.

For studies of eukaryotic cell biology, *S. cerevisiae*, a unicellular fungus also known as bakers' or brewers' yeast, has many of the same experimental advantages. Like *E. coli*, yeast grows rapidly on growth media in the lab and is easily manipulated and mutagenized. It is widely used for studies of organelle function, eukaryotic secretion processes, and protein-protein interactions. You may be surprised to learn that much of what we know about human cell division has come from the study of cell cycle mutants in yeast.

However, use of these two unicellular organisms does have its limitations, especially if you want to study processes in multicellular organisms, including cell differentiation, embryonic development, or cell-to-cell communication. For these types of studies, you may have heard biologists talk about experiments using "flies and worms." They are referring to the fruit fly *Drosophila melanogaster*, and the microscopic roundworm *Caenorhabditis elegans*, both of which are extensively used for studies of the genetics and development of multicellular, eukaryotic organisms.

The discovery of genetic recombination by Thomas Hunt Morgan and colleagues in the early 1900s resulted from their use of *Drosophila* and its experimental advantages: it is easy to grow and manipulate in the lab, has a short generation time (about two weeks), produces numerous progeny, and has easily observable physical characteristics (such as eye color and wing shape). Today it is widely used in genetic studies, in part because there are thousands of mutant strains available, each defective in a particular gene, and its genome has been sequenced. Also, it is being increasingly used in studies of embryogenesis, developmental biology, and cell signaling (see Box 14B, page 410).

Similarly, *C. elegans* is a valuable model organism for studies of cell differentiation and development and of apoptosis (programmed cell death) in multicellular organisms. Advantages of this model organism include its ease of manipulation, relatively short life cycle, and small genome, the first of any multicellular organism

to be sequenced. It is also one of the simplest animals to possess a nervous system. Its development from a fertilized egg is remarkably predictable, and the origin and fate of each of its approximately 1000 cells has been mapped out, as have the hundreds of connections among the roughly 200 nerve cells. Also, the tiny worms are transparent, and thus it is easy to see individual cells and view fluorescently labeled molecules in the living organism.

For studies of cellular and physiological processes specific to mammals and humans, the common laboratory mouse (*Mus musculus*) has become the primary model organism. It shares many cellular, anatomical, and physiological similarities with humans and is widely used for research in medicine, immunology, and aging. It is subject to, and therefore useful for the study of, a variety of diseases that also affect us, such as cancer, diabetes, and osteoporosis. Numerous mouse strains have been bred or engineered in which particular genes have either been "knocked out" or introduced, making them extremely valuable in biomedical research.

For studies of processes unique to plants, and some processes common to all organisms, *Chlamydomonas reinhardtii*, a unicellular green alga is often used. Like *E. coli* and yeast, "Chlamy" is easily grown in the lab on Petri plates and has been used to study photosynthesis, light perception, mating type, cellular motility, and DNA methylation. For flowering plant studies, *Arabidopsis thaliana* is a powerful model organism. It has one of the smallest genomes of any plant and a relatively rapid life cycle (6 weeks), facilitating genetic studies. Its complete genome has been sequenced, and thousands of mutant strains have been created, enabling detailed studies of plant gene function.

Many other model organisms are currently being used in biology to study a wide variety of cellular, genetic, and biochemical processes. As you proceed through your studies in cell biology, keep in mind that much of what we know is based upon research using relatively few of the millions of living organisms on Earth, and remember that is always important to understand how we know what we know.

ing vast amounts of data are described as *in silico*, referring to the silicon used to make computer chips. But all these approaches use the same basic steps in the scientific method.

To a practicing scientist, the scientific method is more a way of thinking than a set of procedures to be followed. Most likely, this is the way our ancestors explained natural phenomena long before scientists were trained at universities—and long before students read about the scientific method! As we consider the scientific method, we need to recognize several important terms that scientists use to indicate the degree of certainty with which a specific explanation or concept is regarded as true. Three terms are especially significant: *hypothesis*, *theory*, and *law*.

Of the three, the most tentative is a **hypothesis**, a statement or explanation that is consistent with most of the observations and experimental evidence to date.

Often, a hypothesis takes the form of a *model* that appears to provide a reasonable explanation of the phenomenon in question. To be useful to scientists, a hypothesis must be *testable* using the scientific method.

If a hypothesis or model has been tested critically under many different conditions—usually by many different investigators using a variety of approaches—and is consistently supported by the evidence, it gradually acquires the status of a **theory**. By the time an explanation or model comes to be regarded as a theory, it is generally and widely accepted by most scientists in the field. The *cell theory* described earlier in this chapter is an excellent example. There is little or no dissent or disagreement among biologists concerning its three principles.

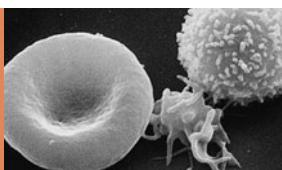

When a theory has been thoroughly tested and confirmed over a long period of time by such a large number of

investigators that virtually no doubt of its validity remains, it may come to be regarded as a **law**. The *law of gravity* comes readily to mind, as do the *laws of thermodynamics* that we will encounter in Chapter 5. You may also be familiar with *Fick's law of diffusion*, the *ideal gas laws*, and Mendel's *laws of heredity*, for instance.

However, biologists are generally quite conservative in using the term *law*. Even after more than 150 years of finding no exceptions, the cell theory is still referred to as a "theory." Like the *germ theory*, which proposes that diseases can be caused by microorganisms, and the *theory of evolution*, which describes the origin of biological diversity, there really is no doubt about the validity of the cell theory, and it could easily be considered a law. Perhaps

our reluctance to label explanations of biological phenomena as laws is a reflection of the difficulty we have in convincing ourselves that we will never find organisms or cells that are exceptions to even our most well-documented theories.

As you have now seen, the facts presented in biology textbooks such as this one are simply our best current attempts to describe and explain the biological world we live in. As you proceed through this text, watch for applications of the scientific method. You will find that, regardless of the approach, the conclusions from each experiment add to our knowledge of how biological systems work and usually lead to more questions as well, continuing the cycle of scientific inquiry.

SUMMARY OF KEY POINTS

The Cell Theory: A Brief History

- The biological world is a world of cells. The cell theory states that all organisms are made of cells, the basic units of biological structure, and that cells arise only from preexisting cells.
- The cell theory was developed through the work of many different scientists, including Hooke, van Leeuwenhoek, Brown, Schleiden, Schwann, Nägeli, and Virchow.
- Although the importance of cells in biological organization has been appreciated for about 150 years, the discipline of cell biology as we know it today is of much more recent origin.

The Emergence of Modern Cell Biology

- Modern cell biology has come about by the interweaving of three historically distinct strands—cytology, biochemistry, and genetics—which in their early development probably did not seem at all related.
- The contemporary cell biologist must understand all three strands because they complement one another in the quest to learn what cells are made of and how they function.

The Cytological Strand Deals with Cellular Structure

- The light microscope has allowed us to visualize individual cells, which are approximately 1–50 μm in size. Historically, its limited resolving power did not allow us to see details of structure smaller than about 0.2 μm (200 nm), but modern light microscopes are surpassing that limit.
- Several types of light microscopes allow us to view preserved or living specimens at magnifications of about 1000 \times . These include brightfield, phase-contrast, differential interference contrast, fluorescence, confocal, and digital video microscopes, each of which offers particular advantages in studying and understanding cells.

- The electron microscope uses a beam of electrons, rather than visible light, for imaging specimens. It can magnify objects up to 100,000 \times with a resolving power of less than 1 nm, enabling us to view subcellular structures such as membranes, ribosomes, organelles, and even individual DNA and protein molecules.

The Biochemical Strand Covers the Chemistry of Biological Structure and Function

- Discoveries in biochemistry have revealed how many of the chemical processes in cells are carried out, greatly expanding our knowledge of how cells function.
- Major discoveries in biochemistry were the identification of enzymes as biological catalysts, the discovery of adenosine triphosphate (ATP) as the main carrier of energy in living organisms, and the description of the major metabolic pathways cells use to harness energy and synthesize cellular components.
- Several important biochemical techniques that have allowed us to understand cell structure and function are subcellular fractionation, ultracentrifugation, chromatography, electrophoresis, and mass spectrometry.

The Genetic Strand Focuses on Information Flow

- The chromosome theory of heredity states that the characteristics of organisms passed down from generation to generation result from the inheritance of chromosomes carrying discrete physical units known as genes.
- Each gene is a specific sequence of DNA that contains the information to direct the synthesis of one cellular protein.
- DNA itself is a double helix of complementary strands held together by precise base pairing. This structure allows the DNA to be accurately duplicated as it is passed down to successive generations.

- Bioinformatics and nanotechnology allow us to compare and analyze thousands of genes or other molecules simultaneously, causing a revolution in genomic, proteomic, and numerous other fields of “-omics” research.

“Facts” and the Scientific Method

- Science is not a collection of facts but a process of discovering answers to questions about our natural world. Scientists gain knowledge by using the scientific method, which involves creating a hypothesis that can be tested for validity by collecting data through well-designed, controlled experiments.

- Science as a field of study is based on consistency and reproducibility. As a hypothesis becomes more accepted, it is referred to as a theory; and, as a theory becomes indisputable, it becomes a law.
- However, some of the most “proven” theories or laws have been modified, extended, or even refuted. Science is a dynamic, ever-changing field, and it is likely that some of the scientific facts you are now learning will eventually change.
- Scientists use a variety of well-studied model organisms to test new hypotheses, develop new theories, and advance our knowledge of cell biology.

MAKING CONNECTIONS

Now that you are familiar with the cell theory, the origins of modern cell biology, and some of the classic and cutting-edge techniques used to study cells, let’s think about where we are going next in our studies here. After reviewing some chemistry and the structure of macromolecules in the next two chapters, we will be introduced to cellular organelles in Chapter 4. Our subsequent studies of bioenergetics and enzyme function in the next two chapters, coupled with an investigation of membrane structure and function in Chapters 7 and 8, will prepare us for an in-depth look at energy metabolism in the cell. How do cells obtain energy from food or from the sun and use this energy for all their necessary vital processes? Answering these questions is the focus of Chapters 9–11. In Chapters 12–17, we will begin to explore some of the most exciting areas in contemporary cell biology: the precise trafficking of proteins and other molecules through the cell; cell-to-cell communication involving both electrical and chemical signals; the cytoskeleton and its role in cell movement

and muscle contraction; and the connections between cells that allow them to communicate and interact. Chapters 18–23 will give us a detailed look at DNA and the structural basis of cellular information flow. We will be studying several exciting, rapidly changing areas of cell biology while investigating how DNA is organized into chromosomes in the nucleus, how it is repaired when damaged, how it is recombined to generate genetic variability, and how it can be used in recombinant DNA technology. After studying how DNA is replicated and expressed during the normal cell cycle, we will finish our studies in this textbook by looking at the biology of cancer cells. What happens when the normal cell cycle is disrupted and cells proliferate uncontrollably? We hope that by then you will be well educated in most aspects of current cell biology. You may also be so excited about the future of cell biology that you will be prepared to ask educated questions—and perhaps, to make the next great scientific contribution.

PROBLEM SET

More challenging problems are marked with a •.

- 1-1 The Historical Strands of Cell Biology.** For each of the following events, indicate whether it belongs mainly to the cytological (C), biochemical (B), or genetic (G) strand in the historical development of cell biology.

- (a) Köllicker describes “sarcosomes” (now called mitochondria) in muscle cells (1857).
- (b) Hoppe-Seyler isolates the protein hemoglobin in crystalline form (1864).
- (c) Haeckel postulates that the nucleus is responsible for heredity (1868).
- (d) Ostwald proves that enzymes are catalysts (1893).
- (e) Muller discovers that X-rays induce mutations (1927).
- (f) Davson and Danielli postulate a model for the structure of cell membranes (1935).
- (g) Beadle and Tatum formulate the one gene–one enzyme hypothesis (1940).

- (h) Claude isolates the first mitochondrial fractions from rat liver (1940).
- (i) Lipmann postulates the central importance of ATP in cellular energy transactions (1940).
- (j) Avery, MacLeod, and McCarty demonstrate that bacterial transformation is attributable to DNA, not protein (1944).
- (k) Palade, Porter, and Sjøstrand each develop techniques for fixing and sectioning biological tissue for electron microscopy (1952–1953).
- (l) Lehninger demonstrates that oxidative phosphorylation depends for its immediate energy source on the transport of electrons in the mitochondrion (1957).

- 1-2 Cell Sizes.** To appreciate the differences in cell size illustrated in Figure 1A-1, consider these specific examples. *Escherichia coli*, a typical bacterial cell, is cylindrical in shape, with a diameter of about 1 μm and a length of about 2 μm . As a typical animal cell, consider a human liver cell, which is roughly spherical and has a diameter of about 20 μm . For a typical plant cell, consider the

columnar *palisade cells* located just beneath the upper surface of many plant leaves. These cells are cylindrical, with a diameter of about 20 μm and a length of about 35 μm .

- (a) Calculate the approximate volume of each of these three cell types in cubic micrometers. (Recall that $V = \pi r^2 h$ for a cylinder and that $V = 4\pi r^3/3$ for a sphere.)
- (b) Approximately how many bacterial cells would fit in the internal volume of a human liver cell?
- (c) Approximately how many liver cells would fit inside a palisade cell?

1-3 Sizing Things Up. To appreciate the sizes of the subcellular structures shown in Figure 1A-2, consider the following calculations:

- (a) All cells and many subcellular structures are surrounded by a membrane. Assuming a typical membrane to be about 8 nm wide, how many such membranes would have to be aligned side by side before the structure could be seen with the light microscope? How many with the electron microscope?
- (b) Ribosomes are the cell structures in which the process of protein synthesis takes place. A human ribosome is a roughly spherical structure with a diameter of about 30 nm. How many ribosomes would fit in the internal volume of the human liver cell described in Problem 1-2 if the entire volume of the cell were filled with ribosomes?
- (c) The genetic material of the *Escherichia coli* cell described in Problem 1-2 consists of a DNA molecule with a diameter of 2 nm and a total length of 1.36 mm. (The molecule is actually circular, with a circumference of 1.36 mm.) To be accommodated in a cell that is only a few micrometers long, this large DNA molecule is tightly coiled and folded into a *nucleoid* that occupies a small proportion of the cell's internal volume. Calculate the smallest possible volume the DNA molecule could fit into, and express it as a percentage of the internal volume of the bacterial cell that you calculated in Problem 1-2a.

1-4 Limits of Resolution Then and Now. Based on what you learned in this chapter about the limit of resolution of a light microscope, answer each of the following questions. Assume that the unaided human eye has a limit of resolution of about 0.25 mm and that a modern light microscope has a useful magnification of about 1000 \times .

- (a) Define *limit of resolution* in your own words. What was the limit of resolution of Hooke's microscope? What about van Leeuwenhoek's microscope?
- (b) What are the approximate dimensions of the smallest structure that Hooke would have been able to observe with his microscope? Would he have been able to see any of the structures shown in Figure 1A-1? If so, which ones? And if not, why not?
- (c) What are the approximate dimensions of the smallest structure that van Leeuwenhoek would have been able to observe with his microscope? Would he have been able to see any of the structures shown in Figure 1A-1? If so, which ones? And if not, why not?
- (d) What are the approximate dimensions of the smallest structure that a contemporary cell biologist should be able to observe with a modern light microscope?

- (e) Consider the eight structures shown in Figure 1A-1 and 1A-2. Which of these structures would both Hooke and van Leeuwenhoek have been able to see with their respective microscopes? Which, if any, would van Leeuwenhoek have been able to see that Hooke could not? Explain your reasoning. Which, if any, would a contemporary cell biologist be able to see that neither Hooke nor van Leeuwenhoek could see?

1-5 The Contemporary Strands of Cell Biology. For each pair of techniques listed, indicate whether its members belong to the cytological, biochemical, or genetic strand of cell biology (see Figure 1-2). Suggest one advantage that the second technique has over the first technique.

- (a) Light microscopy/electron microscopy
- (b) Centrifugation/ultracentrifugation
- (c) Nucleic acid hybridization/DNA sequencing
- (d) Sequencing of a genome/bioinformatics
- (e) Transmission electron microscopy/scanning electron microscopy
- (f) Chromatography/electrophoresis

1-6 The “Facts” of Life. Each of these statements was once regarded as a biological fact but is now understood to be untrue. In each case, indicate why the statement was once thought to be true and why it is no longer considered a fact.

- (a) Plant and animal tissues are constructed quite differently because animal tissues do not have conspicuous boundaries that divide them into cells.
- (b) Living organisms are not governed by the laws of chemistry and physics, as is nonliving matter, but are subject to a “vital force” that is responsible for the formation of organic compounds.
- (c) Genes most likely consist of proteins because the only other likely candidate, DNA, is a relatively uninteresting molecule consisting of only four kinds of monomers (nucleotides) arranged in a relatively invariant, repeating tetranucleotide sequence.
- (d) The fermentation of sugar to alcohol can take place only if living yeast cells are present.

• 1-7 More “Facts” of Life. Each of these statements was regarded as a biological fact until quite recently but is now either rejected or qualified to at least some extent. In each case, speculate on why the statement was once thought to be true, and then try to determine what evidence might have made it necessary to reject or at least to qualify the statement.
(Note: This question requires a more intrepid sleuth than Problem 1-6 does, but chapter references are provided to aid in your sleuthing.)

- (a) A biological membrane can be thought of as a protein-lipid “sandwich” consisting of an exclusively phospholipid interior coated on both sides with thin layers of protein (Chapter 7).
- (b) DNA always exists as a duplex of two strands wound together into a right-handed helix (Chapter 18).
- (c) The flow of genetic information in a cell is always from DNA to RNA to protein (Chapter 21).

• **1-8 Pizza, Heartburn, and the Scientific Method.** Although the scientific method may sound rather foreign when described in formal terms, you probably use the scientific method frequently without even realizing it. Suppose, for example, that recently you often have heartburn. You realize that the heartburn is most likely to occur on nights after you have eaten your favorite pizza, with pepperoni, anchovies, and onions. You wonder if the heartburn is caused by eating pizza and, if so, which of the ingredients might be the culprit. Describe how you might go about determining whether the heartburn is due to the pizza and, if so, to which of the ingredients.

1-9 A New Biofuel. As a recent cell biology graduate, you have just been hired by a biotechnology company to develop a

biofuel using algal cells that produce an oil very similar to diesel fuel. What model organism(s) might you use for each of the following aspects of this project? What tools and techniques would you use?

- (a) Determining which genes and enzymes are required to produce the oil.
- (b) Producing large amounts of a certain enzyme for further research.
- (c) Studying whether any of the cellular enzymes interact with each other.
- (d) Examining the involvement of any cellular organelles in storage or secretion of the oil.

The Chemistry of the Cell

S

Students just beginning in cell biology are sometimes surprised—occasionally even dismayed—to find that almost all courses and textbooks dealing with cell biology involve a substantial amount of chemistry. Yet biology in general and cell biology in particular depend heavily on both chemistry and physics. After all, cells and organisms follow all the laws of the physical universe, so biology is really just the study of chemistry in systems that happen to be alive. In fact, everything cells are and do has a molecular and chemical basis. Therefore, we can truly understand and appreciate cellular structure and function only when we can describe that structure in molecular terms and express that function in terms of chemical reactions and events.

Trying to appreciate cellular biology without a knowledge of chemistry would be like trying to appreciate a translation of Chekhov without a knowledge of Russian. Most of the meaning would probably get through, but much of the beauty and depth of appreciation would be lost in the translation. For this reason, we will consider the chemical background necessary for the cell biologist. Specifically, this chapter will provide an overview of several principles that underlie much of cellular biology, preparing, in turn, for the next chapter, which focuses on the major classes of chemical constituents in cells.

The main points of this chapter can conveniently be structured around five principles:

1. The importance of carbon. *The chemistry of cells is essentially the chemistry of carbon-containing compounds, because the carbon atom has several unique properties that make it especially suitable as the backbone of biologically important molecules.*
2. The importance of water. *The chemistry of cells is also the chemistry of water-soluble compounds, because the water molecule has several unique properties that make it especially suitable as the universal solvent of living systems.*

3. The importance of selectively permeable membranes. *Given that most biologically important molecules are soluble in water, membranes that do not dissolve in water are important in defining cellular spaces and compartments. Because membranes are differentially permeable to specific solutes, they also control the movements of molecules and ions into and out of cells and cellular compartments.*
4. The importance of synthesis by polymerization of small molecules. *Most biologically important molecules are either small, water-soluble organic molecules that can be transported across membranes or large macromolecules that cannot. Biological macromolecules are polymers formed by the linking together of many similar or identical small molecules known as monomers. The synthesis of macromolecules by polymerization of monomers is an important principle of cellular chemistry.*
5. The importance of self-assembly. *Proteins and other biological macromolecules made of repeating monomers are often capable of self-assembly into higher levels of structural organization. Self-assembly is possible because the information needed to specify the spatial configuration of the molecule is inherent in the linear array of monomers present in the polymer.*

A study of these five principles will help us to appreciate the main topics in cellular chemistry that we will need to understand before venturing further into our exploration of what it means to be a cell.

The Importance of Carbon

To study cellular molecules really means to study compounds containing carbon. Almost without exception, molecules of importance to the cell biologist have a backbone, or skeleton, of carbon atoms linked together covalently in chains or rings. Actually, the study of

carbon-containing compounds is the domain of **organic chemistry**. In its early days, organic chemistry was synonymous with *biological chemistry* because the carbon-containing compounds that chemists first investigated were obtained from biological sources (hence the word *organic*, acknowledging the organismal origins of the compounds).

The terms *organic chemistry* and *biological chemistry* have long since gone their separate ways, however, because organic chemists have now synthesized an incredible variety of carbon-containing compounds that do not occur naturally in the biological world. Organic chemistry therefore includes all classes of carbon-containing compounds, whereas **biological chemistry** (*biochemistry* for short) deals specifically with the chemistry of living systems and is, as we have already seen, one of the several historical strands that form an integral part of modern cell biology (see Figure 1-2).

The **carbon atom** (C) is the most important atom in biological molecules. Carbon-containing compounds owe their diversity and stability to specific bonding properties of the carbon atom. Especially important are the ways that carbon atoms interact with each other and with other chemical elements of biological importance.

An extremely important property of the carbon atom is its *valence* of four, allowing it to form four chemical bonds with other atoms. This means that the outermost electron orbital of a carbon atom lacks four of the eight electrons needed to fill it completely and make it the most stable (Figure 2-1a). Therefore, carbon atoms tend to associate with each other or with other electron-deficient atoms, allowing adjacent atoms to share a pair of electrons, one from each atom, so that each atom has a total of eight electrons. Atoms that share electrons in this way are held together and are said to be joined by a **covalent bond**. Because four electrons are required to fill the outer orbital of carbon, stable organic compounds have four covalent bonds for every carbon atom. This gives carbon-containing molecules great diversity in molecular structure and function.

Carbon atoms are most likely to form covalent bonds with one another and with atoms of oxygen (O), hydrogen (H), nitrogen (N), and sulfur (S). The electronic configurations of several of these atoms are shown in Figure 2-1a (sulfur has the same valence as oxygen). Notice that, in each case, one or more electrons are required to complete the outer orbital. The number of “missing” electrons corresponds in each case to the valence of the atom, which indicates, in turn, the number of covalent bonds the atom can form. (Hydrogen is different because its outermost electron orbital can hold only two electrons; and, thus, it has a valence of one and forms only one covalent bond.) Carbon, oxygen, hydrogen, and nitrogen are the lightest elements that form covalent bonds by sharing electron pairs. Their low atomic weight makes the resulting compounds especially stable because the strength of a covalent bond is inversely proportional to the atomic weights of the elements involved in the bond.

The sharing of one pair of electrons between atoms results in a **single bond**. Methane, ethanol, and methylamine are simple examples of carbon-containing compounds

containing only single bonds between atoms (Figure 2-1b). Sometimes, two or even three pairs of electrons can be shared by two atoms, giving rise to **double bonds** or **triple bonds**. Ethylene and carbon dioxide are examples of double-bonded compounds (Figure 2-1c). Notice that, in these compounds, each carbon atom still forms a total of four covalent bonds, either one double bond and two single bonds or two double bonds. Triple bonds are rare but can be found in molecular nitrogen, hydrogen cyanide, and acetylene (Figure 2-1d). Thus, both the valence and the low atomic weight of carbon give it unique properties that account for the diversity and stability of carbon-containing compounds, giving carbon a preeminent role in biological molecules.

Carbon-Containing Molecules Are Stable

The stability of organic molecules is a property of the favorable electronic configuration of each carbon atom in the molecule. This stability is expressed as **bond energy**—the amount of energy required to break 1 *mole* (about

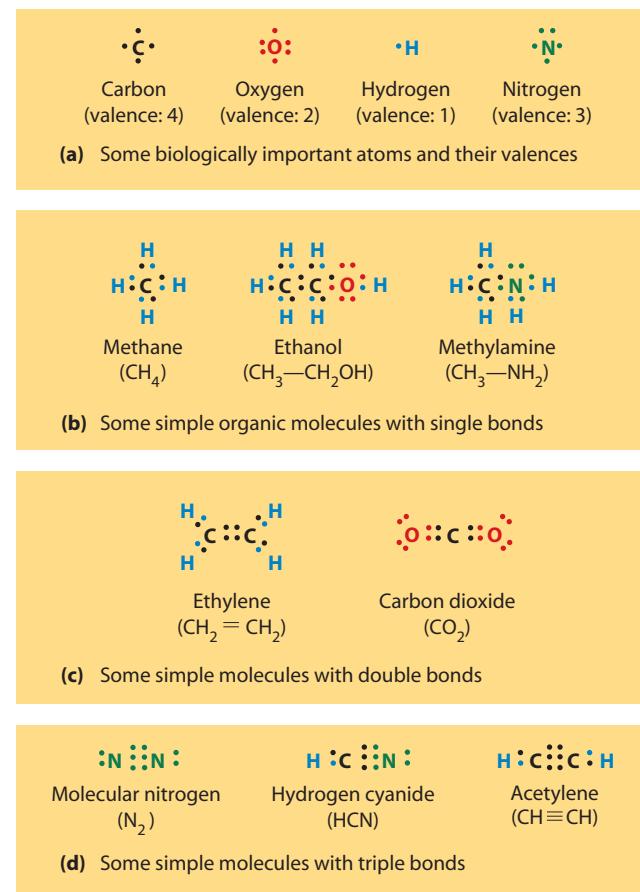

FIGURE 2-1 Electron Configurations of Some Biologically Important Atoms and Molecules. Electronic configurations are shown for (a) atoms of carbon, oxygen, hydrogen, and nitrogen and for simple organic molecules with (b) single bonds, (c) double bonds, and (d) triple bonds. Only electrons in the outermost electron orbital are shown. In each case, the two electrons positioned between adjacent atoms represent a shared electron pair, with one electron provided by each of the two atoms.

6×10^{23}) of such bonds. (The term *bond energy* is a frequent source of confusion. Be careful not to think of it as energy that is somehow “stored” in the bond but rather as the amount of energy needed to *break* the bond.) Bond energies are usually expressed in *calories per mole* (*cal/mol*), where a **calorie** is the amount of energy needed to raise the temperature of 1 gram of water by 1°C and a **kilocalorie** (*kcal*) is equal to 1000 calories.

It takes a large amount of energy to break a covalent bond. For example, the carbon-carbon ($\text{C}—\text{C}$) bond has a bond energy of 83 kilocalories per mole (*kcal/mol*). The bond energies for carbon-nitrogen ($\text{C}—\text{N}$), carbon-oxygen ($\text{C}—\text{O}$), and carbon-hydrogen ($\text{C}—\text{H}$) bonds are all in the same range: 70, 84, and 99 kcal/mol, respectively. Even more energy is required to break a carbon-carbon double bond ($\text{C}=\text{C}$; 146 kcal/mol) or a carbon-carbon triple bond ($\text{C}\equiv\text{C}$; 212 kcal/mol), so these compounds are even more stable.

We can appreciate the significance of these bond energies by comparing them with other relevant energy values, as shown in **Figure 2-2**. Most noncovalent bonds in biologically important molecules, such as the hydrogen bonds we will see later in this chapter, have energies of only a few kilocalories per mole. The energy of thermal vibration is even lower—only about 0.6 kcal/mol. Covalent bonds are much higher in energy than noncovalent bonds and are therefore much more stable.

The fitness of the carbon-carbon bond for biological chemistry on Earth is especially clear when we compare its energy with that of solar radiation. As shown in **Figure 2-3**, there is an inverse relationship between the wavelength of electromagnetic radiation and its energy content. From this figure, we can see that the visible portion of sunlight (wavelengths of 400–700 nm) is lower in energy than

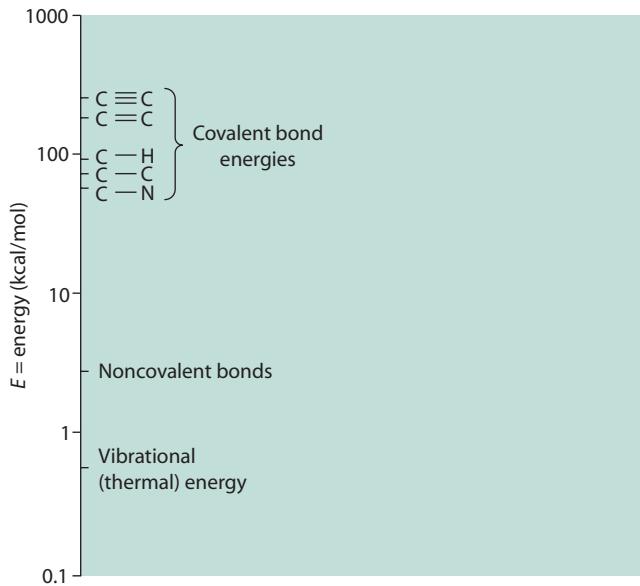

FIGURE 2-2 Energies of Biologically Important Bonds.
Notice that energy is plotted on a logarithmic scale to accommodate the wide range of values shown.

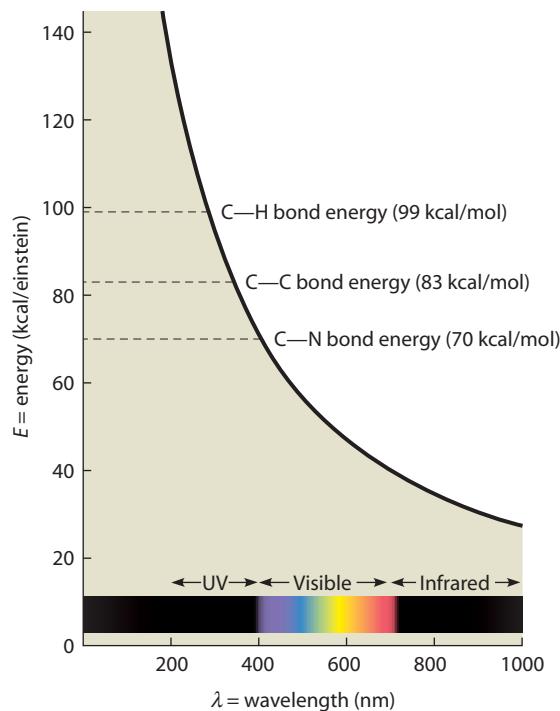

FIGURE 2-3 The Relationship Between Energy (*E*) and Wavelength (λ) for Electromagnetic Radiation. The dashed lines mark the bond energies of the $\text{C}—\text{H}$, the $\text{C}—\text{C}$, and the $\text{C}—\text{N}$ single bonds. The bottom of the graph shows the approximate range of wavelengths for ultraviolet (UV), visible, and infrared radiation.

the carbon-carbon bond is. If this were not the case, visible light would break covalent bonds spontaneously, and life as we know it would not exist.

Figure 2-3 illustrates another important point: the hazard that ultraviolet radiation poses to biological molecules due to its high energy. At a wavelength of 300 nm, for example, ultraviolet light has an energy content of about 95 kcal/einstein (one einstein equals one mole of photons). This is enough to break carbon-carbon bonds spontaneously. This threat underlies the current concern about pollutants that destroy the ozone layer in the upper atmosphere because the ozone layer filters out much of the ultraviolet radiation that would otherwise reach Earth’s surface and disrupt the covalent bonds that hold biological molecules together.

Carbon-Containing Molecules Are Diverse

In addition to their inherent stability, carbon-containing compounds are characterized by the great diversity of molecules that can be generated from relatively few different kinds of atoms. Again, this diversity is due to the tetravalent nature of the carbon atom and the resulting ability of each carbon atom to form covalent bonds to four other atoms. Because one or more of these bonds can be to other carbon atoms, molecules consisting of long chains of carbon atoms can be built up. Ring compounds are also common. Further variety is possible by the introduction

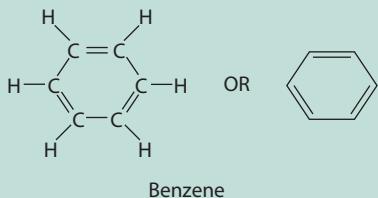

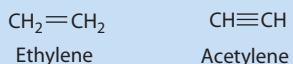

FIGURE 2-4 Some Simple Hydrocarbon Compounds.

Compounds in the top row have single bonds only, whereas those in the second row have double or triple bonds. The condensed structure shown on the right for benzene is an example of the simplified structures that chemists frequently use for such compounds.

of branching and the presence of double bonds in the carbon-carbon chains.

When only hydrogen atoms are bonded to carbon atoms in linear or circular molecules, the resulting compounds are called **hydrocarbons** (Figure 2-4). Hydrocarbons are important economically because gasoline and other petroleum products—such as hexane (C_6H_{14}), octane (C_8H_{18}), and decane ($\text{C}_{10}\text{H}_{22}$)—are mixtures of short-chain hydrocarbons with from five to twelve carbon atoms. The natural gas that many of us use for fuel is a mixture of methane, ethane, propane, and butane, which are hydrocarbons with one to four carbon atoms, respectively.

In biology, on the other hand, hydrocarbons play only a limited role because they are essentially insoluble in water, the universal solvent in biological systems. However, they play an important role in the structure of biological membranes. The interior of every biological membrane is a nonaqueous environment consisting of the long hydrocarbon “tails” of phospholipid molecules that project into the interior of the membrane from either surface. This feature of membranes has important implications for their role as permeability barriers, as we will see shortly.

Most biological compounds contain, in addition to carbon and hydrogen, one or more atoms of oxygen and often nitrogen, phosphorus, or sulfur as well. These atoms are usually part of various **functional groups**, which are specific arrangements of atoms that confer characteristic chemical properties on the molecules to which they are attached. Some of the more common functional groups present in biological molecules are shown in Figure 2-5. At the near-neutral pH of most cells, several of these groups are ionized because they have gained or lost a proton via protonation or deprotonation, respectively.

These groups include the negatively charged *carboxyl* and *phosphate* groups, which have been deprotonated and the positively charged *amino* group, which has become protonated. Other groups, such as the *hydroxyl*, *sulphydryl*, *carbonyl*, and *aldehyde* groups, are uncharged at pH values near neutrality. However, the presence of oxygen or sulfur atoms bound to carbon or hydrogen in these uncharged groups results in a *polar bond* with unequal sharing of electrons. This is due to the higher *electronegativity*, or affinity for electrons, of oxygen and sulfur compared to carbon and hydrogen. The resulting polar bonds have higher water solubility and chemical reactivity than C—C or C—H bonds, in which electrons are equally shared.

Carbon-Containing Molecules Can Form Stereoisomers

Carbon-containing molecules are capable of still greater diversity because the carbon atom is a **tetrahedral** structure (Figure 2-6). When four different atoms or groups of atoms are bonded to the four corners of such a tetrahedral structure, two different spatial configurations are possible. Although both forms have the same structural formula, they are not superimposable but are, in fact, mirror images of each other. Such mirror-image forms of the same compound are called **stereoisomers**.

A carbon atom that has four different substituents is called an **asymmetric carbon atom**. Because two stereoisomers are possible for each asymmetric carbon atom, a compound with n asymmetric carbon atoms will

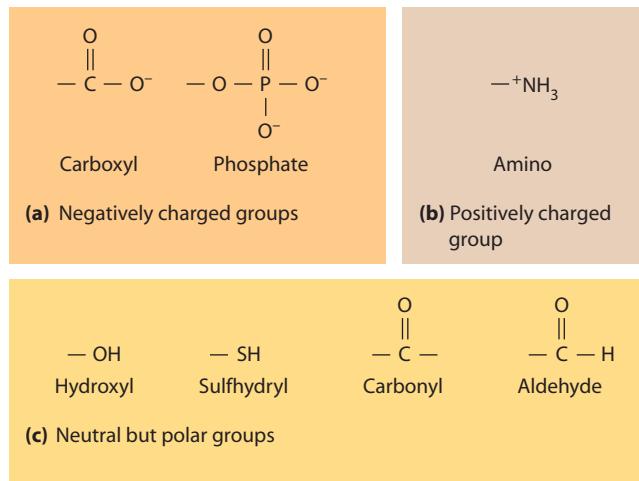

FIGURE 2-5 Some Common Functional Groups Found in Biological Molecules. Each functional group is shown in the form that predominates at the near-neutral pH of most cells. (a) The carboxyl and phosphate groups are deprotonated and therefore negatively charged. (b) The amino group, on the other hand, is protonated and is therefore positively charged. (c) Hydroxyl, sulphydryl, carbonyl, and aldehyde groups are uncharged at pH values near neutrality but are much more polar than hydrocarbons, thereby conferring greater polarity and water solubility on the organic molecules to which they are attached.

ACTIVITIES www.thecellplace.com Functional groups

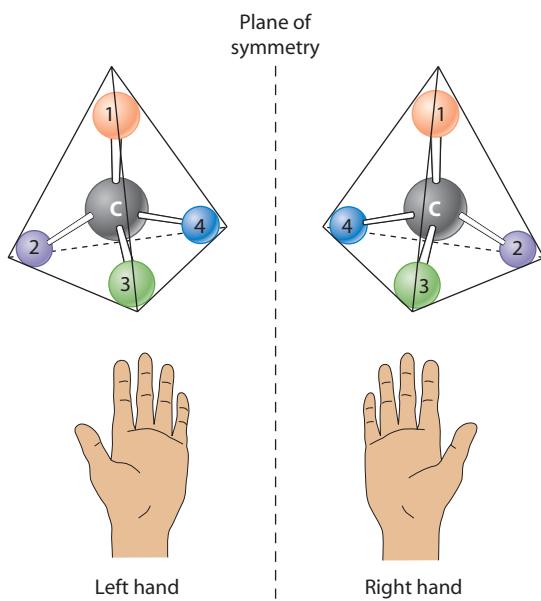

FIGURE 2-6 Stereoisomers. Stereoisomers of organic compounds occur when four different groups are attached to a tetrahedral carbon atom. Stereoisomers, like left and right hands, are mirror images of each other and cannot be superimposed on one another. (The dashed line down the center of the figure is the plane of symmetry, which can be thought of as the plane of the mirror.)

 [ACTIVITIES www.thecellplace.com](http://www.thecellplace.com) Isomers

have 2^n possible stereoisomers. As shown in **Figure 2-7a**, the three-carbon amino acid *alanine* has a single asymmetric carbon atom (in the center) and thus has two stereoisomers, called *L*-alanine and *D*-alanine. Neither of the other two carbon atoms of alanine is an asymmetric carbon atom because one has three identical substituents and the other has two bonds to a single oxygen atom. Both stereoisomers of alanine occur in nature, but only *L*-alanine is present as a component of proteins.

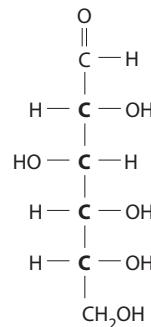

As an example of a compound with multiple asymmetric carbon atoms, consider the six-carbon sugar *glucose* shown in Figure 2-7b. Of the six carbon atoms of glucose, the four shown in boldface are asymmetric. (Can you figure out why the other two carbon atoms are not asymmetric?) With four asymmetric carbon atoms, the structure shown (*D*-glucose) is only one of 2^4 , or 16, possible stereoisomers of the $C_6H_{12}O_6$ molecule.

The Importance of Water

Just as the carbon atom is uniquely significant because of its role as the universal backbone of biologically important molecules, the water molecule commands special attention because of its indispensable role as the universal solvent in biological systems. Water is, in fact, the single most abundant component of cells and organisms. Typically, about 75–85% of a cell by weight is water, and many cells depend on an extracellular environment that is essentially aqueous as well. In some cases this is a body of water—

(a)

(b)

D-glucose

FIGURE 2-7 Stereoisomers of Biological Molecules. (a) The amino acid alanine has a single asymmetric carbon atom (in boldface) and can therefore exist in two spatially different forms, designated as *L*- and *D*-alanine. (The dashed line down the center of the figure is the plane of symmetry.) (b) The six-carbon sugar glucose has four asymmetric carbon atoms (in boldface), so *D*-glucose is just one of 16 (2^4) possible stereoisomers of the $C_6H_{12}O_6$ molecule.

whether an ocean, lake, or river—where the cell or organism lives, and in other cases, it may be the body fluids with which the cell is bathed.

Water is indispensable for life as we know it. True, there are life forms that can become dormant and survive periods of severe water scarcity. Seeds of plants and spores of bacteria and fungi are clearly in this category. Some plants and animals—notably certain mosses, lichens, nematodes, and rotifers—can also undergo physiological adaptations that allow them to dry out and survive in a highly dehydrated form, sometimes for surprisingly long periods of time. Such adaptations are clearly an advantage in environments that are characterized by periods of drought. Yet all of these are, at best, temporary survival mechanisms. Resumption of normal activity always requires rehydration.

To understand why water is so uniquely suitable for its role, we need to look at its chemical properties. The most critical attribute is its *polarity* because this property accounts for its *cohesiveness*, its *temperature-stabilizing capacity*, and its *solvent properties*, all of which have important consequences for biological chemistry.

Water Molecules Are Polar

An unequal distribution of electrons gives the water molecule its **polarity**, which we can define as an uneven distribution of charge within a molecule. To understand the polar nature of water, we need to consider the shape of the molecule. As shown in **Figure 2-8a**, the water molecule is bent rather than linear in shape, with the two hydrogen atoms bonded to the oxygen at an angle of 104.5° rather than 180° . It is no overstatement to say that life as we know it depends critically on this angle because of the distinctive properties that the resulting asymmetry produces in the water molecule. Although the molecule as a whole is uncharged, the electrons are unevenly distributed. The oxygen atom at the head of the molecule is highly **electronegative**—it tends to draw electrons toward it, giving that end of the molecule a partial negative charge and leaving the other end of the molecule with a partial positive charge around the hydrogen atoms.

Water Molecules Are Cohesive

Because of their polarity, water molecules are attracted to each other and tend to orient themselves spontaneously so that the electronegative oxygen atom of one molecule is associated with the electropositive hydrogen atoms of adjacent molecules. Each such association is called a **hydrogen bond** and is represented by a dotted line, as shown in Figure

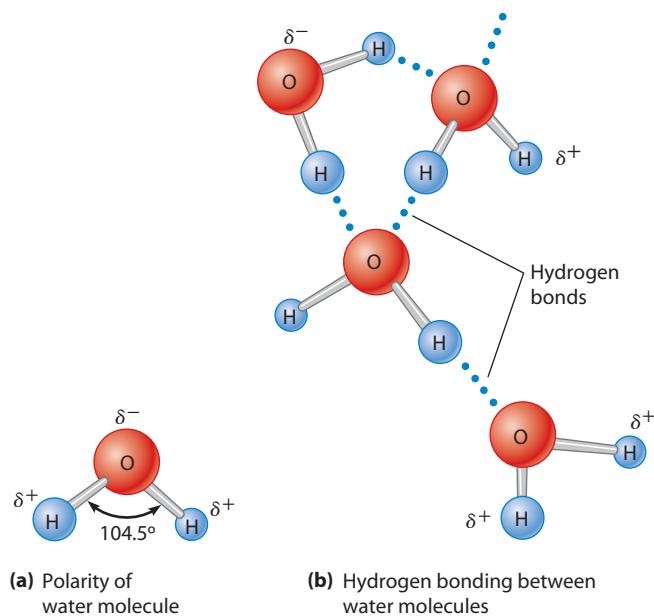

FIGURE 2-8 Hydrogen Bonding Between Water Molecules.

- (a) The water molecule is polar because it has an asymmetric charge distribution. The oxygen atom bears a partial negative charge (denoted as δ^- , with the Greek letter delta standing for “partial”), and each of the two hydrogen atoms has a partial positive charge (δ^+).
(b) The extensive association of water molecules with one another in either the liquid or the solid state is due to hydrogen bonds (dotted lines) between the highly electronegative oxygen atom of one water molecule and the electropositive hydrogen atoms of adjacent molecules. In ice, the resulting crystal lattice is regular and complete. Every oxygen is hydrogen bonded to hydrogens of two adjacent molecules.

FIGURE 2-9 Walking on Water. The high surface tension of water results from the collective strength of vast numbers of hydrogen bonds, and it enables insects such as this water strider to walk on the surface of a pond without breaking the surface.

2-8b. A hydrogen bond is a type of noncovalent interaction that is about one-tenth as strong as a covalent bond.

Each oxygen atom can bond to two hydrogens, and both of the hydrogen atoms can associate in this way with the oxygen atoms of adjacent molecules. As a result, water is characterized by an extensive three-dimensional network of hydrogen-bonded molecules. Although individual hydrogen bonds are weak, the combined effect of large numbers of them can be quite significant. In liquid water, the hydrogen bonds between adjacent molecules are constantly being broken and reformed, with a typical bond having a half-life of a few microseconds. On the average, however, each molecule of water in the liquid state is hydrogen-bonded to at least three neighbor molecules at any given time. In ice, the hydrogen bonding is still more extensive, giving rise to a rigid, hexagonal crystalline lattice with every oxygen hydrogen-bonded to hydrogens of two adjacent molecules and every water molecule therefore hydrogen-bonded to four neighboring molecules.

It is this tendency to form hydrogen bonds between adjacent molecules that makes water so highly *cohesive*. This cohesiveness accounts for the high *surface tension* of water, as well as for its high *boiling point*, high *specific heat*, and high *heat of vaporization*. The high surface tension of water allows some insects to move across the surface of a pond without breaking the surface (**Figure 2-9**). It is also important in allowing water to move upward through the conducting tissues of plants.

Water Has a High Temperature-Stabilizing Capacity

An important property of water that stems directly from the hydrogen bonding between adjacent molecules is the high specific heat that gives water its *temperature-stabilizing capacity*. **Specific heat** is the amount of heat a substance must absorb per gram to increase its temperature 1°C . The specific heat of water is 1.0 calorie per gram.

Due to its extensive hydrogen bonding, the specific heat of water is much higher than that of most other liquids. In other liquids, much of the energy would cause an increase in the motion of solvent molecules and therefore an increase in temperature. In water, the energy is used instead to break hydrogen bonds between neighboring water molecules, buffering aqueous solutions against large changes in temperature. This capability is an important consideration for the cell biologist because cells release large amounts of energy as heat during metabolic reactions. If not for the extensive hydrogen bonding and the resulting high specific heat of water molecules, this release of energy would pose a serious overheating problem for cells, and life as we know it would not be possible.

Water also has a high *heat of vaporization*, which is defined as the amount of energy required to convert 1 gram of a liquid into vapor. This value is high for water because of the hydrogen bonds that must be disrupted in the process. This property makes water an excellent coolant and explains why people perspire, why dogs pant, and why plants lose water through transpiration. In each case, the heat required to evaporate water is drawn from the organism, which is therefore cooled in the process.

Water Is an Excellent Solvent

From a biological perspective, one of the most important properties of water is its excellence as a general solvent. A **solvent** is a fluid in which another substance, called the **solute**, can be dissolved. Water is an especially good solvent for biological purposes because of its remarkable capacity to dissolve a great variety of solutes.

It is the polarity of water that makes it so useful as a solvent. Most of the molecules in cells are also polar (or charged) and therefore form hydrogen bonds (or ionic bonds) with water molecules. Solutes that have an affinity for water and therefore dissolve readily in it are called **hydrophilic** ("water-loving"). Most small organic molecules found in cells are hydrophilic. Examples are

sugars, organic acids, and some of the amino acids. Molecules that are not very soluble in water are termed **hydrophobic** ("water-fearing"). Among the more important hydrophobic compounds found in cells are the lipids and proteins found in biological membranes. In general, polar molecules and ions are hydrophilic, and nonpolar molecules are hydrophobic. Some biological macromolecules, notably proteins, have both hydrophobic and hydrophilic regions, so some parts of the molecule have an affinity for water while other parts of the molecule do not.

To understand why polar substances dissolve so readily in water, let's consider a salt such as sodium chloride (NaCl) (**Figure 2-10**). Because it is a salt, NaCl exists in crystalline form as a lattice of positively charged sodium *cations* (Na^+) and negatively charged chloride *anions* (Cl^-). For NaCl to dissolve in a liquid, solvent molecules must overcome the attraction of the Na^+ cations and Cl^- anions for each other. When NaCl is placed in water, both the sodium and chloride ions become involved in *electrostatic interactions* with the water molecules instead of with each other, and the Na^+ and Cl^- ions separate and become dissolved. Because of their polarity, water molecules can form *spheres of hydration* around both Na^+ and Cl^- , thus neutralizing their attraction for each other and decreasing their likelihood of reassociation.

As Figure 2-10a shows, the sphere of hydration around a cation such as Na^+ involves water molecules clustered around the ion with their negative (oxygen) ends pointing toward it. For an anion such as Cl^- , the orientation of the water molecules is reversed, with the positive (hydrogen) ends of the solvent molecules pointing in toward the ion (Figure 2-10b). Similar spheres of hydration develop around charged functional groups (see Figure 2-5a, b), increasing their solubility. Even uncharged polar functional groups, such as aldehyde or sulphydryl groups (see Figure 2-5c), will have a sphere of hydration, as the polar oxygen or sulfur atoms attract the positively-charged ends of the polar water molecule and increase solubility.

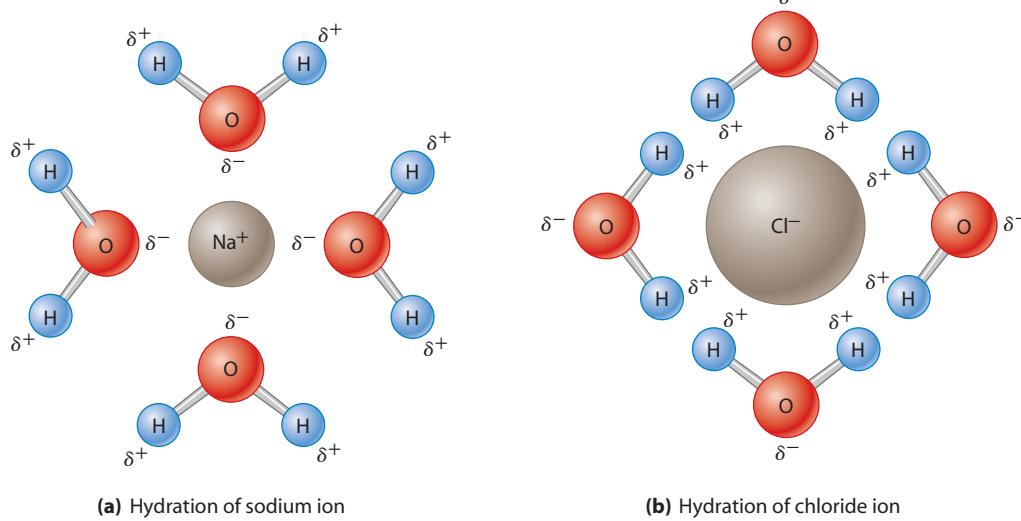

FIGURE 2-10 The Solubilization of Sodium Chloride. Sodium chloride (NaCl) dissolves in water because spheres of hydration are formed around both (a) the sodium ions and (b) the chloride ions. The oxygen atom and the sodium and chloride ions are drawn to scale.

Some biological compounds are soluble in water because they exist as ions at the near neutral pH of the cell and are therefore solubilized and hydrated like the ions of Figure 2-10. Compounds containing carboxyl, phosphate, or amino groups are in this category (see Figure 2-5). Most organic acids, for example, are almost completely ionized by deprotonation at a pH near 7 and therefore exist as anions that are kept in solution by spheres of hydration, as we have just seen with the chloride ion in Figure 2-10b. Amines, on the other hand, are usually protonated at cellular pH and thus exist as hydrated cations, and behave like the sodium ion in Figure 2-10a.

Often, organic molecules have no net charge—that is, they have neither lost nor gained protons and are therefore neutral molecules. However, many organic molecules are nonetheless hydrophilic because they have some regions that are positively charged and other regions that are negatively charged. Water molecules tend to cluster around such regions, and the resulting electrostatic interactions between solute and water molecules keep the solute molecules from associating with one another. Compounds containing the hydroxyl, sulfhydryl, carbonyl, or aldehyde groups shown in Figure 2-5 are usually in this category.

Hydrophobic molecules such as hydrocarbons, on the other hand, have no such polar regions and therefore show no tendency to interact electrostatically with water molecules. In fact, they actually disrupt the hydrogen-bonded structure of water and, for this reason, tend to be excluded by the water molecules. Therefore, hydrophobic molecules tend to coalesce as they associate with one another rather than with the water. This association is driven not so much by any specific affinity of the hydrophobic molecules for one another as by the strong tendency of water molecules to form hydrogen bonds and to exclude molecules that disrupt hydrogen bonding. As we will see later in the chapter, such associations of hydrophobic molecules (or parts of molecules) are a major driving force in the folding of molecules, the assembly of cellular structures, and the organization of membranes.

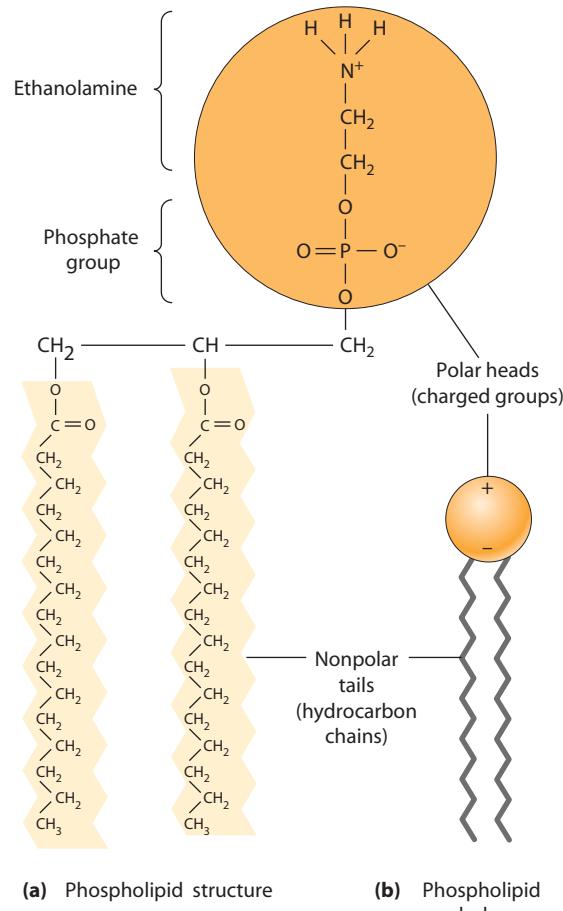

The Importance of Selectively Permeable Membranes

Every cell and organelle needs some sort of physical barrier to keep its contents in and external materials out. A cell also needs some means of controlling exchange between its internal environment and the extracellular environment. Ideally, such a barrier should be impermeable to most of the molecules and ions found in cells and their surroundings. Otherwise, substances could diffuse freely in and out, and the cell would not really have a defined content at all. On the other hand, the barrier cannot be completely impermeable or else necessary exchanges between the cell and its environment could not take place. The barrier must be insoluble in water so that it will not be dissolved by the aqueous medium of the cell. At the same time, it must be readily permeable to water because water

is the basic solvent system of the cell and must be able to flow into and out of the cell as needed.

As you might expect, the membranes that surround cells and organelles satisfy these criteria admirably. A cellular **membrane** is essentially a hydrophobic permeability barrier that consists of *phospholipids*, *glycolipids*, and *membrane proteins*. In most organisms other than bacteria, the membranes also contain *sterols*—*cholesterol* in the case of animal cells, *ergosterols* in fungi, and *phytosterols* in the membranes of plant cells. (Don't be concerned if you haven't encountered these kinds of molecules before; we'll meet them all again in Chapter 3.)

Most membrane lipids and proteins are not simply hydrophobic or hydrophilic. They typically have both hydrophilic and hydrophobic regions and are therefore referred to as **amphipathic molecules** (the Greek prefix *amphi-* means “of both kinds”). The amphipathic nature of membrane phospholipids is illustrated in **Figure 2-11**,

(a) Phospholipid structure

(b) Phospholipid symbol

FIGURE 2-11 The Amphipathic Nature of Membrane Phospholipids.

Phospholipids. (a) A phospholipid molecule consists of two long nonpolar tails (yellow) and a polar head (orange). Illustrated here is phosphatidyl ethanolamine, an example of the phosphoglyceride class of membrane phospholipids. The polarity of the head of a phospholipid molecule results from a negatively charged phosphate group linked to a positively charged group—an amino group, in the case of phosphatidyl ethanolamine. (b) A phospholipid molecule is often represented schematically by a circle for the polar head (notice the plus and minus charges) and two zigzag lines for the nonpolar hydrocarbon chains.

which shows the structure of *phosphatidyl ethanolamine*, a prominent phospholipid in many kinds of membranes. The distinguishing feature of amphipathic phospholipids is that each molecule consists of a polar *head* and two non-polar hydrocarbon *tails*. The polarity of the hydrophilic head is due to the presence of a negatively charged phosphate group that is often linked to a positively charged group—an amino group, in the case of phosphatidyl ethanolamine and most other phosphoglycerides. We will learn more about phospholipids in Chapter 3.

Soap is a familiar amphipathic molecule that you all have likely used to dissolve grease, oil, and other nonpolar substances. The nonpolar hydrocarbon tails of the soap molecules interact with and surround the oil or grease, and the polar heads interact with water, enabling the oil or grease to be washed away. In the lab, we often use the amphipathic detergent sodium dodecyl sulfate (SDS) to isolate insoluble proteins and lipids. SDS has a negatively charged sulfate group attached to a hydrocarbon chain of 12 carbons, and acts much like the soap described above to solubilize nonpolar and amphipathic molecules.

A Membrane Is a Lipid Bilayer with Proteins Embedded in It

When exposed to an aqueous environment, amphipathic molecules undergo hydrophobic interactions. In a membrane, for example, phospholipids are organized into two layers: Their polar heads face outward toward the aqueous environment on both sides, and their hydrophobic tails are

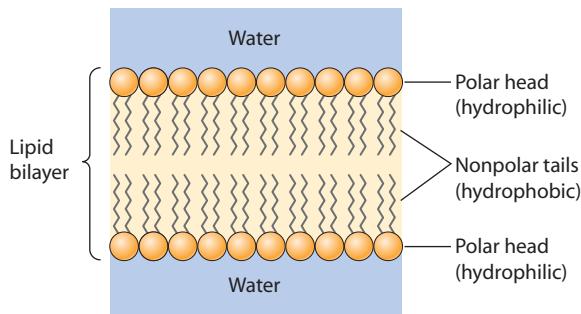

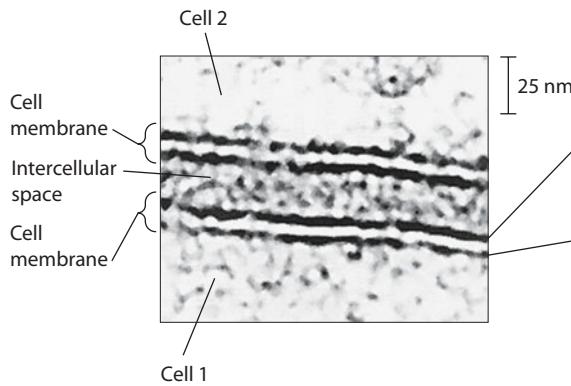

FIGURE 2-12 The Lipid Bilayer as the Basis of Membrane Structure.

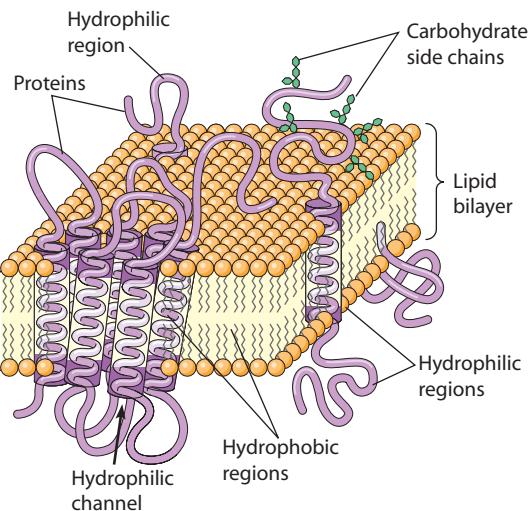

Structure. Because of their amphipathic nature, phospholipids in an aqueous environment orient themselves in a double layer, with the hydrophobic tails (zigzag lines) buried on the inside and the hydrophilic heads (orange) interacting with the aqueous environment on either side of the membrane.

hidden from the water by interacting with the tails of other molecules oriented in the opposite direction. The resulting structure is the **lipid bilayer**, shown in **Figure 2-12**. The heads of both layers face outward, and the hydrocarbon tails extend inward, forming the continuous hydrophobic interior of the membrane.

Every known biological membrane has such a lipid bilayer as its basic structure. Each of the lipid layers is typically 3–4 nm thick, so the bilayer has a width of 7–8 nm. It is the lipid bilayer that gives each membrane its characteristic “railroad track” appearance when seen in cross section with the transmission electron microscope (TEM; **Figure 2-13a**). The osmium used to prepare the tissue for electron

(b) Model of a membrane as a lipid bilayer with proteins embedded in it

FIGURE 2-13 Membranes and Membrane Structure. (a) With the transmission electron microscope (TEM), each of the cell membranes surrounding two adjacent cells appears as a pair of dark bands that result when osmium interacts with the hydrophilic heads of the phospholipid molecules but not with their hydrophobic tails. (b) Biological membranes consist of amphipathic proteins embedded within a lipid bilayer. Proteins are positioned in the membrane so that their hydrophobic regions are located in the hydrophobic interior of the phospholipid bilayer and their hydrophilic regions are exposed to the aqueous environment on either side of the membrane.

VIDEOS www.thecellplace.com Dynamics of a lipid bilayer

microscopy reacts with the hydrophilic heads of the phospholipid molecules at both surfaces of the membrane but not with the hydrophobic tails in the interior of the membrane, giving each membrane its three-layered appearance.

The structure of biological membranes is illustrated in Figure 2-13b. Embedded within or associated with the membrane lipid bilayer are various membrane proteins. These proteins are almost always amphipathic, and they become oriented in the lipid bilayer accordingly. Hydrophobic regions of the protein associate with the interior of the membrane, whereas hydrophilic regions protrude into the aqueous environment on either or both surfaces of the membrane.

Depending on the particular membrane, the membrane proteins may play any of a variety of roles. Some are *transport proteins*, responsible for moving specific substances across an otherwise impermeable membrane. Others are *enzymes* that catalyze reactions associated with the specific membrane. Still others are the *receptors* on the outer surface of the cell membrane, the *electron transport intermediates* of the mitochondrial membrane, or the *chlorophyll-binding proteins* of the chloroplast. We will encounter each of these kinds of membrane proteins in subsequent chapters, beginning with Chapter 4 (see, for example, Figure 4-9).

Membranes Are Selectively Permeable

Because of its hydrophobic interior, a membrane is readily permeable to nonpolar molecules. However, it is quite impermeable to most polar molecules and is highly impermeable to all ions. Because most cellular constituents are either polar or charged, they have little or no affinity for the membrane interior and are effectively prevented from entering or escaping from the cell. Very small molecules are an exception, however. Compounds with molecular weights below about 100 diffuse across membranes regardless of whether they are nonpolar (O_2 and CO_2) or polar (ethanol and urea). Water is an especially important example of a very small molecule that, although polar, diffuses rapidly across membranes and can readily enter or leave cells.

In contrast, even the smallest ions are effectively excluded from the hydrophobic interior of the membrane. For example, a lipid bilayer is at least 10^8 times less permeable to such small cations as Na^+ or K^+ than it is to water. This striking difference is due to both the charge on an ion and the sphere of hydration surrounding the ion.

Of course, it is essential that cells have ways of transferring not only ions such as Na^+ , and K^+ , but also a wide variety of polar molecules across membranes that are not otherwise permeable to these substances. As already noted, membranes are equipped with transport proteins to serve this function. A transport protein is a specialized transmembrane protein that serves either as a *hydrophilic channel* through an otherwise hydrophobic membrane or as a *carrier* that binds a specific solute on one side of the

membrane and then undergoes a conformational change to move the solute across the membrane.

Whether a channel or a carrier, each transport protein is specific for a particular molecule or ion (or, in some cases, for a class of closely related molecules or ions). Moreover, the activities of these proteins can be carefully regulated to meet cellular needs. As a result, biological membranes are best described as *selectively permeable*. Except for very small molecules and nonpolar molecules, molecules and ions can move across a particular membrane only if the membrane contains an appropriate transport protein.

The Importance of Synthesis by Polymerization

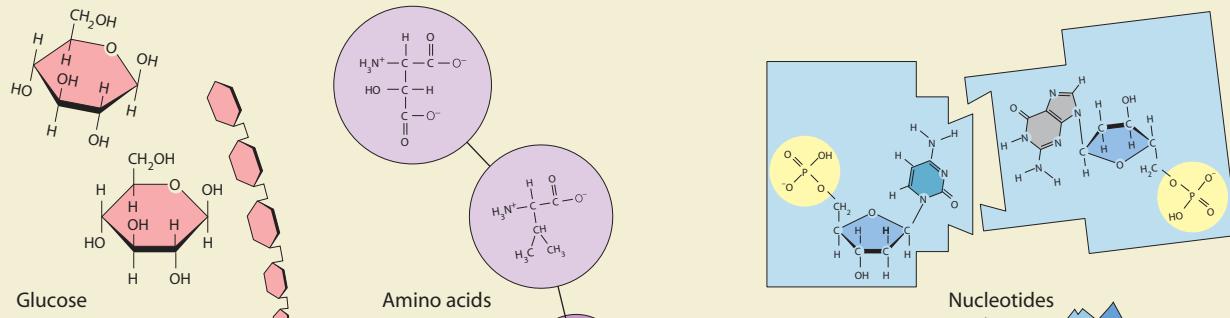

For the most part, cellular structures such as ribosomes, chromosomes, membranes, flagella, and cell walls are made up of ordered arrays of linear *polymers* that are called **macromolecules**. Important macromolecules in cells include *proteins*, *nucleic acids* (both DNA and RNA), and *polysaccharides* such as starch, glycogen, and cellulose. *Lipids* are sometimes regarded as macromolecules as well; however, they differ somewhat from the other classes of macromolecules in the way they are synthesized and will not be discussed further until Chapter 3. Macromolecules are important in both the structure and the function of cells. To understand the biochemical basis of cell biology, therefore, really means to understand macromolecules—how they are made, how they are assembled, and how they function.

Macromolecules Are Responsible for Most of the Form and Function in Living Systems

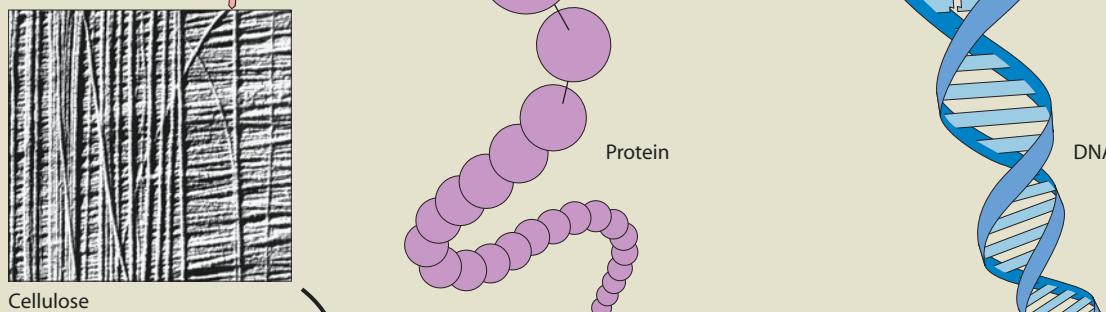

The importance of macromolecules in cell biology is emphasized by the cellular hierarchy shown in **Figure 2-14**. We use the term *hierarchy* here to denote how biological molecules and structures can be organized into a series of levels, each level building on the preceding one. Most cellular structures are composed of small, water-soluble *organic molecules* (level 1) that cells either obtain from other cells or synthesize from simple nonbiological molecules such as carbon dioxide, ammonia, or phosphate ions that are available from the environment. Small organic molecules polymerize to form *biological macromolecules* (level 2) such as polysaccharides, proteins, or nucleic acids. These macromolecules may function on their own, or they can then be assembled into a variety of *supramolecular structures* (level 3). These supramolecular structures are themselves components of *organelles* and other *subcellular structures* (level 4) that make up the *cell* itself (level 5).

One of the examples in Figure 2-14 is that of cell wall biogenesis (panels on left). In plants, a major component of the primary cell wall (level 3) is the polysaccharide cellulose (level 2). Cellulose is a repeating polymer of the simple monosaccharide glucose (level 1), a sugar formed by the plant cell from carbon dioxide and water in the process of photosynthesis.

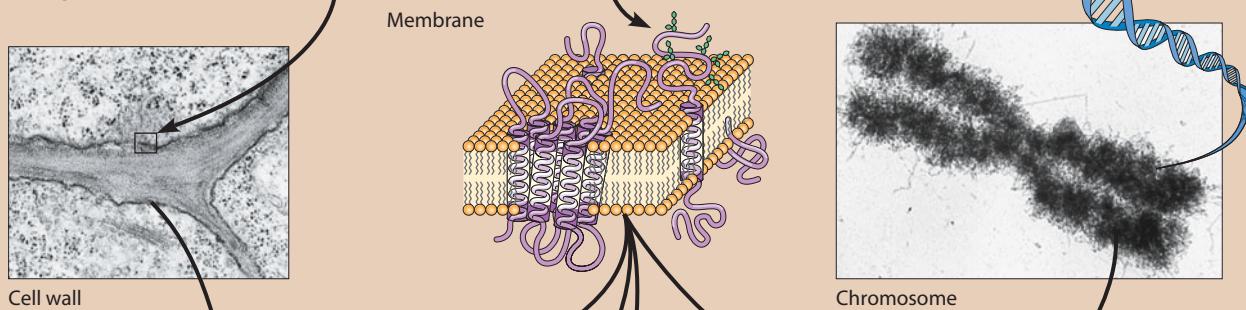

Level 1: Small organic molecules

Level 2: Macromolecules

Level 3: Supramolecular structures

Level 4: Organelles and other structures

Level 5: The cell

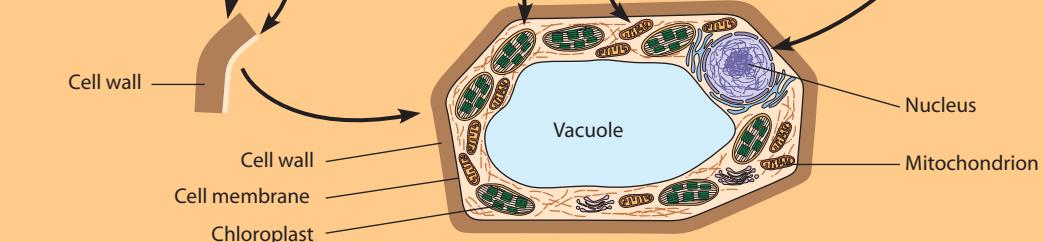

FIGURE 2-14 The Hierarchical Nature of Cellular Structures and Their Assembly. Small organic molecules (level 1) are synthesized from simple inorganic substances and are polymerized to form macromolecules (level 2). The macromolecules then assemble into the supramolecular structures (level 3) that make up organelles and other subcellular structures (level 4) and, ultimately, the cell itself (level 5). The supramolecular structures shown as level 3 are more complex in their chemical composition than the figure suggests. Chromosomes, for example, contain proteins as well as DNA—in about equal amounts, in fact. Similarly, membranes contain not only lipids but also a variety of proteins; and cell walls contain not just cellulose but also other carbohydrates and proteins.

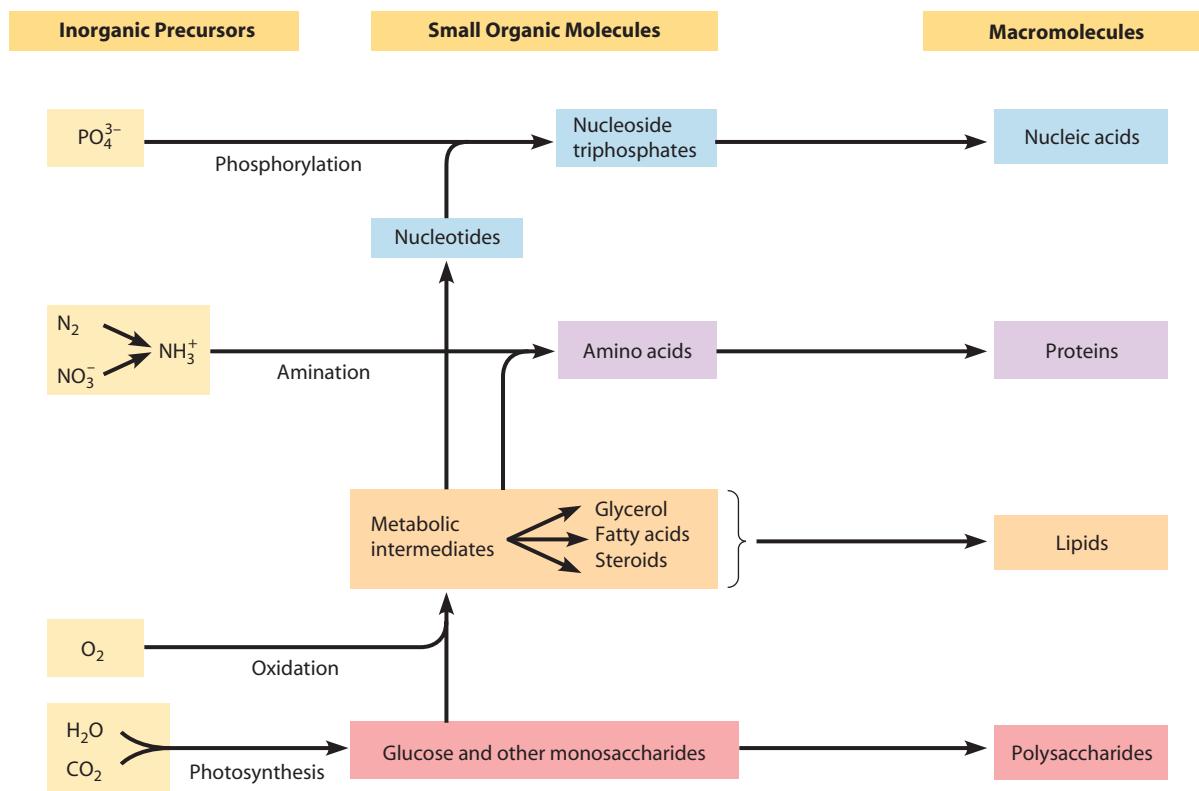

FIGURE 2-15 The Synthesis of Biological Macromolecules. Simple inorganic precursors (left) react to form small organic molecules (center), which are the monomers used in synthesizing the macromolecules (right) that make up most cellular structures.

From such examples, a general principle emerges: *The macromolecules that are responsible for most of the form and order characteristic of living systems are generated by the polymerization of small organic molecules.* This strategy of forming large molecules by joining smaller units in a repetitive manner is illustrated in **Figure 2-15**. The importance of this strategy can hardly be overemphasized because it is a fundamental principle of cellular chemistry. The many enzymes responsible for catalyzing cellular reactions, the nucleic acids involved in storing and expressing genetic information, the glycogen stored by your liver, and the cellulose that gives rigidity to a plant cell wall are all variations on the same design theme. Each is a macromolecule made by the linking together of small repeating units.

Examples of such repeating units, or **monomers**, are the *glucose* present in cellulose or starch, the *amino acids* needed to make proteins, and the *nucleotides* that make up nucleic acids. In general these are small, water-soluble organic molecules with molecular weights less than about 350. They can be transported across most biological membranes, provided the appropriate transport proteins are present in the membrane. By contrast, most macromolecules that are synthesized from these monomers are too large to traverse membranes and therefore must be made in the cell or compartment where they are needed.

Cells Contain Three Different Kinds of Macromolecules

The three major kinds of macromolecular polymers found in the cell are proteins, nucleic acids, and polysaccharides. **Table 2-1** describes the general functions of these macromolecules, gives a few examples of each, and describes the type and variety of monomeric subunits comprising each polymer. For nucleic acids and proteins, the exact order of the different monomers is critical for function. In both nucleic acids and proteins, there are nearly limitless ways in which the different monomers can be arranged in a linear order. Thus, there are millions of different DNA, RNA, and protein sequences. In contrast, polysaccharides are typically composed of a single monomer or of two different monomers. These monomers occur in a repetitive pattern and, thus, there are relatively few different types of polysaccharides.

Nucleic acids (both DNA and RNA) are often called **informational macromolecules** because the order of the four kinds of nucleotide monomers in each is nonrandom and carries important information. A critical role of many DNA and RNA molecules is to serve a *coding* function, meaning that they contain the information necessary to specify the precise amino acid sequences of particular proteins. In this manner, the specific order of the monomeric units in nucleic acids stores and transmits the genetic

Table 2-1 Biologically Important Macromolecules

	Proteins	Nucleic Acids	Polysaccharides	
General function	Various (see below)	Informational	Storage	Structural
Examples	Enzymes, hormones, antibodies, carriers, ion channels	DNA, RNA	Starch, glycogen	Cellulose, chitin
Type of monomer	Amino acids	Nucleotides	Monosaccharides	Monosaccharides
Number of different monomers	20	4	One or a few	One or a few

information of the cell. As we will learn later, other DNA and RNA sequences have regulatory or enzymatic functions.

Proteins are a second type of macromolecule composed of a nonrandom series of monomers—in this case, amino acids. In contrast to nucleic acids, the monomer sequence does not transmit information but rather determines the three-dimensional structure of the protein, which—as we shall soon see—dictates its biological activity. Because there are 20 different amino acids found in proteins, there is a nearly infinite variety of possible protein sequences. Thus, proteins have a wide range of functions in the cell, including roles in structure, defense, transport, catalysis, and signaling. Because the precise sequence of amino acids in a protein is so important, variations in that sequence often negatively affect the ability of the protein to perform its function.

Polysaccharides, on the other hand, typically consist of either a single repeating subunit or two subunits occurring in strict alternation. The order of monomers in a polysaccharide therefore carries no information and is not essential to the function of the polymer. Most polysaccharides are either **storage macromolecules** or **structural macromolecules**. The most familiar storage polysaccharides are the *starch* of plant cells and the *glycogen* found in bacteria and animal cells. As shown in **Figure 2-16a**, both of these storage polysaccharides consist of a single repeating monomer—the simple sugar glucose—and they both function in energy storage.

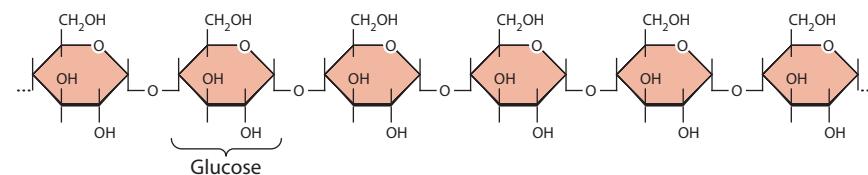

The best-known example of a structural polysaccharide is the *cellulose* present in plant cell walls and woody tissues. Like starch and glycogen, cellulose consists solely of glucose

units; however, in cellulose the units are linked together by a somewhat different bond, as we will see in Chapter 3. Another example of a structural polysaccharide formed from a single type of monosaccharide is *chitin*, found in insect exoskeletons, fungal cell walls, and crustacean shells. Chitin consists of *N*-acetylglucosamine (GlcNAc) units only. The cell walls of most bacteria contain a more complicated kind of structural polysaccharide that consists of two kinds of monomers—GlcNAc and *N*-acetylmuramic acid (MurNAc) in strictly alternating sequence (Figure 2-16b).

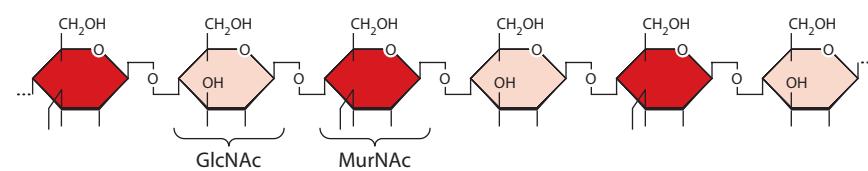

Macromolecules Are Synthesized by Stepwise Polymerization of Monomers

In Chapter 3, we will look at each of the major kinds of biologically important macromolecules. First, however, it will be useful to consider several important principles that underlie the polymerization processes by which all of these macromolecules arise. Although the chemistry of the monomeric units, and hence of the resulting polymers, differs markedly among macromolecules, the following basic principles apply in each case:

1. Macromolecules are always synthesized by the stepwise polymerization of similar or identical small molecules called *monomers*.
2. The addition of each monomer occurs with the removal of a water molecule and is therefore termed a **condensation reaction**.

(a) A storage polysaccharide (segment of a starch or glycogen molecule)

(b) A structural polysaccharide (segment of a bacterial cell wall component)

FIGURE 2-16 Storage and Structural Macromolecules. Storage and structural macromolecules contain one or a few kinds of repeating units in a repetitive sequence. (a) A portion of the sequence of a linear segment of the storage polysaccharide starch or glycogen, consisting of glucose units linked together by glycosidic bonds. (b) A portion of the sequence of a bacterial cell wall polysaccharide, consisting of the sugar derivatives *N*-acetylglucosamine (GlcNAc) and *N*-acetylmuramic acid (MurNAc) in strict alternation.

- The monomeric units that are to be joined together must be present as **activated monomers** before condensation can occur.
- Activation usually involves coupling of the monomer to a **carrier molecule**, forming an activated monomer.
- The energy needed to couple the monomer to the carrier molecule is provided by a molecule called *adenosine triphosphate* (ATP) or a related high-energy compound.
- Because of the way they are synthesized, macromolecules have an inherent **directionality**. This means that the two ends of the polymer chain are chemically different from each other.

Because the elimination of a water molecule is essential in all biological polymerization reactions, each monomer must have both an available hydrogen (H) and an available hydroxyl group ($-\text{OH}$) elsewhere on the molecule. This structural feature is depicted schematically in **Figure 2-17a**, in which the monomeric units (M) are represented as boxes labeled with the relevant hydrogen and hydroxyl group. For a given kind of polymer, the monomers may differ from one another in other aspects of their structure; but each monomer possesses an available hydrogen and hydroxyl group.

Figure 2-17a also shows monomer activation, an energy-requiring process. Regardless of the polymer type, the addition of each monomer to a growing chain is always energetically unfavorable unless the incoming monomer is in an activated, energized form. Activation usually involves coupling of the monomer to a carrier molecule (C). The energy to drive this activation process is provided by ATP or a closely related *high-energy compound*—one that releases a large amount of energy upon hydrolysis (see pp. 225–226). A different kind of carrier molecule is used for each kind of polymer. For protein synthesis, amino acids are activated by linking them to carriers called *transfer RNA* (or tRNA) molecules. Polysaccharides are synthesized from sugar (often glucose) molecules that are activated by linking them to derivatives of nucleotides (*adenosine diphosphate* for starch, *uridine diphosphate* for glycogen). In nucleic acid synthesis, there is no need for specific carrier molecules because the nucleotides themselves (e.g., ATP or GTP) are high-energy molecules.

Once activated, monomers are capable of reacting with each other in a condensation reaction that is followed or accompanied by the release of the carrier molecule from one of the two monomers (see Figure 2-17b). Subsequent elongation of the polymer is a sequential, stepwise process. One activated monomeric unit is added at a time, thus lengthening the elongating polymer by one unit. Figure 2-17c illustrates the *n*th step in such a process, during

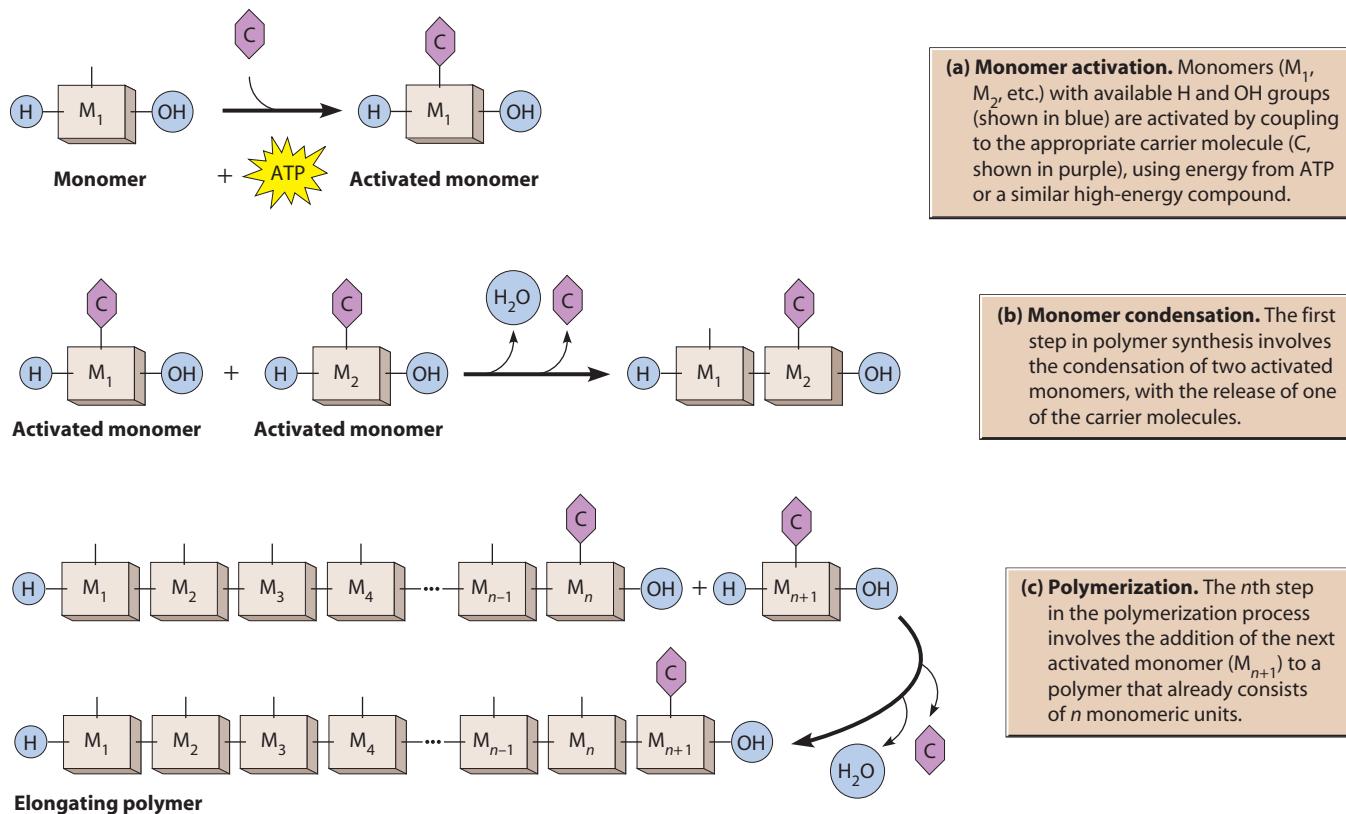

FIGURE 2-17 Macromolecule Biosynthesis. Biological macromolecules are synthesized in a process involving (a) monomer activation, (b) condensation, and (c) polymerization. Depending on the polymer, the monomers may be identical (some polysaccharides) or may differ from one another (proteins and nucleic acids).

which the next monomer unit is added to an elongating polymer that already contains n monomeric units. The chemical nature of the energized monomers, the carrier, and the actual activation process differ for each biological polymer, but the general principle is always the same: *Polymer synthesis always involves activated monomers joined via condensation reactions, and ATP or a similar high-energy compound is required to activate the monomers by linking them to an appropriate carrier molecule.*

The *degradation*, or breakdown, of macromolecules occurs in a manner opposite to the condensation reactions used for synthesis. During degradation, monomers are removed from the polymer by **hydrolysis**—the addition of a water molecule that breaks the bond between adjacent monomers. In the process, one monomer receives a hydroxyl group from the water molecule and the other receives a hydrogen atom, reforming the original monomers.

The Importance of Self-Assembly

So far, we have seen that the macromolecules that characterize biological organization and function are polymers of small, hydrophilic, organic molecules. The only requirements for polymerization are an adequate supply of the monomeric subunits and a source of energy—and, in the case of proteins and nucleic acids, sufficient information to specify the order of the monomers. Still to be considered are the steps that lie beyond—the processes through which these macromolecules are organized into the supramolecular assemblies and organelles that are readily recognizable as cellular structures. Or, in light of Figure 2-14, we need to ask how the macromolecules of level 2 are assembled into the higher-level structures of levels 3, 4, and 5.

Crucial to our understanding of these higher-level structures is the principle of **self-assembly**, which asserts that *the information required to specify the folding of macromolecules and their interactions to form more complex structures with specific biological functions is inherent in the polymers themselves.* This principle says that once macromolecules are synthesized in the cell, their assembly into more complex structures will occur spontaneously, without further input of energy or information. As we will see shortly, this principle has been qualified somewhat by the recognition that proteins called *molecular chaperones* are needed in some cases of protein folding to prevent incorrect molecular interactions that would give rise to inactive structures. Even in such cases, however, the chaperone molecules do not provide additional information. They simply assist the assembly process by inhibiting interactions that would produce incorrect structures.

Many Proteins Self-Assemble

A prototype that is useful for understanding self-assembly processes is the coiling and folding necessary to form a functional three-dimensional protein from one or more linear chains of amino acids. Although the distinction is not always

properly made, the immediate product of amino acid polymerization is actually not a protein, but a **polypeptide**. To become a functional protein, one or more such linear polypeptide chains must coil and fold in a precise, predetermined manner to assume the unique three-dimensional structure, or *conformation*, necessary for biological activity.

The evidence for self-assembly of proteins comes largely from studies in which the *native*, or natural, conformation of a protein is disrupted by changing the environmental conditions. Such disruption, or unfolding, can be achieved by raising the temperature, by making the pH of the solution highly acidic or highly alkaline, or by adding certain chemical agents such as urea or any of several alcohols. The unfolding of a polypeptide under such conditions is called **denaturation** because it results in the loss of the natural three-dimensional structure of the protein—and the loss of its function as well. In the case of an enzyme, denaturation results in the loss of catalytic activity.

When the denatured polypeptide is returned to conditions in which the native conformation is stable, the polypeptide may undergo **renaturation**, the return to its correct three-dimensional conformation. In at least some cases, the renatured protein also regains its biological function—catalytic activity, in the case of an enzyme.

Figure 2-18a depicts the denaturation and subsequent renaturation of *ribonuclease*, the protein used by Christian Anfinsen and his colleagues in their classic studies of protein self-assembly. When a solution of ribonuclease is heated, the protein denatures, resulting in an unfolded, randomly coiled polypeptide with no fixed shape and no catalytic activity. If the solution of the denatured molecules is then allowed to cool slowly, the ribonuclease molecules regain their original conformation and again have catalytic activity. Thus, all of the information necessary to specify the three-dimensional structure of the ribonuclease molecule is inherent in its amino acid sequence. Similar results have been obtained from denaturation/renaturation experiments with other proteins, although renaturation is much more difficult, if not impossible, to demonstrate with larger, more complex proteins.

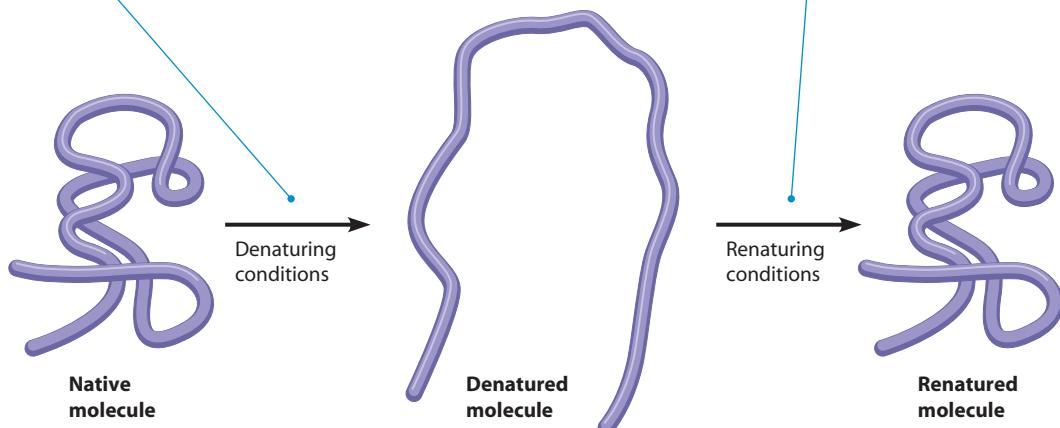

Molecular Chaperones Assist the Assembly of Some Proteins

Based on the ability of some denatured proteins to return to their original configuration and to regain biological function, biologists initially assumed that proteins and protein-containing structures self-assemble in cells as well. As illustrated in Figure 2-18b for ribonuclease, protein synthesis takes place on ribosomes. The polypeptide elongates as successive amino acids are added to one end. The self-assembly model envisions polypeptide chains coiling and folding spontaneously and progressively as polypeptides are synthesized in this way.

By the time the fully elongated polypeptide is released from the ribosome, it is thought to have attained a stable, predictable, three-dimensional structure without any input

(a) Spontaneous refolding of ribonuclease following denaturation. Anfinsen's experiment showed that all the information needed for the proper folding of a ribonuclease polypeptide into its native three-dimensional conformation is present in its amino acid sequence.

1 Denaturation. First, the folded polypeptide was exposed to denaturing conditions (heating) that disrupted noncovalent interactions between its amino acid R groups, resulting in a ribonuclease molecule with no fixed shape and no enzymatic activity.

2 Renaturation. Then, renaturing conditions (cooling) allowed renewed interactions between the amino acid R groups. The polypeptide returned spontaneously to its native conformation, regaining enzymatic activity.

(b) Spontaneous folding of ribonuclease during synthesis. The same interactions between amino acid R groups act on the elongating polypeptide during its synthesis on a ribosome (left to right). This results in the spontaneous folding of the polypeptide into its unique conformation.

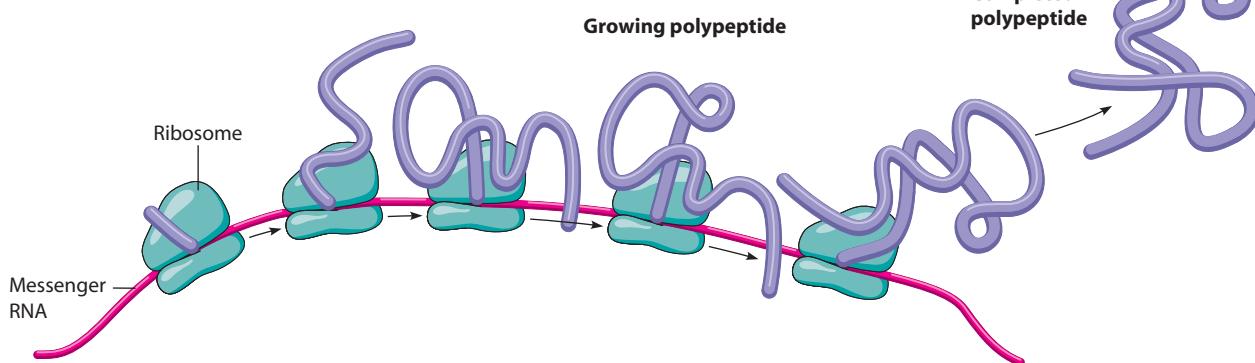

FIGURE 2-18 The Spontaneity of Polypeptide Folding. The protein depicted here is the enzyme ribonuclease, shown (a) as used in Anfinsen's classic *in vitro* protein folding experiments and (b) during *in vivo* synthesis.

of energy or information beyond the basic polymerization process. Furthermore, folding is assumed to be unique, in the sense that each polypeptide with the same amino acid sequence will fold in an identical, reproducible manner under the same conditions. Thus, the self-assembly model assumes that interactions occurring within and between polypeptides are all that is necessary for the biogenesis of proteins in their functional forms.

However, this model for self-assembly *in vivo* (in the cell) is based entirely on studies with isolated proteins; and, even under laboratory conditions, not all proteins regain their native structure. Based on their work with one such protein (*ribulose bisphosphate carboxylase/oxygenase*, the

chloroplast enzyme that catalyzes the conversion of CO₂ to sugar in the process of photosynthesis), John Ellis and his colleagues at Warwick University concluded that the self-assembly model may not be adequate for all proteins. They proposed that the interactions that drive protein folding may need to be assisted and controlled by proteins known as **molecular chaperones** to reduce the probability of the formation of incorrect structures having no biological activity.

Molecular chaperones are proteins that facilitate the correct assembly of proteins and protein-containing structures but are not components of the assembled structures. The molecular chaperones that have been identified to date do not convey information either for polypeptide folding or for

the assembly of multiple polypeptides into a single protein. Instead, they function by binding to specific regions that are exposed only in the early stages of assembly, thereby inhibiting unproductive assembly pathways that would lead to incorrect structures. Commenting on the term *molecular chaperone*, Ellis and Van der Vies observed that “the term chaperone is appropriate for this family of proteins because the role of the human chaperone is to prevent incorrect interactions between people, not to provide steric information for those interactions” (Ellis and Van der Vies, 1991, p. 323).

The mode of action of molecular chaperones is best described as **assisted self-assembly**. We can therefore distinguish two types of self-assembly: *strict self-assembly*, for which no factors other than the information contained in the polypeptide itself are required for proper folding; and *assisted self-assembly*, in which the appropriate molecular chaperone is required to ensure that correct assembly will predominate over incorrect assembly.

The list of known molecular chaperones has grown steadily since Ellis and his colleagues first proposed the term in 1987. The first molecular chaperones studied were those of chloroplasts, mitochondria, and bacteria. Within a few years, however, chaperones were identified in other eukaryotic locations. Chaperone proteins are abundant under normal conditions and increase to still higher levels in response to stresses such as increased temperature—a condition called *heat shock*—or an increase in the cellular content of unfolded proteins. Many common chaperone proteins fall into two families, called *Hsp60* and *Hsp70*. “Hsp” stands for *heat-shock protein*, and the numbers refer to the approximate molecular weights of the protein’s polypeptide monomers—60,000 and 70,000, respectively. The proteins within each Hsp family are evolutionarily related, and they are found throughout the biological world. *Hsp70* proteins, for example, have been found in bacteria and in cells of a wide variety of eukaryotes, where they are present in several intracellular locations.

Noncovalent Bonds and Interactions Are Important in the Folding of Macromolecules

Whether assisted by molecular chaperones or not, polypeptides fold and self-assemble without the input of further information. Also, the three-dimensional structure of a protein or protein complex is remarkably stable once it has been attained. To understand the self-assembly of proteins (and, as it turns out, of other biological molecules and structures as well), we need to consider the covalent as well as noncovalent bonds that hold polypeptides and other macromolecules together.

Covalent bonds are easy to understand. Every protein or other macromolecule in the cell is held together by strong covalent bonds such as those discussed earlier in the chapter. A covalent bond forms whenever two atoms *share* electrons rather than gaining or losing electrons completely. Electron sharing is an especially prominent feature of the carbon atom, which has four electrons in its outer orbital and is

therefore at the midpoint between the tendency to gain or lose electrons. Covalent bonds link the monomers of a polypeptide together; they also can stabilize the three-dimensional structure of many proteins. In Chapter 3 we will see how covalent disulfide bonds formed between pairs of cysteine amino acids play an important role in protein structure. But, as important as covalent bonds are in cellular chemistry, the complexity of molecular structure cannot be described by patterns of covalent bonding alone. Most of the cell’s structures are held together by **noncovalent bonds and interactions**—much weaker forces that occur in macromolecules.

The most important noncovalent bonds and interactions in biological macromolecules are *hydrogen bonds*, *ionic bonds*, *van der Waals interactions*, and *hydrophobic interactions*. Each of these interactions is introduced here and discussed in more detail in Chapter 3 (see Figure 3-5). As we’ve already noted, *hydrogen bonds* involve weak, attractive interactions between an electronegative atom such as oxygen (or nitrogen) and a hydrogen atom that is covalently bonded to a second electronegative atom. We will soon see that hydrogen bonds are extremely important in maintaining the three-dimensional structure of proteins and in holding together the two strands of the DNA double helix.

Ionic bonds are noncovalent electrostatic interactions between two oppositely charged ions. Typically, in the case of macromolecules, ionic bonds form between positively charged and negatively charged functional groups such as amino groups, carboxyl groups, and phosphate groups. Ionic bonds between functional groups of amino acids in the same protein molecule play a major role in determining and maintaining the structure of the protein. They are also important in the binding of different macromolecules to each other as, for example, in the binding of positively charged proteins to negatively charged DNA molecules.

Van der Waals interactions (or forces) are weak attractive interactions between two atoms that occur only if the atoms are very close to one another and are oriented appropriately. However, when atoms or groups of atoms get too close together, they begin to repel each other because of their overlapping outer electron orbitals. The *van der Waals radius* of a specific atom specifies the “private space” around it that limits how close other atoms can come. This radius is typically about 0.12 to 0.19 nm. Van der Waals radii provide the basis for *space-filling models* of biological macromolecules, such as that for the protein insulin shown in **Figure 2-19** and the DNA molecule shown in Figure 3-19b.

The term *hydrophobic interactions* describes the tendency of nonpolar groups within a macromolecule to associate with each other as they minimize their contact with surrounding water molecules and with any hydrophilic groups in the same or another macromolecule. Hydrophobic interactions among nonpolar groups are common in proteins and will cause nonpolar groups to be found in the interior of a protein molecule or imbedded in the nonpolar interior of a membrane (see Figure 2-13b).

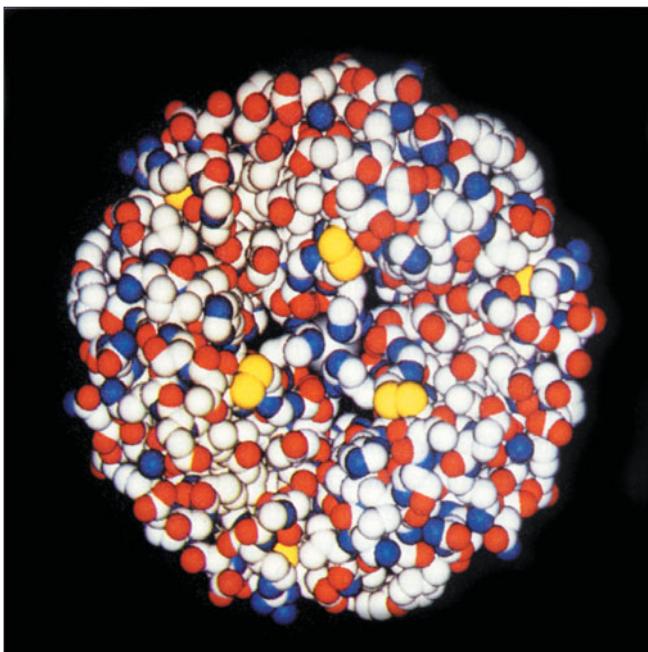

FIGURE 2-19 A Space-Filling Model of Insulin. All of the atoms and chemical groups in this model of the protein insulin are represented as spheres with the appropriate van der Waals radii. Notice how tightly the atoms pack against one another. (Color key: C = red, H = white, O = blue, S = yellow.)

Self-Assembly Also Occurs in Other Cellular Structures

The same principle of self-assembly that accounts for the folding and interactions of polypeptides also applies to more complex cellular structures. Many of the characteristic structures of the cell are complexes of two or more different kinds of polymers and involve interactions that are chemically distinct from those of polypeptide folding and association. However, the principle of self-assembly may nonetheless apply. For example, *ribosomes* contain both RNA and proteins, and *membranes* are made up of both phospholipids and proteins. The *primary cell wall* that surrounds a plant cell, although composed mainly of cellulose fibrils, also contains a variety of other carbohydrates as well as a small but crucial protein component. Yet, despite the chemical differences among such polymers as proteins, nucleic acids, and polysaccharides, the noncovalent interactions that drive these supramolecular assembly processes are similar to those that dictate the folding of individual protein molecules.

The Tobacco Mosaic Virus Is a Case Study in Self-Assembly

Some of the most definitive findings concerning the self-assembly of complex biological structures have come from studies of viruses. As we will learn in Chapter 4, a *virus* is a complex of proteins and nucleic acid, either DNA or RNA. A virus is not itself alive; but it can invade and infect a living cell, take over the synthetic machinery of the cell,

and use the cell to produce more virus components. When the components—viral nucleic acid and viral proteins—are synthesized, these macromolecules spontaneously assemble into the mature virus particles.

An especially good example is tobacco mosaic virus (TMV), a plant virus that molecular biologists have studied for many years. TMV is a rodlike particle about 18 nm in diameter and 300 nm in length. It consists of a single strand of RNA with 6395 nucleotides and about 2130 copies of a single kind of polypeptide—the *coat protein*, each containing 158 amino acids. The RNA molecule forms a helical core, with a cylinder of protein subunits clustered around it (Figure 2-20).

Heinz Fraenkel-Conrat and his colleagues carried out several important experiments that contributed significantly to our understanding of self-assembly. They separated TMV into its RNA and protein components and then allowed them to reassemble *in vitro*. Functional, infectious viral particles formed spontaneously, providing one of the first and most convincing demonstrations that the components of a complex biological structure can reassemble spontaneously without external information. Especially interesting was the finding that mixing the RNA from one strain of virus strain with the protein from another formed a hybrid virus that was also infectious.

The assembly process has since been studied in detail and is known to be surprisingly complex (Figure 2-21). The basic unit of assembly is a two-layered disk of coat protein that undergoes a conformational change to a helical shape as it interacts with a short segment of the RNA molecule. This transition allows another disk to bind, and each successive disk undergoes the same conformational change from a cylinder to a helix as it binds another segment of RNA. The process continues until the end of the RNA molecule is reached, producing the mature virus particle, its RNA completely covered with coat protein.

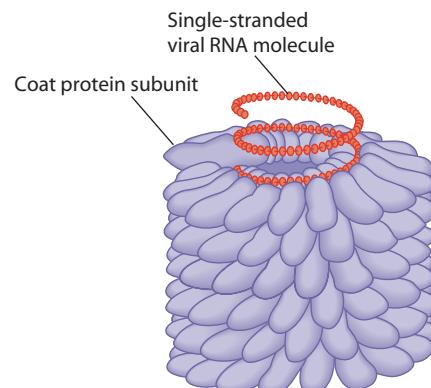

FIGURE 2-20 A Structural Model of Tobacco Mosaic Virus (TMV). A single-stranded RNA molecule is coiled into a helix, surrounded by a coat consisting of 2130 identical protein subunits. Only a portion of the entire TMV virion is shown here, and several layers of protein have been omitted from the upper end of the structure to reveal the helical RNA molecule inside.

(a) The unit of assembly of the protein coat of TMV consists of 34 identical coat protein subunits that spontaneously assemble to form a double-layered disk with 17 subunits per layer.

(b) The viral RNA molecule associates with a disk, causing the RNA molecule to form a loop of 102 nucleotides as the disk changes from a cylindrical to a helical conformation.

(c) Another disk is then added, and another loop of the RNA associates with it. The prior disk, meanwhile, has changed from a cylindrical to a helical conformation that resembles a lockwasher.

(d) Each incoming disk adds two more layers of protein subunits and associates with another loop of RNA, which forms into a spiral. The process continues until the entire RNA molecule is covered and the virion is complete.

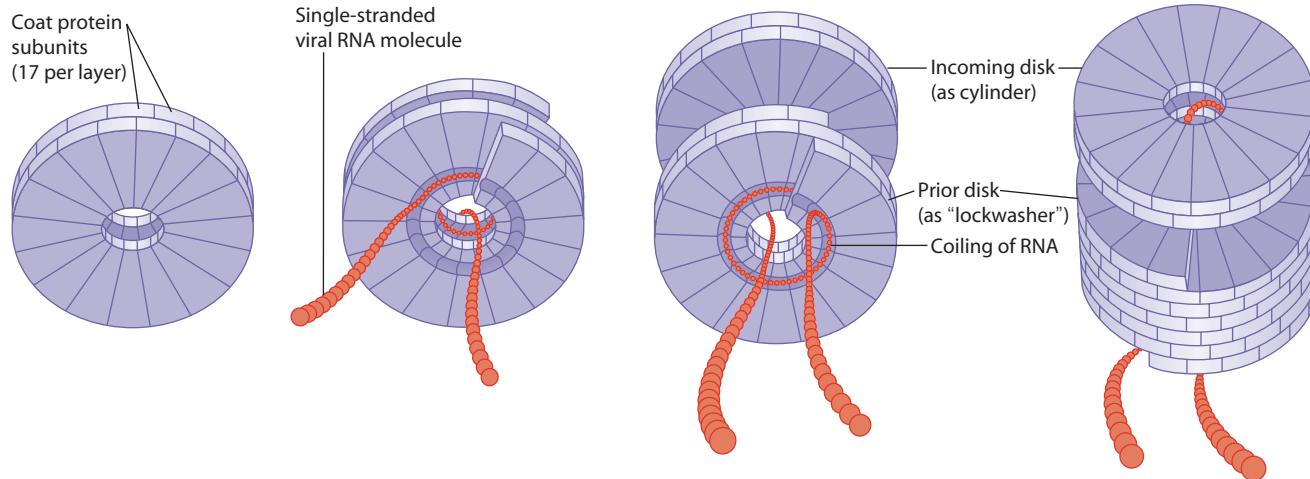

FIGURE 2-21 Spontaneous Self-Assembly of the Tobacco Mosaic Virus (TMV) Virion. Parts (a) through (d) show how the TMV virion will assemble spontaneously from a mixture of its coat protein and RNA constituents. All the information needed for proper assembly is contained in the proteins and RNA themselves, and no energy input is required.

VIDEOS www.thecellplace.com Tobacco mosaic virus (TMV), a self-assembling structure

Recently, scientists have begun exploiting the ability of viral particles to self-assemble in order to produce custom-made synthetic molecular complexes for use in nanotechnology and biomedicine. Individual coat protein molecules can be modified or engineered to have specific properties, such as electrical conductivity, then allowed to self-assemble into predictable structures. These self-assembling structures are being tested for use in a variety of applications including construction of nanometer-sized biosensors, drug delivery, and quantum computing.

Self-Assembly Has Limits

In many cases, the information required to specify the exact conformation of a cellular structure seems to lie entirely within the polymers that contribute to the structure. Such self-assembling systems achieve stable three-dimensional conformations without additional information input because the information content of the component polymers is adequate to specify the complete assembly process. Even in assisted self-assembly, the molecular chaperones that are involved provide no additional information.

However, there appear to be some assembly systems that depend, additionally, on information supplied by a preexisting structure. In such cases, the ultimate structure arises not by assembling the components into a new struc-

ture but rather by ordering the components into the matrix of an existing structure. Examples of cellular structures that are routinely built up by adding new material to existing structures include membranes, cell walls, and chromosomes.

On the other hand, such structures are not yet sufficiently characterized to determine whether the presence of a preexisting structure is obligatory or whether, under the right conditions, the components might be capable of self-assembly. Evidence from studies with artificial membranes and with chromatin (isolated chromosomal components), for example, suggests that a preexisting structure, though routinely present *in vivo*, may not be an indispensable requirement for the assembly process. Additional insight will be necessary before we can say with certainty whether, and to what extent, external information is required or exploited in cellular assembly processes.

Hierarchical Assembly Provides Advantages for the Cell

Each of the assembly processes we have examined exemplifies the basic cellular strategy of **hierarchical assembly** illustrated in Figure 2-14. Biological structures are almost always constructed hierarchically, with subassemblies acting as important intermediates en route from simple starting

Tempus Fugit and the Fine Art of Watchmaking

"Drat! Another defective watch!" With a look of disgust, Tempus Fugit the watchmaker tossed the faulty timepiece into the wastebasket and grumbled to himself, "That's two out of the last three watches I've had to throw away. What kind of a watchmaker am I, anyway?"

"A good question, Fugit," came a voice from the doorway. Tempus looked up to see Caveat Emptor entering the shop. "Maybe I can help you with it if you'll tell me a bit about how you make your watches."

"Nobody asked for your help, Emptor," growled Tempus testily, wishing fervently he hadn't been caught thinking out loud.

"Ah well, you'll get it just the same," continued Caveat, quite unperturbed. "Now tell me exactly how you make a watch and how long it takes you. I'd be especially interested in comparing your procedure with the way Pluribus Unum does it in his new shop down the street."

At the very mention of his competitor's name, Tempus groaned again. "Unum!" he blustered. "What does he know about the fine art of watchmaking?"

"A good deal, apparently—probably more than you do," replied Caveat. "But tell me exactly how you go about it. How many steps does it take you per watch, and how often do you make a mistake?"

"It takes exactly 100 operations to make a watch. Every step has to be done exactly right, or the watch won't work. It's tricky business, but I've got my error rate down to 1%," said Tempus with at least a trace of pride in his voice. "I can make a watch from start to finish in exactly one hour, but I only make 36 watches each week because I always take Tuesday afternoons off to play darts."

"Well now, let's see," said Caveat, as he pulled out a pocket calculator. "That means, my good Mr. Fugit, that you only make about 13 watches per week that actually work. All the rest you have to throw away just like the one you pitched as I entered your shop."

"How did you know that, you busybody?" Tempus asked defensively, wondering how this know-it-all with his calculator had guessed his carefully kept secret.

"Elementary, my dear Watson," returned Caveat gleefully. "Simple probability is all it takes. You told me that each watch requires 100 operations and that there's a 99% chance that you'll get a given step right. That's 0.99 times itself 100 times, which

comes out to 0.366. So only about 37% of your watches will be put together right, and you can't even tell anything about a given watch until it's finished and you test it. Want to know how that compares with Unum's shop?"

Tempus was about to protest, but his tormentor hurried on with scarcely a pause for breath. "He can manage 100 operations per hour, too, and his error rate is exactly the same as yours. He's also off every Tuesday afternoon, but he gets about 27 watches made every week. That's twice your output, Fugit! No wonder he's got so many watches in his window and so many customers at his door. I've heard that he's even thinking of expanding his shop. Want to know how he does it?"

Tempus was too depressed to even attempt a protest. And besides, although he wouldn't like to admit it, he really was dying to know how Unum managed it.

"*Subunit assembly, Fugit, that's the answer! Subunit assembly!* Instead of making each watch from scratch in 100 separate steps, Unum assembles the components into 10 pieces, each requiring 10 steps." Caveat began pushing calculator buttons again. "Let's see, he performs 10 operations with a 99% success rate for each, so I take 0.99 to the tenth power instead of the hundredth. That's 0.904, which means that about 90% of his subunits have no errors in them. So he spends about 33 hours each week making 330 subunits, throws the defective ones away, and still has about 300 to assemble into 30 watches during the last three hours on Friday afternoon. That takes 10 steps per watch, with the same error rate as before, so again he comes up with about 90% success. He has to throw away about 3 of his finished watches and ends up with about 27 watches to show for his efforts. Meanwhile, you've been working just as hard and just as accurately, yet you only make half as many watches. What do you have to say to that, my dear Fugit?"

Tempus managed a weary response. "Just one question, Emptor, and I'll probably hate myself for asking. But do you happen to know what Unum does on Tuesday afternoons?"

"I'm glad you asked," replied Caveat as he slipped his calculator back into his pocket and headed for the door. "But I don't think you'll be able to interest him in darts—he spends every Tuesday afternoon giving watchmaking lessons."

molecules to the end products of organelles, cells, and organisms. Consider how cellular structures are made. First, large numbers of similar, or even identical, monomeric sub-units are assembled by condensation into polymers. These polymers then aggregate spontaneously but specifically into characteristic multimeric units. The multimeric units can, in turn, give rise to still more complex structures and eventually to assemblies that are recognizable as distinctive sub-cellular structures.

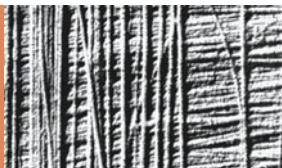

This hierarchical process has the double advantage of chemical simplicity and efficiency of assembly. To appreciate the chemical simplicity, we need only recognize that almost all structures found in cells and organisms are synthesized from about 30 small precursor molecules, which George Wald has called the "alphabet of biochemistry."

This alphabet includes the 20 amino acids that are found in proteins, the 5 aromatic bases present in nucleic acids, 2 sugars, and 3 lipid molecules. We will encounter each of these in Chapter 3 (see Table 3-1, page 42). Given these building blocks and the polymers that can be derived from them through just a few different kinds of condensation reactions, most of the structural complexity of life can be readily elaborated by hierarchical assembly into successively more complex structures.

The second advantage of hierarchical assembly lies in the "quality control" that can be exerted at each level of assembly, allowing defective components to be discarded at an early stage rather than being built into a more complex structure that would be more costly to reject and replace (see the story in **Box 2A**). Thus, if the

wrong subunit becomes inserted into a polymer at some critical point in the chain, that particular molecule may have to be discarded; but the cell will be spared the cost of synthesizing a more complicated supramolecular assembly or even an entire organelle before the defect is

discovered. As we proceed through this course, we will often see how cells have exquisite means for ensuring the proper structure and function of cellular components; we will also see how cells can recognize and replace components that are defective.

SUMMARY OF KEY POINTS

The Importance of Carbon

- The carbon atom has several properties that make it uniquely suited as the basis for life. Each atom forms four stable covalent bonds and can participate in single, double, or triple bonds with one or more other carbon atoms. This creates a wide variety of linear, branched, and ring-containing compounds.
- Carbon also readily bonds to several other types of atoms commonly found in cellular compounds, including hydrogen, oxygen, nitrogen, phosphorus, and sulfur. These elements are frequently found in functional groups attached to carbon skeletons—groups such as the hydroxyl, sulfhydryl, carboxyl, amino, phosphate, carbonyl, and aldehyde groups.

The Importance of Water

- The unique chemical properties of water help to make it the most abundant compound in cells. These properties include its cohesiveness, its high specific heat, its temperature-stabilizing capacity, and its ability to act as a solvent for most biological molecules.
- These chemical properties are a result of the polarity of the water molecule. Its polarity arises from the unequal sharing of electrons in the oxygen-hydrogen covalent bonds and its bent shape, causing the oxygen end of the atom to be slightly negative and the hydrogen atoms to be slightly positive.
- This polarity leads to extensive hydrogen bonding between water molecules, as well as between water and other polar molecules, rendering them soluble in aqueous solutions.

The Importance of Selectively Permeable Membranes

- All cells are surrounded by a defining cell membrane that is selectively permeable, controlling the flow of materials into and out of the cell.
- Biological membranes have a phospholipid bilayer structure with a hydrophobic interior that blocks the direct passage of large polar molecules, charged molecules, and ions.
- However, large polar and charged molecules and ions can cross membranes via membrane-spanning transport proteins

that form hydrophilic channels to allow passage of specific molecules.

The Importance of Synthesis by Polymerization

- The molecular building blocks of the cell are small organic molecules put together by stepwise polymerization to form the macromolecules so important to cellular structure and function. Relatively few kinds of monomeric units comprise most of the polysaccharide, protein, and nucleic acid polymers in cells.
- Polymerization of monomers requires that they first be activated, usually at the expense of ATP. Monomers are then linked together by removal of water in condensation reactions. Polymers are degraded by the reverse reaction—hydrolysis.
- Because they are added to only one specific end of these macromolecules, all biological polymers have directionality.

The Importance of Self-Assembly

- While energy input is required for polymerization of monomers into macromolecules, most macromolecules fold into their final three-dimensional conformations spontaneously. The information needed for this folding is inherent in the chemical nature of the monomeric units and the order in which the monomers are put together.
- For example, the unique three-dimensional conformation of a protein forms by spontaneous folding of the linear polypeptide chain, and this conformation depends only on the specific order of amino acids in the protein. The final structure is the result of several covalent and noncovalent interactions, including disulfide bonding, hydrogen bonding, ionic bonding, van der Waals interactions, and hydrophobic interactions.
- Individual polymers can interact with each other in a unique and predictable manner to generate successively more complex structures. This hierarchical assembly process has the dual advantages of chemical simplicity and efficiency of assembly. It also allows quality control at multiple steps to ensure proper production of cell components.

MAKING CONNECTIONS

Now that we've reviewed some basic chemistry, you may ask: Where will we use chemistry in our upcoming study of cell biology? The simple one-word answer: everywhere. In the next chapter we will study macromolecules in more detail and see how chemical interactions determine their structure and function. What do the hundreds of enzymes in a cell do? They carry out the chemical reactions that are necessary for life. When we study the bioenergetics of respiration, fermentation, and photosynthesis, what will help us to understand these processes? Chemistry. Similarly,

when we learn about cell-to-cell communication and nervous system function, the cytoskeleton and its role in cell movement, and how hormones regulate gene activity, what underlies the workings of these processes? Chemistry. And, later in the course, when we study cell reproduction, nucleic acid and protein synthesis, and how normal cell cycle control is altered in cancer cells, what will help us understand these important aspects of cell biology? You guessed it—chemistry!

PROBLEM SET

More challenging problems are marked with a •.

2-1 The Fitness of Carbon. Each of the properties that follow is characteristic of the carbon atom. In each case, indicate how the property contributes to the role of the carbon atom as the most important atom in biological molecules.

- (a) The carbon atom has a valence of four.
- (b) The carbon-carbon bond has a bond energy that is above the energy of photons of light in the visible range (400–700 nm).
- (c) A carbon atom can bond simultaneously to two other carbon atoms.
- (d) Carbon atoms can bond readily to hydrogen, nitrogen, and sulfur atoms.
- (e) Carbon-containing compounds can contain asymmetric carbon atoms.

2-2 The Fitness of Water. For each of these statements about water, decide whether the statement is true and describes a property that makes water a desirable component of cells (T); is true but describes a property that has no bearing on water as a cellular constituent (X); or is false (F). For each true statement, indicate a possible benefit to living organisms.

- (a) Water is a polar molecule and hence an excellent solvent for polar compounds.
- (b) Water can be formed by the reduction of molecular oxygen (O_2).
- (c) The density of water is less than the density of ice.
- (d) The molecules of liquid water are extensively hydrogen-bonded to one another.
- (e) Water does not absorb visible light.
- (f) Water is odorless and tasteless.
- (g) Water has a high specific heat.
- (h) Water has a high heat of vaporization.

2-3 Wrong Again. For each of the following false statements, change the statement to make it true.

- (a) Hydrogen, nitrogen, and carbon are the elements that most readily form strong multiple bonds.
- (b) Water has a higher specific heat than most other liquids because of its low molecular weight.

- (c) Oil droplets in water coalesce to form a separate phase because of the strong attraction of hydrophobic molecules for each other.
- (d) In a hydrogen bond, electrons are shared between a hydrogen atom and two neighboring electronegative atoms.
- (e) Biological membranes are called selectively permeable because large polar molecules and ions can never pass through them.

2-4 Solubility in Benzene. Consider the chemical structure of benzene that is shown in Figure 2-4. Which cellular molecules would you expect to be soluble in a container of benzene?

2-5 Drug Targeting. Your company has developed a new anti-cancer drug, but it will not cross through the membrane of target cells because it is large and contains many polar functional groups. Can you design a strategy to get this new drug into the cancer cells?

2-6 It's All About Membranes. Answer each of the following questions about biological membranes in 50 words or less:

- (a) What is an amphipathic molecule? Why are amphipathic molecules important constituents of membranes?
- (b) Why do membranes consist of lipid bilayers rather than lipid monolayers?
- (c) What does it mean to say that a membrane is selectively permeable?
- (d) If a lipid bilayer is at least 10^8 times less permeable to K^+ ions than it is to water, how do the K^+ ions that are needed for many cellular functions get into the cell?
- (e) It is often possible to predict the number of times a membrane protein crosses the membrane by determining how many short sequences of hydrophobic amino acids are present in the amino acid sequence of the protein. Explain.
- (f) Why are the several carbohydrate side chains attached to hydrophilic rather than hydrophobic regions of the membrane protein shown in Figure 2-13b?

2-7 The Polarity of Water. Defend the assertion that all of life as we know it depends critically on the fact that the angle between the two hydrogen atoms in the water molecule is 104.5° and not 180° .

- 2-8 The Principle of Polymers.** Polymers clearly play an important role in the molecular economy of the cell. What advantage does each of the following features of biological polymers have for the cell?
- (a) A particular kind of polymer is formed using the same kind of condensation reaction to add each successive monomeric unit to the growing polymer.
 - (b) The bonds between monomers are formed by the removal of water and are broken or cleaved by the addition of water.

• 2-9 TMV Assembly. Each of these statements is an experimental observation concerning the reassembly of tobacco mosaic virus (TMV) virions from TMV RNA and coat protein subunits. In each case, carefully state a reasonable conclusion that can be drawn from the experimental finding.

- (a) When RNA from a specific strain of TMV is mixed with coat protein from the same strain, infectious virions are formed.
- (b) When RNA from strain A of TMV is mixed with coat protein from strain B, the reassembled virions are

infectious, giving rise to strain A virus particles in the infected tobacco cells.

- (c) Isolated coat protein monomers can polymerize into a viruslike helix in the absence of RNA.
- (d) In infected plant cells, the TMV virions that form contain only TMV RNA and never any of the various kinds of cellular RNAs present in the host cell.
- (e) Regardless of the ratio of RNA to coat protein in the starting mixture, the reassembled virions always contain RNA and coat protein in the ratio of three nucleotides of RNA per coat protein monomer.

The Macromolecules of the Cell

In Chapter 2, we looked at some of the basic chemical principles of cellular organization. We saw that each of the major kinds of biological macromolecules—proteins, nucleic acids, and polysaccharides—consists of a relatively small number (from 1 to 20) of repeating monomeric units. These polymers are synthesized by condensation reactions in which activated monomers are linked together by the removal of water. Once synthesized, the individual polymer molecules fold and coil spontaneously into stable, three-dimensional shapes. These folded molecules then associate with one another in a hierarchical manner to generate higher levels of structural complexity, usually without further input of energy or information.

We are now ready to examine the major kinds of biological macromolecules. In each case, we will focus first on the chemical nature of the monomeric components and then on the synthesis and properties of the polymer itself. As we will see shortly, most biological macromolecules in cells are synthesized from about 30 common small molecules. We begin our survey with proteins because they play such important and widespread roles in cellular structure and function. We then move on to nucleic acids and polysaccharides. The tour concludes with lipids, which do not quite fit the definition of a polymer but are important cellular components whose synthesis resembles that of true polymers.

Proteins

Proteins are a class of extremely important and ubiquitous macromolecules in all organisms, occurring nearly everywhere in the cell. In fact, their importance is implied by their name, which comes from the Greek word *proteios*, meaning “first place.” Whether we are talking about conversion of carbon dioxide to sugar in photosynthesis, oxygen transport in the blood, the regulation of gene expression by transcription factors, cell-to-cell communication, or the motility of a flagellated bacterium, we are dealing with

processes that depend crucially on particular proteins with specific properties and functions.

Based on function, proteins fall into nine major classes. Many proteins are *enzymes*, serving as catalysts that greatly increase the rates of the thousands of chemical reactions on which life depends. *Structural proteins*, on the other hand, provide physical support and shape to cells and organelles, giving them their characteristic appearances. *Motility proteins* play key roles in the contraction and movement of cells and intracellular structures. *Regulatory proteins* are responsible for control and coordination of cellular functions, ensuring that cellular activities are regulated to meet cellular needs. *Transport proteins* are involved in the movement of other substances into, out of, and within the cell. *Hormonal proteins* mediate communication between cells in distant parts of an organism, and *receptor proteins* enable cells to respond to chemical stimuli from their environment. Finally, *defensive proteins* provide protection against disease, and *storage proteins* serve as reservoirs of amino acids.

Because virtually everything that a cell is or does depends on the proteins it contains, it is clear we need to understand what proteins are and why they have the properties they do. We begin our discussion by looking at the amino acids present in the proteins, and then we will consider some properties of proteins themselves.

The Monomers Are Amino Acids

Proteins are linear polymers of **amino acids**. Although more than 60 different kinds of amino acids are typically present in a cell, only 20 kinds are used in protein synthesis, as indicated in **Table 3-1**. Some proteins contain more than 20 different kinds of amino acids, but the additional ones usually are a result of modifications that occur after the protein has been synthesized. Although most proteins contain all or most of the 20 amino acids, the

Source: Adapted from Wald (1994).

proportions vary greatly, and no two different proteins have the same amino acid sequence.

Every amino acid has the basic structure illustrated in **Figure 3-1**, with a carboxyl group, an amino group, a hydrogen atom, and a side chain known as an R group. All are attached to a central carbon atom known as the *α carbon*. Except for glycine, for which the R group is just a hydrogen atom, all amino acids have an asymmetric α carbon atom and therefore exist in two stereoisomeric forms, called L- and D-amino acids (see Figures 2-6 and 2-7). Both kinds exist in nature, but only L-amino acids occur in proteins.

Because the carboxyl and amino groups shown in Figure 3-1 are common features of all amino acids, the specific properties of the various amino acids vary depending on the chemical nature of their R groups, which range from a single hydrogen atom to relatively complex aromatic groups. Shown in **Figure 3-2** are the structures of the 20 L-amino acids found in proteins. The three-letter abbreviations given in parentheses for each amino acid are widely used by biochemists and molecular biologists. **Table 3-2** lists these three-letter abbreviations and the corresponding one-letter abbreviations that are also commonly used.

Nine of these amino acids have nonpolar, *hydrophobic* R groups (Group A). As you look at their structures, you will notice the hydrocarbon nature of the R groups, with few or no oxygen and nitrogen atoms. These hydrophobic amino acids are usually found in the interior of the molecule as a polypeptide folds into its three-dimensional shape. If a protein (or a region of the molecule) has a preponderance of hydrophobic amino acids, the whole protein (or the hydrophobic portion of the molecule) will be excluded from aqueous environments and will instead be found in hydrophobic locations, such as the interior of a membrane.

The remaining 11 amino acids have *hydrophilic* R groups that are either distinctly polar (Group B) or actually charged at the pH values characteristic of cells (Group C). Notice that the two acidic amino acids are negatively charged, and the three basic amino acids are positively charged. Hydrophilic amino acids tend to occur on the

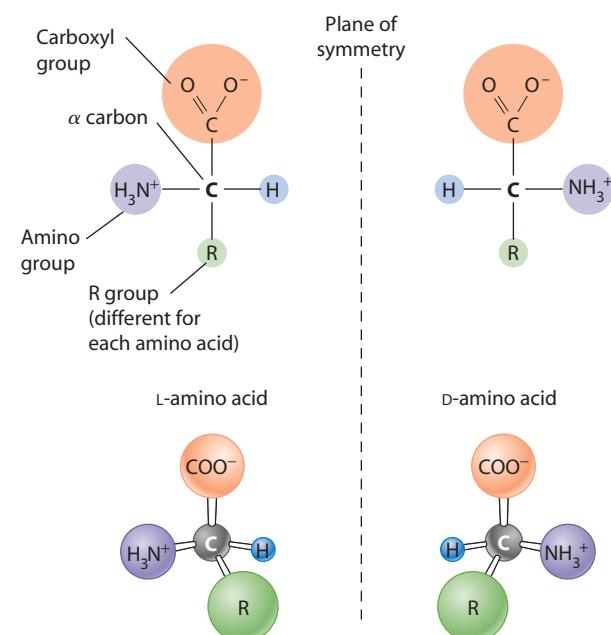

FIGURE 3-1 The Structure and Stereochemistry of an Amino Acid. Because the central carbon atom is asymmetric in all amino acids except glycine, most amino acids can exist in two isomeric forms, designated L and D and shown here as (top) conventional structural formulas and (bottom) ball-and-stick models. The L and D forms are stereoisomers, with the vertical dashed line as the plane of symmetry. Of the two forms, only L-amino acids are present in proteins.

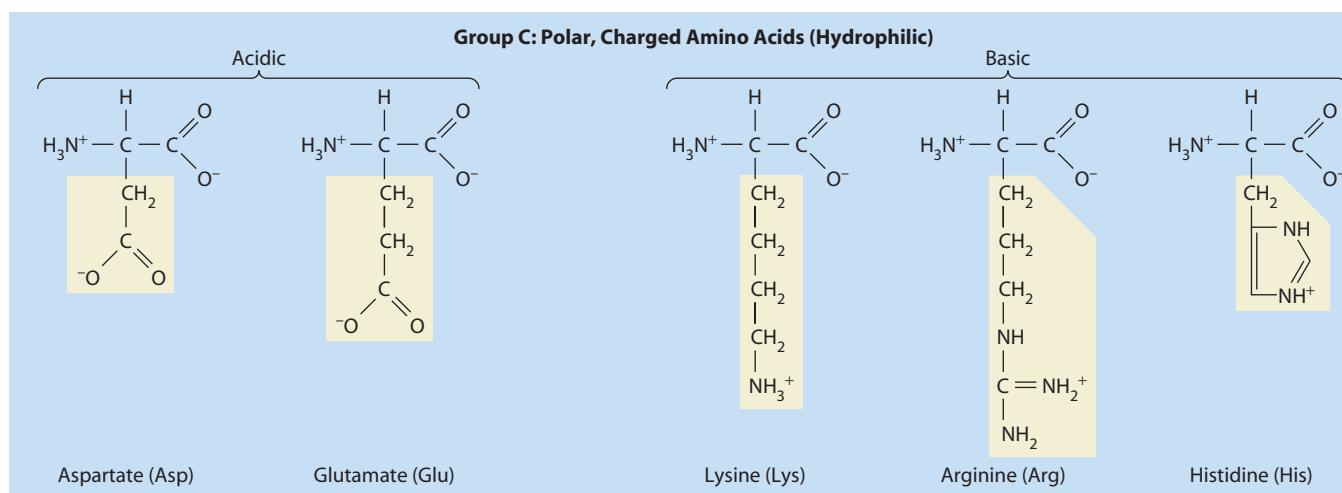

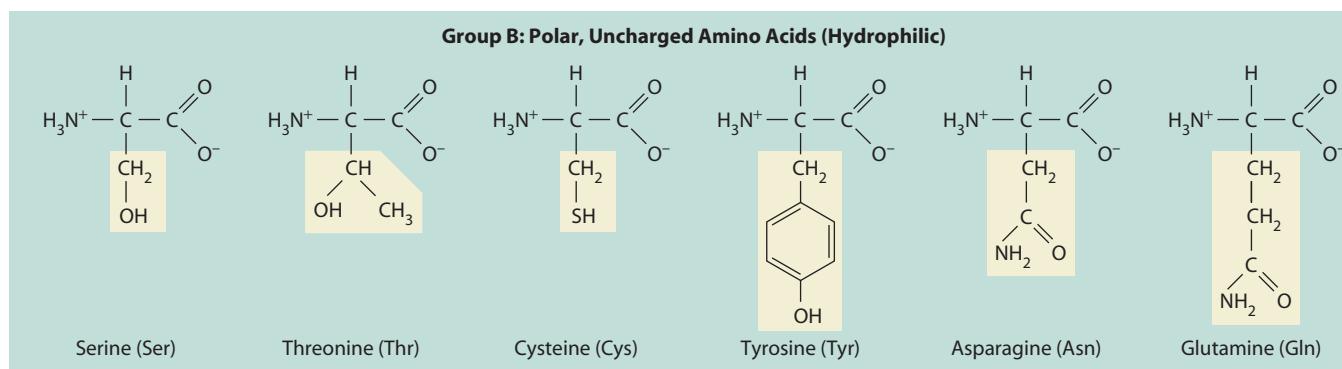

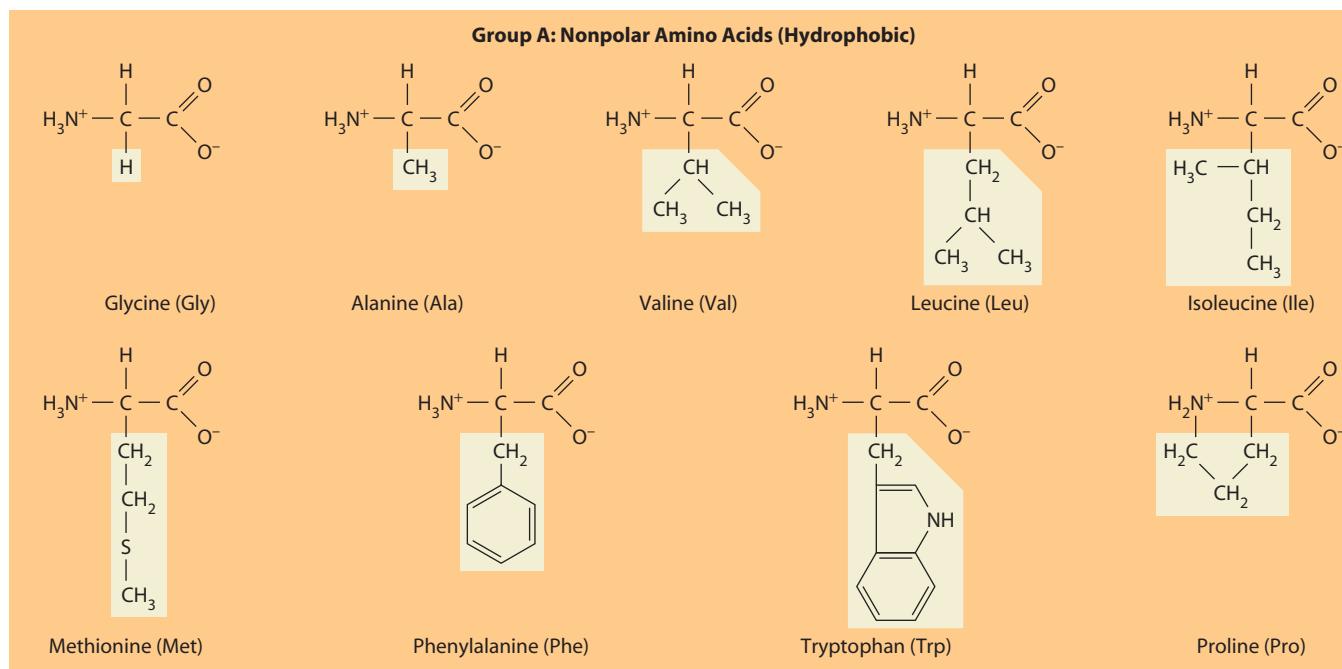

FIGURE 3-2 The Structures of the 20 Amino Acids Found in Proteins. All amino acids have a carboxyl group and an amino group attached to the central (α) carbon, but each has its own distinctive R group (light boxes). Those in Group A have nonpolar R groups and are therefore hydrophobic; notice the hydrocarbon nature of their R groups. The others are hydrophilic, either because the R group is polar (Group B) or because the R group is protonated or deprotonated at cellular pH and thus carries a formal electrostatic charge (Group C). Notice the unusual structure of proline—its R group is covalently linked to the amino nitrogen.

Table 3-2

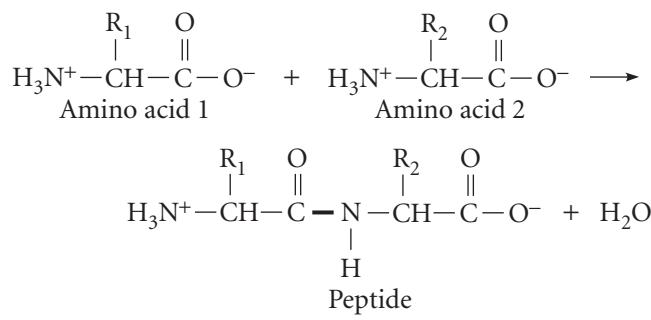

Abbreviations for Amino Acids

Amino Acid	Three-Letter Abbreviation	One-Letter Abbreviation
Alanine	Ala	A
Arginine	Arg	R
Asparagine	Asn	N
Aspartate	Asp	D
Cysteine	Cys	C
Glutamate	Glu	E
Glutamine	Gln	Q
Glycine	Gly	G
Histidine	His	H

Threonine	Thr	T
Tryptophan	Trp	W
Tyrosine	Tyr	Y
Valine	Val	V

surface of proteins, thereby maximizing their interactions with water molecules and other polar or charged substances in the surrounding environment.

The Polymers Are Polypeptides and Proteins

The process of stringing individual amino acids together into a linear polymer involves the stepwise addition of each new amino acid to the growing chain by a *dehydration* (or *condensation*) reaction (see Figure 2-17). As the three atoms comprising H₂O are removed, the carboxyl carbon of one amino acid and the amino nitrogen of a second are linked directly. This covalent C—N bond linking two amino acids is known as a **peptide bond**, shown below in bold:

As each new peptide bond is formed by dehydration, the growing chain of amino acids is lengthened by one amino acid. Peptide bond formation is illustrated schematically in **Figure 3-3** using ball-and-stick models

of the amino acids glycine and alanine. Because of electron delocalization between the peptide bond and the adjacent carbon-oxygen bond, peptide bonds have partial double-bond character, and thus the six nearest atoms are nearly planar (shaded rectangle in Figure 3-3).

Notice that the chain of amino acids formed in this way has an intrinsic *directionality* because it always has an amino group at one end and a carboxyl group at the other end. The end with the amino group is called the **N- (or amino) terminus**, and the end with the carboxyl group is called the **C- (or carboxyl) terminus**.

Although this process of elongating a chain of amino acids is often called *protein synthesis*, the term is not entirely accurate because the immediate product of amino acid polymerization is not a protein but a **polypeptide**. A protein is a polypeptide chain (or a complex of several polypeptides) that has attained a unique, stable, three-dimensional shape and is biologically active as a result. Some proteins consist of a single polypeptide, and their final shape is due to the folding and coiling that occur spontaneously as the chain is being formed (see Figure 2-18b). Such proteins are called **monomeric proteins**. Many other proteins are **multimeric proteins**, consisting of two or more polypeptides that are often called polypeptide subunits.

Be careful with the terminology, though: On the one hand, a polypeptide is a *polymer*, with amino acids as its monomeric repeating units; on the other hand, the entire polypeptide may sometimes be a *monomer* unit that is part of a multimeric protein. If a multimeric protein is composed of two polypeptides, it is referred to as a *dimer*; and if it has three polypeptides, it is known as a *trimer*. The hemoglobin that carries oxygen in your bloodstream is a multimeric protein known as a *tetramer* because it contains four polypeptides, two each of two different types known as the α and the β *subunits* (**Figure 3-4**). In the case of multimeric proteins, protein synthesis involves not only elongation and folding of the individual polypeptide subunits but also their subsequent interaction and assembly into the multimeric protein.

Several Kinds of Bonds and Interactions Are Important in Protein Folding and Stability

As we noted in Chapter 2, the initial folding of a polypeptide into its proper shape, or **conformation**, depends on several different kinds of bonds and interactions, including the covalent disulfide bond and several noncovalent interactions. In addition, the association of individual polypeptides to form a multimeric protein relies on these same bonds and interactions, which are depicted in **Figure 3-5**. These interactions involve the carboxyl, amino, and R groups of the individual amino acids, which are known as *amino acid residues* once they are incorporated into the polypeptide.

Disulfide Bonds. A special type of covalent bond that contributes to the stabilization of protein conformation is the **disulfide bond**, which forms between the sulfur atoms of two cysteine amino acid residues. These become

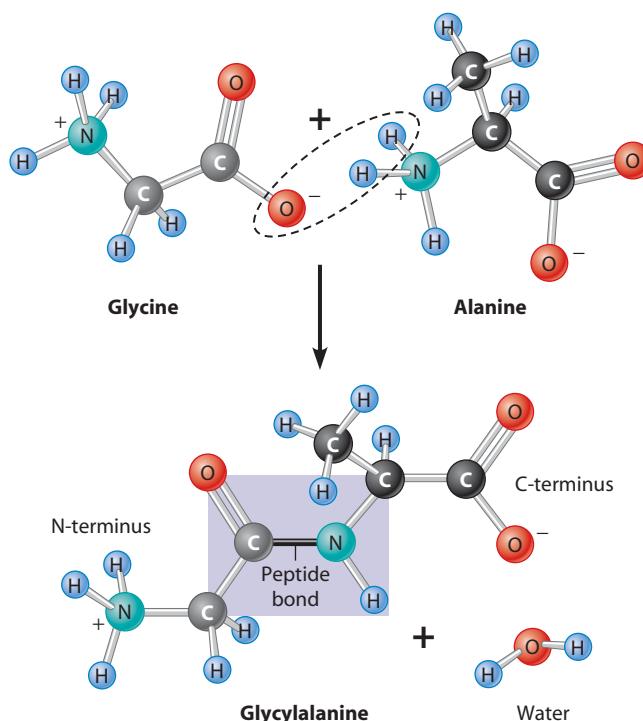

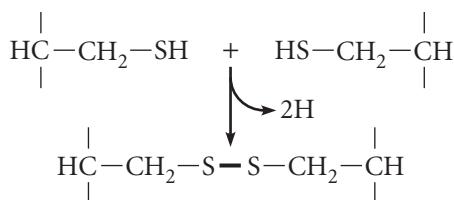

FIGURE 3-3 Peptide Bond Formation. Successive amino acids in a polypeptide are linked to one another by peptide bonds that are formed between the carboxyl group of one amino acid and the amino group of the next as a water molecule is removed (dotted oval). Shown here is the formation of a peptide bond between the amino acids glycine and alanine. The six atoms in the shaded rectangle are nearly planar.

covalently linked following an oxidation reaction that removes the two hydrogen atoms from the sulfhydryl groups of the two cysteines, forming a disulfide bond, shown below in bold and in Figure 3-5a:

Once formed, a disulfide bond confers considerable stability to the structure of the protein because of its covalent nature. It can be broken only by reducing it again—by adding two hydrogen atoms and regenerating the two sulfhydryl groups in the reverse of the reaction above. In many cases, the cysteine residues involved in a particular disulfide bond are a part of the same polypeptide. They may be quite distant from each other along the polypeptide but are brought close together by the folding process. Such *intramolecular disulfide bonds* stabilize the conformation of the polypeptide. In the case of multimeric proteins, a disulfide bond may form between cysteine residues located in two different polypeptides. Such *intermolecular disulfide bonds* link the two polypeptides to one another covalently. The hormone insulin is a dimeric protein that has its two subunits linked in this manner.

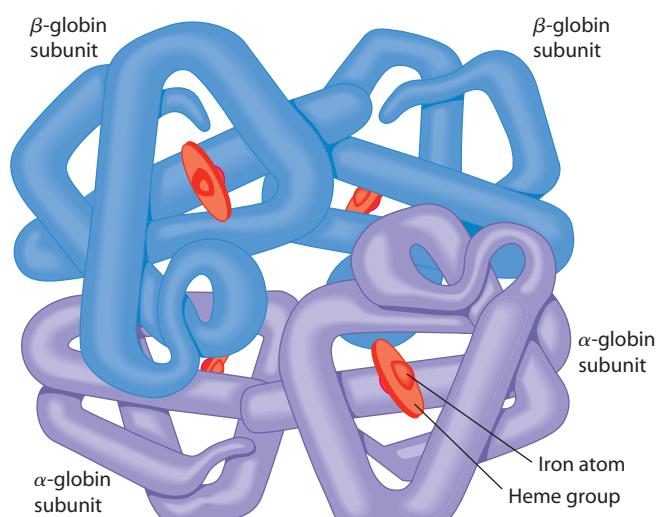

FIGURE 3-4 The Structure of Hemoglobin. Hemoglobin is a multimeric protein composed of four polypeptide subunits (two α chains and two β chains). Each subunit contains a heme group with an iron atom that can bind a single oxygen molecule.

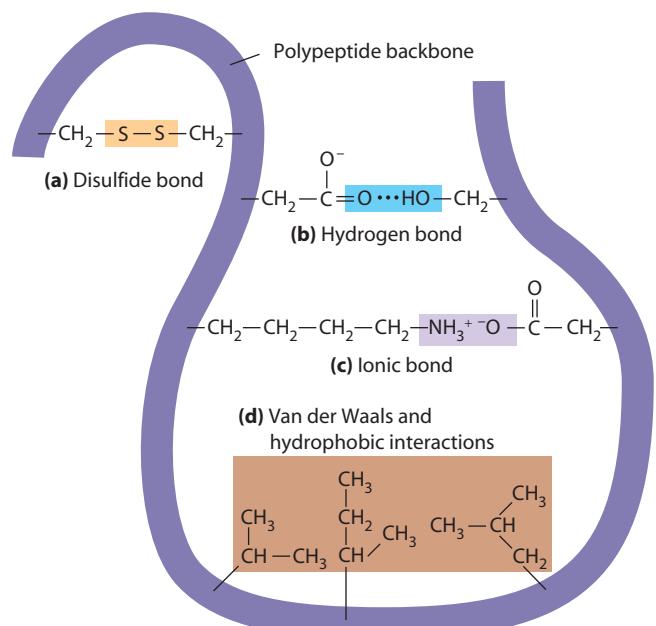

FIGURE 3-5 Bonds and Interactions Involved in Protein Folding and Stability. The initial folding and subsequent stability of a polypeptide depend on (a) covalent disulfide bonds as well as on several kinds of noncovalent bonds and interactions, including (b) hydrogen bonds, (c) ionic bonds, (d) van der Waals interactions, and hydrophobic interactions.

In addition to covalent disulfide bonds, **noncovalent bonds and interactions** are also important in maintaining protein structure. Although individually much weaker than covalent bonds, they are diverse and numerous and collectively exert a powerful influence on protein structure and stability. As we noted briefly in Chapter 2, these include *hydrogen bonds*, *ionic bonds*, *van der Waals interactions*, and *hydrophobic interactions* (see Figure 3-5).

Hydrogen Bonds. Hydrogen bonds are familiar from our discussion of the properties of water in Chapter 2. In water, a hydrogen bond forms between a covalently bonded hydrogen atom on one water molecule and an oxygen atom on another molecule (see Figure 2-8b). In polypeptides, hydrogen bonding is particularly important in stabilizing helical and sheet structures that are prominent parts of many proteins, as we will soon see. In addition, the R groups of many amino acids have functional groups that are able to participate in hydrogen bonding. This allows hydrogen bonds to form between amino acid residues that may be distant from one another along the amino acid sequence but are brought into close proximity by the folding of the polypeptide (Figure 3-5b).

Hydrogen bond *donors* have a hydrogen atom that is covalently linked to a more electronegative atom, such as oxygen or nitrogen, and hydrogen bond *acceptors* have an electronegative atom that attracts this hydrogen atom. Examples of good donors include the hydroxyl groups of several amino acids and the amino groups of others. The carbonyl and sulfhydryl groups of several other amino acids are examples of good acceptors. An individual hydrogen bond is quite weak (about 2–5 kcal/mol, compared to 70–100 kcal/mol for covalent bonds). But because hydrogen bonds are abundant in biological macromolecules such as proteins and DNA, they become a formidable force when present in large numbers.

Ionic Bonds. The role of **ionic bonds** (or *electrostatic interactions*) in protein structure is easy to understand. Because the R groups of some amino acids are positively charged and the R groups of others are negatively charged, polypeptide folding is dictated in part by the tendency of charged groups to repel groups with the same charge and to attract groups with the opposite charge (Figure 3-5c). Several features of ionic bonds are particularly significant. The strength of such interactions—about 3 kcal/mol—allows them to exert an attractive force over greater distances than some of the other noncovalent interactions. Moreover, the attractive force is nondirectional, so that ionic bonds are not limited to discrete angles, as is the case with covalent bonds. Because ionic bonds depend on both groups remaining charged, they will be disrupted if the pH value becomes so high or so low that either of the groups loses its charge. This loss of ionic bonds accounts in part for the denaturation that most proteins undergo at high or low pH.

Van der Waals Interactions. Interactions based on charge are not limited to ions that carry a discrete charge. Even molecules with nonpolar covalent bonds may have transient positively and negatively charged regions. Momentary asymmetries in the distribution of electrons and hence in the separation of charge within a molecule are called *dipoles*. When two molecules that have such transient dipoles are very close to each other and are oriented appropriately, they are attracted to each other, though for only as long as the asymmetric electron distribution persists in both molecules.

This transient attraction of two nonpolar molecules is called a **van der Waals interaction**, or *van der Waals force* (Figure 3-5d). A single such interaction is transient and very weak—typically 0.1–0.2 kcal/mol—and is effective only when the two molecules are quite close together—within 0.2 nm of each other, in fact. Van der Waals interactions are nonetheless important in the structure of proteins and other biological macromolecules, as well as in the binding together of two molecules with complementary surfaces that fit closely together.

Hydrophobic Interactions. The fourth type of noncovalent interaction that plays a role in maintaining protein conformation is usually called a **hydrophobic interaction**, but it is not really a bond or interaction at all. Rather, it is the tendency of hydrophobic molecules or parts of molecules to be excluded from interactions with water (Figure 3-5d). As already noted, the side chains of the 20 different amino acids vary greatly in their affinity for water. Amino acids with hydrophilic R groups tend to be located near the surface of a folded polypeptide, where they can interact maximally with the surrounding water molecules. In contrast, amino acids with hydrophobic R groups are essentially nonpolar and are usually located on the inside of the polypeptide, where they interact with one another because they are excluded by water.

Thus, polypeptide folding to form the final protein structure is, in part, a balance between the tendency of hydrophilic groups to seek an aqueous environment near the surface of the molecule and the tendency of hydrophobic groups to minimize contact with water by associating with each other in the interior of the molecule. If most of the amino acids in a protein were hydrophobic, the protein would be virtually insoluble in water and would be found instead in a nonpolar environment. Membrane proteins, which have many hydrophobic residues, are localized in membranes for this very reason. Similarly, if all or most of the amino acids were hydrophilic, the polypeptide would most likely remain in a fairly distended, random shape, allowing maximum access of each amino acid to an aqueous environment. But precisely because most polypeptide chains contain both hydrophobic and hydrophilic amino acids, hydrophilic regions of the molecule are drawn toward the surface, whereas hydrophobic regions are driven toward the interior (see Figure 2-19).

Overall, then, the stability of the folded structure of a polypeptide depends on an interplay of covalent disulfide bonds and four noncovalent factors: hydrogen bonds between R groups that are good donors and good acceptors, ionic bonds between charged amino acid R groups, transient van der Waals interactions between nonpolar molecules in very close proximity, and hydrophobic interactions that drive nonpolar groups to the interior of the molecule.

The final conformation of the fully folded polypeptide is the net result of these forces and tendencies. Individually, each of these noncovalent interactions is quite low in energy. However, the cumulative effect of many of them—

Table 3-3 Levels of Organization of Protein Structure

Level of Structure	Basis of Structure	Kinds of Bonds and Interactions Involved
Primary	Amino acid sequence	Covalent peptide bonds
Secondary	Folding into α helix, β sheet, or random coil	Hydrogen bonds
Tertiary	Three-dimensional folding of a single polypeptide chain	Disulfide bonds, hydrogen bonds, ionic bonds, van der Waals interactions, hydrophobic interactions
Quaternary	Association of multiple polypeptides to form a multimeric protein	Same as for tertiary structure

involving the side groups of the hundreds of amino acids that make up a typical polypeptide—greatly stabilizes the conformation of the folded polypeptide.

Protein Structure Depends on Amino Acid Sequence and Interactions

The overall shape and structure of a protein are usually described in terms of four hierarchical levels of organization, each building on the previous one: the *primary*, *secondary*, *tertiary*, and *quaternary* structures (Table 3-3). Primary structure refers to the amino acid sequence, while the higher levels of organization concern the interactions between the amino acid residues. These interactions give the protein its characteristic *conformation*, or three-dimensional arrangement of atoms in space (Figure 3-6).

Secondary structure involves local interactions between amino acid residues that are close together along the chain,

whereas tertiary structure results from long-distance interactions between stretches of amino acid residues from different parts of the molecule. Quaternary structure concerns the interaction of two or more individual polypeptides to form a single multimeric protein. All three of these higher-level structures are dictated by the primary structure, but each is important in its own right in the overall structure of the protein. Secondary and tertiary structures are involved in determining the conformation of the individual polypeptide, while quaternary structure is relevant for proteins consisting of more than one polypeptide.

Primary Structure. As already noted, the **primary structure** of a protein is a formal designation for the amino acid sequence (Figure 3-6a). When we describe the primary structure, we are simply specifying the order in which its amino acids appear from one end of the molecule to the other. By convention, amino acid sequences are

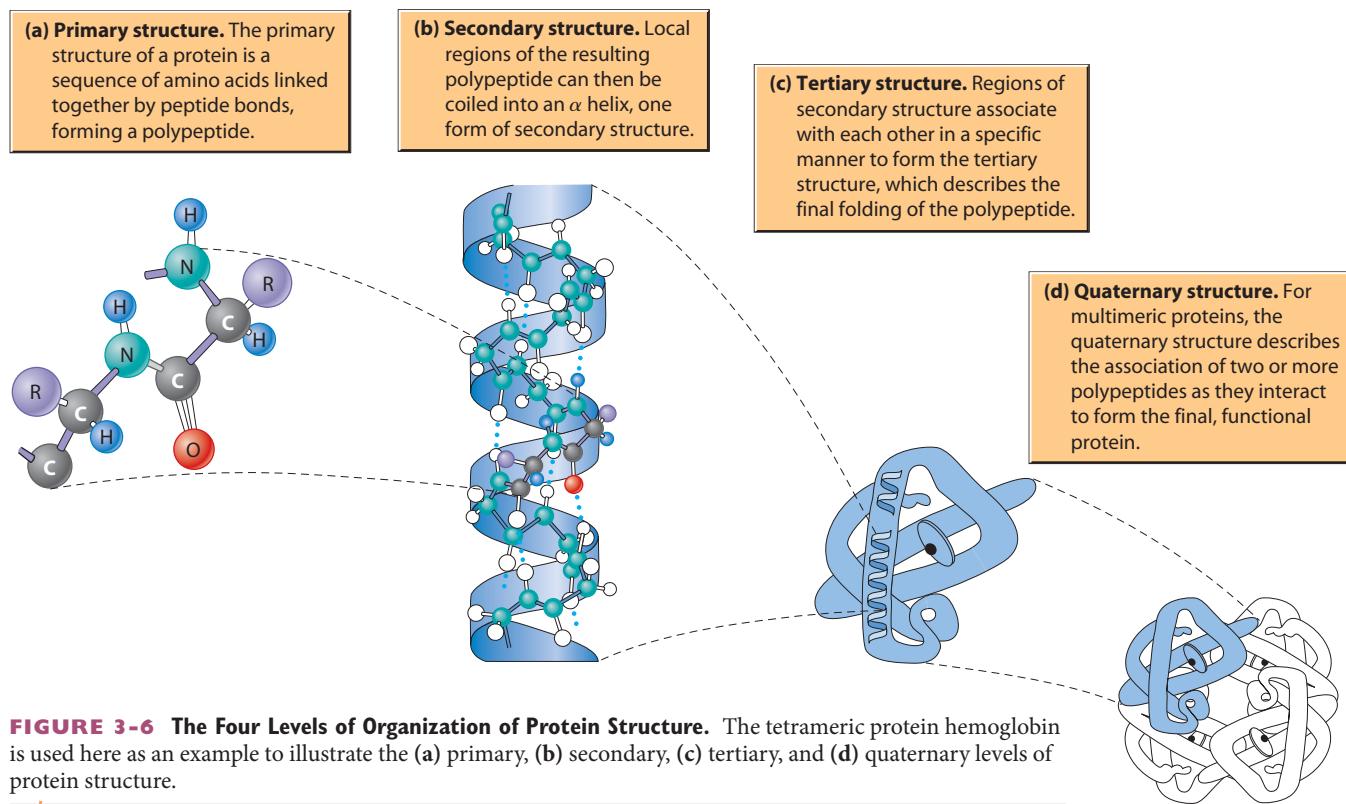

FIGURE 3-6 The Four Levels of Organization of Protein Structure. The tetrameric protein hemoglobin is used here as an example to illustrate the (a) primary, (b) secondary, (c) tertiary, and (d) quaternary levels of protein structure.

ACTIVITIES www.thecellplace.com Protein structure

always written from the N-terminus to the C-terminus of the polypeptide, which is also the direction in which the polypeptide is synthesized.

The first protein to have its complete amino acid sequence determined was the hormone *insulin*. This important technical advance was reported in 1956 by Frederick Sanger, who eventually received a Nobel Prize for the work. To determine the sequence of the insulin molecule, Sanger cleaved it into smaller fragments and analyzed the amino acid order within individual, overlapping fragments. Insulin consists of two polypeptides, called the *A subunit* and the *B subunit*, with 21 and 30 amino acid residues, respectively. **Figure 3-7** shows the primary structure of insulin, illustrating the primary sequence of each subunit in sequence from its N-terminus (left) to its C-terminus (right). Notice also the covalent disulfide ($-S-S-$) bond between two cysteine residues within the A chain and the two disulfide bonds linking the A and B chains. As we will see shortly, disulfide bonds play an important role in stabilizing the tertiary structure of many proteins.

Sanger's techniques paved the way for the sequencing of hundreds of other proteins and led ultimately to the design of machines that can determine an amino acid sequence automatically. A more recent approach for determining protein sequences has emerged from the understanding that nucleotide sequences in DNA code for the amino acid sequences of protein molecules. It is now much easier to determine a DNA nucleotide sequence than to purify a protein and analyze its amino acid sequence. Once a DNA nucleotide sequence has been determined, the amino acid sequence of the polypeptide encoded by that DNA segment can be easily determined. Computerized data banks are now available that contain thousands of polypeptide sequences, making it easy to compare sequences and look for regions of similarity between polypeptides.

The primary structure of a protein is important both genetically and structurally. Genetically, it is significant because the amino acid sequence of the polypeptide is determined by the order of nucleotides in the corresponding messenger RNA. The messenger RNA is in turn encoded by the DNA that represents the gene for this protein, so the primary structure of a protein is the result of the order of nucleotides in the DNA of the gene.

Of more immediate significance are the implications of the primary structure for higher levels of protein structure.

In essence, all three higher levels of protein organization are direct consequences of the primary structure. Thus, if synthetic polypeptides are made that correspond in sequence to the α and β subunits of hemoglobin, they will assume the native three-dimensional conformations of these subunits and will then interact spontaneously to form the native $\alpha_2\beta_2$ tetramer that we recognize as hemoglobin (see Figure 3-4).

Secondary Structure. The **secondary structure** of a protein describes local regions of structure that result from hydrogen bonding between NH and CO groups along the polypeptide backbone. These local interactions result in two major structural patterns, referred to as the **α helix** and **β sheet** conformations (Figure 3-8).

The α helix structure was proposed in 1951 by Linus Pauling and Robert Corey. As shown in Figure 3-8a, an α helix is spiral in shape, consisting of a backbone of amino acids linked by peptide bonds with the specific R groups of the individual amino acid residues jutting out from it. A helical shape is common to repeating polymers, as we will see when we get to the nucleic acids and the polysaccharides. In the α helix there are 3.6 amino acids per turn, bringing the peptide bonds of every fourth amino acid in close proximity. The distance between these peptide bonds is, in fact, just right for the formation of a hydrogen bond between the NH group adjacent to one peptide bond and the CO group adjacent to the other, as shown in Figure 3-8a.

As a result, every peptide bond in the helix is hydrogen-bonded through its CO group to the peptide bond immediately “below” it in the spiral and through its NH group to the peptide bond just “above” it, even though the amino acid residues involved are not directly adjacent. These hydrogen bonds are all nearly parallel to the main axis of the helix and therefore tend to stabilize the spiral structure by holding successive turns of the helix together.

Another form of common secondary structure in proteins is the β sheet, also initially proposed by Pauling and Corey. As shown in Figure 3-8b, this structure is an extended sheetlike conformation with successive atoms in the polypeptide chain located at the “peaks” and “troughs” of the pleats. The R groups of successive amino acids jut out on alternating sides of the sheet. Because the carbon atoms that make up the backbone of the polypeptide chain are successively located a little above and a little below the plane of the β sheet, such structures are sometimes called

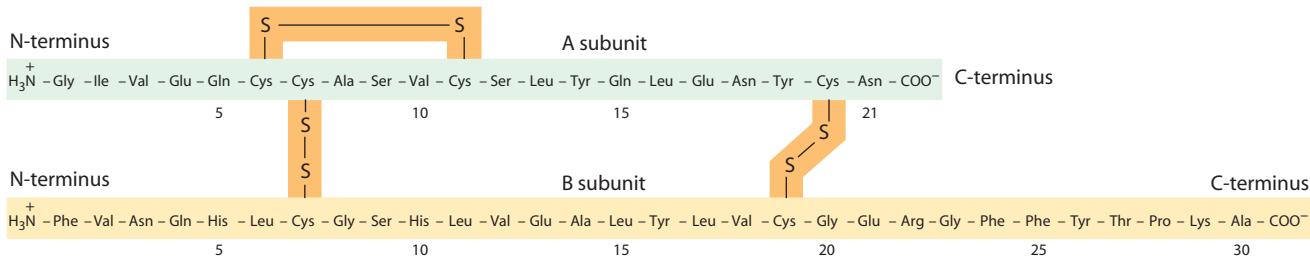

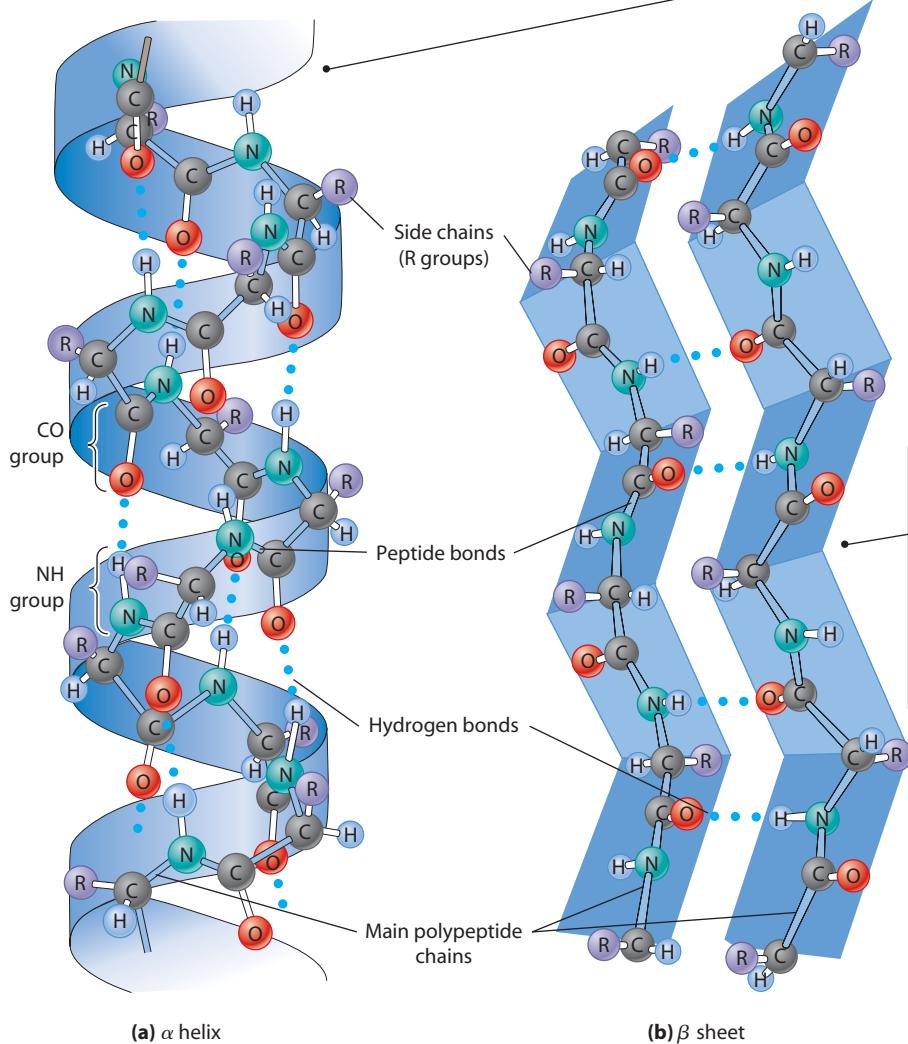

FIGURE 3-7 The Primary Structure of Insulin. Insulin consists of two polypeptides, called the A and B subunits, each shown here from the N-terminus to the C-terminus. The two subunits are covalently linked by two disulfide bonds. (For abbreviations of amino acids, see Table 3-2.)

(a) The α helix. The α helix resembles a coiled telephone cord with each turn of the coil stabilized by hydrogen bonds between the CO and NH groups of one peptide bond and those of the peptide bonds four amino acids away in each direction, just “below” and “above” it in the helix. The hydrogen bonds of an α helix are therefore within a single polypeptide chain and parallel to the polypeptide axis.

(b) The β sheet. The β sheet involves two polypeptide regions and resembles a pleated skirt. The successive atoms of each polypeptide chain run perpendicular to the pleats, and the R groups of the amino acids jut out on alternating sides of the sheet at each fold. This structure is stabilized by hydrogen bonds between the CO and NH groups of peptide bonds in the adjacent polypeptide regions.

FIGURE 3-8 The α Helix and β Sheet. The α helix shown in (a) and the β sheet shown in (b) are important elements in the secondary structure of proteins. Both are stabilized by hydrogen bonds (blue dots), either within a local region of primary sequence (α helix) or between two separate regions (β sheet).

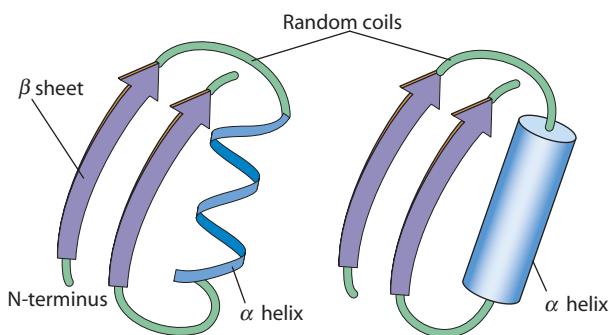

[VIDEOS www.thecellplace.com](http://www.thecellplace.com) An idealized alpha helix; An idealized beta-pleated sheet

β -pleated sheets. Whether a local amino acid sequence forms an α helix or a β sheet depends on the particular combination of amino acids present.

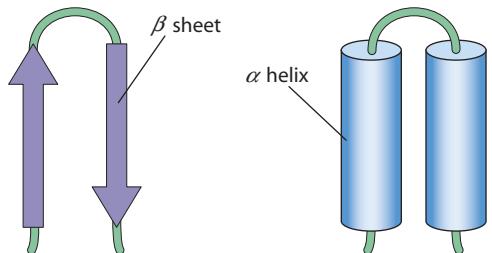

Like the α helix, the β sheet is characterized by a maximum of hydrogen bonding. In both cases, all of the CO groups and NH groups adjacent to the peptide bonds are involved. However, hydrogen bonding in an α helix is invariably intramolecular (within the same polypeptide), whereas hydrogen bonding in the β sheet can be either intramolecular (between two segments of the same polypeptide) or intermolecular (linking two different polypeptides). The protein regions that form β sheets can interact with each other in two different ways. If the two interacting regions run in the same N-terminus-to-C-terminus direction, the structure is called a *parallel* β sheet; if the two strands run in opposite N-terminus-to-C-terminus directions, the structure is called an *antiparallel* β sheet.

Whether a specific segment of a polypeptide will form an α helix, a β sheet, or neither depends on the amino acids present in that segment. For example, leucine, methionine, and glutamate are strong “ α helix formers,” meaning they are commonly found in α -helical regions. Isoleucine, valine, and phenylalanine are strong “ β sheet formers,” often being found in β -sheet regions. Proline is considered a “helix breaker” because its R group is covalently bonded to its amino nitrogen, which therefore lacks the hydrogen atom needed for hydrogen bonding. Proline is rarely found in an α helix and, when present, introduces a bend in the helix.

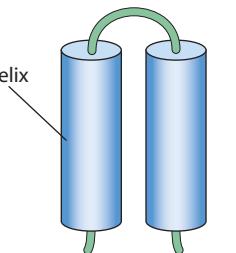

To depict localized regions of structure within a protein, biochemists have adopted the conventions shown in **Figure 3-9**. An α -helical region is represented as either a spiral or a cylinder, whereas a β -sheet region is drawn as a flat ribbon or arrow with the arrowhead pointing in the

(a) β - α - β motif with α helix represented as a spiral (left) or a cylinder (right)

(b) Hairpin loop motif

(c) Helix-turn-helix motif

FIGURE 3-9 Common Structural Motifs. These short sections of polypeptides show three common units of secondary structure: the (a) β - α - β , (b) hairpin loop, and (c) helix-turn-helix motifs. An α helix can be represented as either a spiral or a cylinder, whereas a β sheet is represented as a flat ribbon or arrow pointing toward the C terminus. In (a), the β sheets are parallel; in (b), they are anti-parallel. The short segments (green) connecting α helices and β sheets are called random coils and have no defined secondary structure.

direction of the C-terminus. A looped segment that connects α -helical and/or β -sheet regions is called a *random coil* and is depicted as a narrow cord.

Certain combinations of α helices and β sheets have been identified in many proteins. These units of secondary structure, called **motifs**, consist of small segments of an α helix and/or β sheet connected to each other by looped regions of varying length. Among the most commonly encountered motifs are the β - α - β motif shown in Figure 3-9a and the hairpin loop and helix-turn-helix motifs depicted in Figure 3-9, parts b and c, respectively. When the same motif is present in different proteins, it usually serves the same purpose in each. For example, the helix-turn-helix motif is one of several secondary structure motifs that are characteristic of the DNA-binding proteins we will encounter when we consider the regulation of gene expression in Chapter 23.

Tertiary Structure. The **tertiary structure** of a protein can probably be best understood by contrasting it with the secondary structure (Figure 3-6b, c). Secondary structure is a predictable, repeating conformational pattern that derives from the repetitive nature of the polypeptide

because it involves hydrogen bonding between NH and CO groups adjacent to peptide bonds—the common structural elements along every polypeptide chain. If proteins contained only one or a few kinds of similar amino acids, virtually all aspects of protein conformation could probably be understood in terms of secondary structure, with only modest variations among proteins.

Tertiary structure comes about precisely because of the variety of amino acids present in proteins and the very different chemical properties of their R groups. In fact, tertiary structure depends almost entirely on interactions between the various R groups, regardless of where along the primary sequence they happen to be. Tertiary structure therefore reflects the nonrepetitive and unique aspect of each polypeptide because it depends not on the CO and NH groups common to all of the amino acids in the chain but instead on the very feature that makes each amino acid distinctive—its R group.

Tertiary structure is neither repetitive nor readily predictable; it involves competing interactions between side groups with different properties. Hydrophobic R groups, for example, spontaneously seek out a nonaqueous environment in the interior of the molecule while polar amino acids are drawn to the surface. Oppositely charged R groups can form ionic bonds, while similarly charged groups will repel each other. As a result, the polypeptide chain will be folded, coiled, and twisted into the **native conformation**—the most stable three-dimensional structure for that particular sequence of amino acids.

The relative contributions of secondary and tertiary structures to the overall shape of a polypeptide vary from protein to protein and depend critically on the relative proportions and sequence of amino acids in the chain. Broadly speaking, proteins can be divided into two categories: *fibrous proteins* and *globular proteins*.

Fibrous proteins have extensive secondary structure (either α helix or β sheet) throughout the molecule, giving them a highly ordered, repetitive structure. In general, secondary structure is much more important than tertiary interactions in determining the shape of fibrous proteins, which often have an extended, filamentous structure. Especially prominent examples of fibrous proteins include the *fibroin* protein of silk and the *keratins* of hair and wool, as well as *collagen* (found in tendons and skin) and *elastin* (present in ligaments and blood vessels).

The amino acid sequence of each of these proteins favors a particular kind of secondary structure, which in turn confers a specific set of desirable mechanical properties on the protein. Fibroin, for example, consists mainly of long stretches of antiparallel β sheets, with the polypeptide chains running parallel to the axis of the silk fiber but in opposite directions. The most prevalent amino acids in fibroin are glycine, alanine, and serine. These amino acids have small R groups that pack together well (see Figure 3-2). The result is a silk fiber that is strong and relatively inextensible because the polypeptide chains in a β -sheet conformation are already stretched to nearly their maximum possible length.

Hair and wool fibers, on the other hand, consist of the protein α -keratin, which is almost entirely α helical. The individual keratin molecules are very long and lie with their helix axes nearly parallel to the fiber axis. As a result, hair is quite extensible because stretching of the fiber is opposed not by the covalent bonds of the polypeptide chain, as in β sheets, but by the hydrogen bonds that stabilize the α -helical structure. The individual α helices in a hair are wound together to form a strong, ropelike structure, as shown in **Figure 3-10**. First, two keratin α helices are coiled around each other, and two of these coiled pairs associate to form a protofilament containing four α helices. Groups of eight protofilaments then interact to form intermediate filaments, which bundle together to form the actual hair fiber. Not surprisingly, the α -keratin polypeptides in hair are rich in hydrophobic residues that interact with each other where the helices touch, allowing the tight packing of the filaments in hair.

As important as fibrous proteins may be, they represent only a small fraction of the kinds of proteins present in most cells. Most of the proteins involved in cellular structure are **globular proteins**, so named because their polypeptide chains are folded into compact structures rather than extended filaments (see Figure 2-19). The polypeptide chain of a globular protein is often folded locally into regions with α -helical or β -sheet structures, and these regions of secondary structure are themselves folded on one another to give the protein its compact, globular shape. This folding is possible because regions of α helix or β sheet are interspersed with random coils, irregularly structured regions that allow the polypeptide chain to loop and fold (see Figure 3-9). Thus, every globular protein has its own unique tertiary structure, made up of secondary structural elements (helices and sheets) folded in a specific way that is especially suited to the particular functional role of that protein.

Figure 3-11 shows the native tertiary structure of ribonuclease, a typical globular protein. We encountered ribonuclease in Figure 2-18, as an example of the denaturation and renaturation of a polypeptide and the spontaneity of its folding. Two different conventions are used in Figure 3-11 to represent the structure of ribonuclease: the *ball-and-stick* model used in Figure 3-8 and the *spiral-and-ribbon* model used in Figure 3-9. For clarity, most of the side chains of ribonuclease have been omitted in both models. The groups shown in gold in Figure 3-11a are the four disulfide bonds that help to stabilize the tertiary structure of ribonuclease.

Globular proteins can be mainly α helical, mainly β sheet, or a mixture of both structures. These categories are illustrated in **Figure 3-12** by the coat protein of tobacco mosaic virus (TMV), a portion of an immunoglobulin (antibody) molecule, and a portion of the enzyme hexokinase, respectively. Helical segments of globular proteins often consist of bundles of helices, as seen for the coat protein of TMV in Figure 3-12a. Segments with mainly β -sheet structure are usually characterized by a barrel-like configuration (Figure 3-12b) or by a twisted sheet (Figure 3-12c).

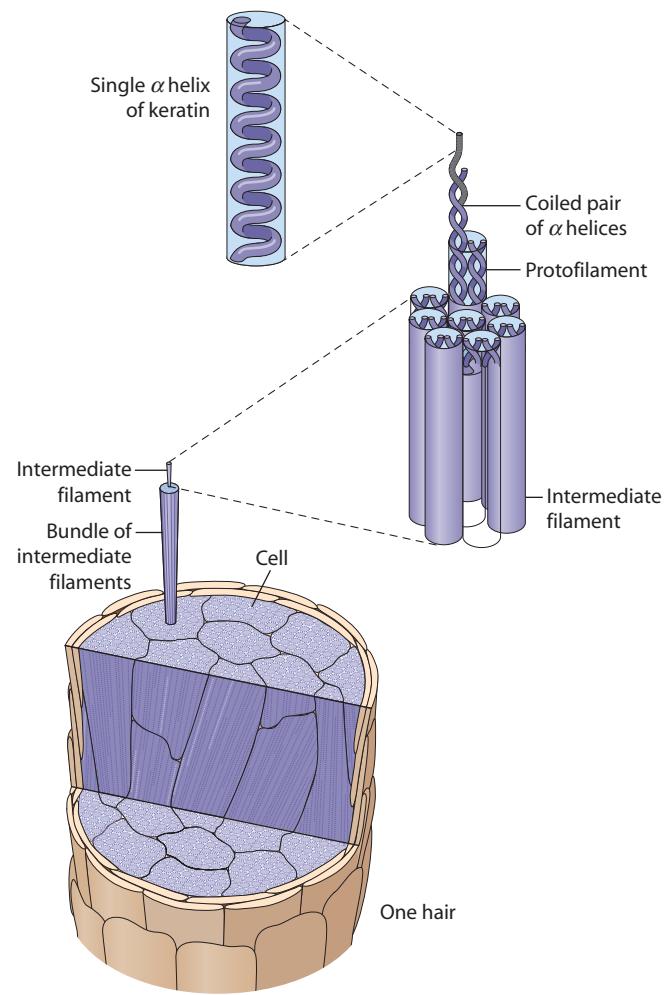

FIGURE 3-10 The Structure of Hair. The main structural protein of hair is α -keratin, a fibrous protein with an α -helical shape. The individual α helices in a hair are wound together to form a strong, ropelike structure. Two keratin α helices are coiled around each other, and two of these coiled pairs associate to form a protofilament containing four α helices. Groups of eight protofilaments then interact to form intermediate filaments, which then bundle together to form the hair fibers (see also Figure 15-23).

Many globular proteins consist of a number of segments called domains. A **domain** is a discrete, locally folded unit of tertiary structure that usually has a specific function. Each domain typically includes 50–350 amino acids, with regions of α helices and β sheets packed together compactly. Small globular proteins are usually folded into a single domain (Figure 3-11b). Large globular proteins usually have multiple domains. The portions of the immunoglobulin and hexokinase molecules shown in Figure 3-12, parts b and c, are, in fact, specific domains of these proteins. **Figure 3-13** shows an example of a protein that consists of a single polypeptide folded into two functional domains.

Proteins that have similar functions (such as binding a specific ion or recognizing a specific molecule) usually have a common domain containing a sequence of identical or very similar amino acid residues. Moreover, proteins

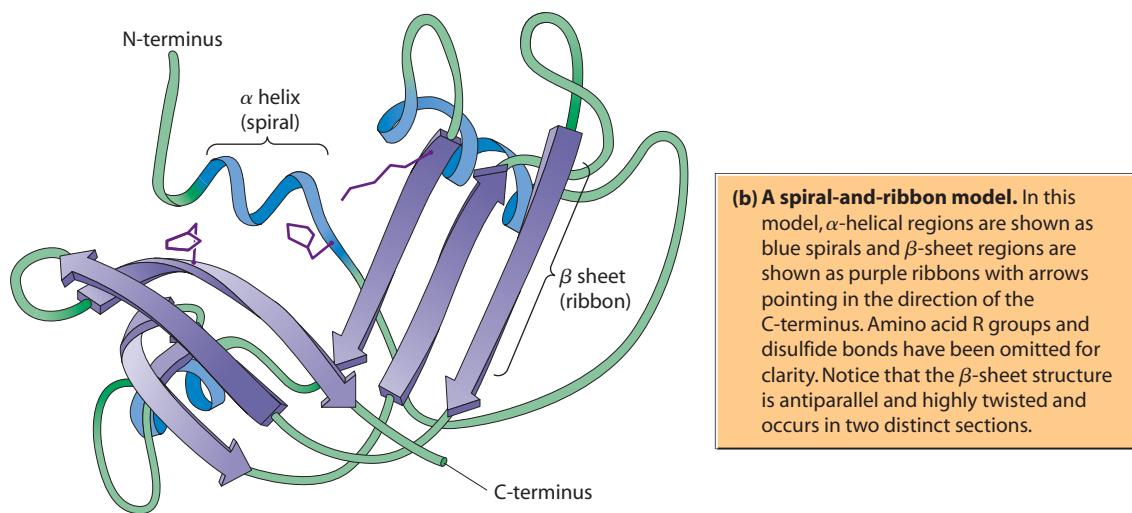

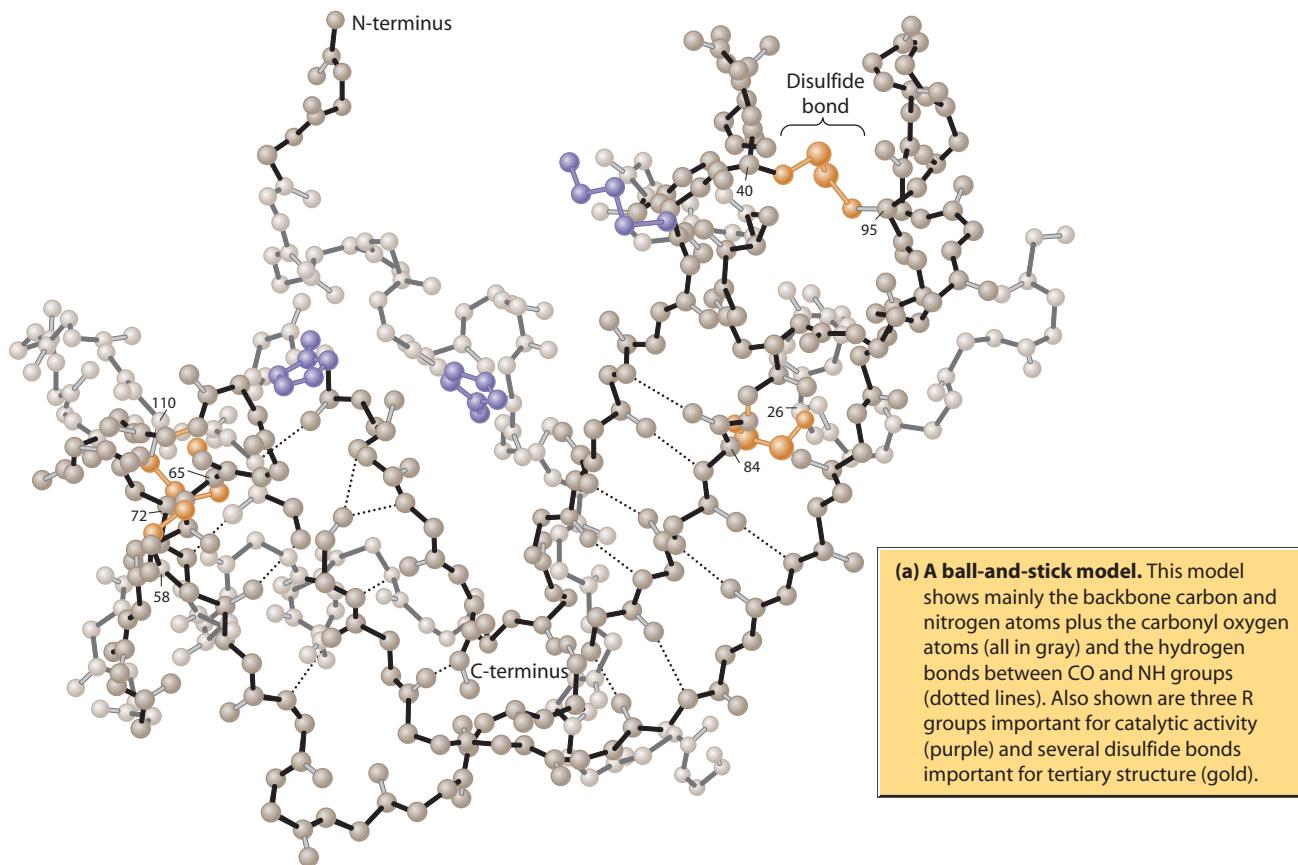

FIGURE 3-11 The Three-Dimensional Structure of Ribonuclease. Ribonuclease is a monomeric globular protein with significant α -helical and β -sheet segments connected by random coils. Its tertiary structure can be represented either by (a) a ball-and-stick model or by (b) a spiral-and-ribbon model.

with multiple functions usually have a separate domain for each function. Thus, domains can be thought of as the modular units of function from which globular proteins are constructed. Many different types of domains have been described in proteins and given names such as the immunoglobulin domain, the kringle domain, or the death domain. Each type is composed of a particular combination of α -helix and β -sheet secondary structures that give the domain a specific function.

Before leaving the topic of tertiary structure, we should emphasize again the dependence of these higher levels of organization on the primary structure of the polypeptide. The significance of primary structure is exemplified especially well by the inherited condition *sickle-cell anemia*. People with this trait have red blood cells that are distorted from their normal disk shape into a “sickle” shape, which causes the abnormal cells to clog blood vessels and impede blood flow, limiting oxygen availability in the tissues.

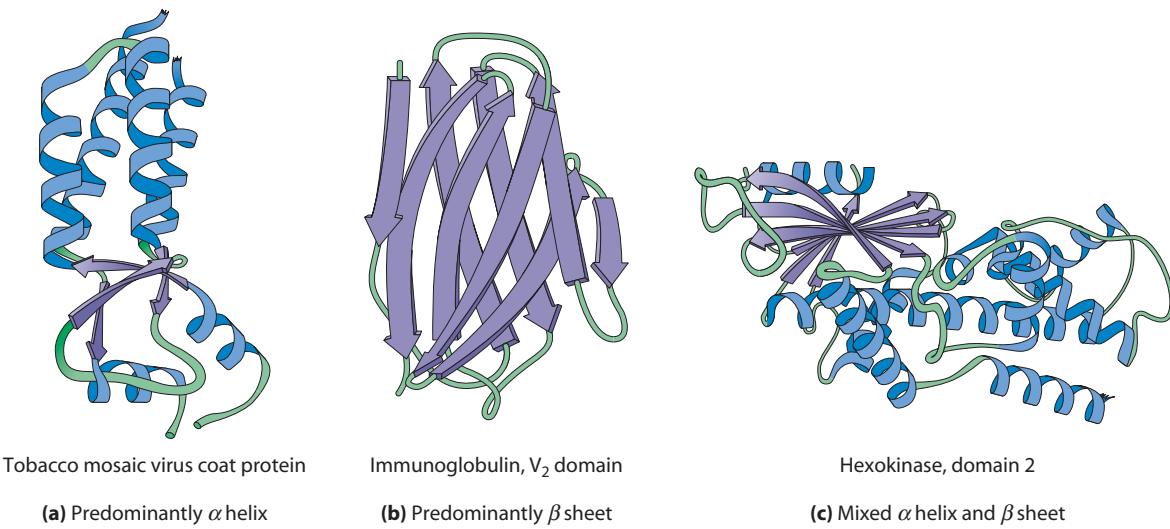

FIGURE 3-12 Structures of Several Globular Proteins. Shown here are proteins with different tertiary structures: (a) a predominantly α -helical structure (blue spirals), the coat protein of tobacco mosaic virus (TMV); (b) a mainly β -sheet structure (purple ribbons with arrows), the V₂ domain of immunoglobulin; and (c) a structure that mixes α helices and β sheets, domain 2 of hexokinase. The immunoglobulin V₂ domain is an example of an antiparallel β -barrel structure, whereas the hexokinase domain 2 illustrates a twisted β sheet. (Green segments are random coils.)

This condition is caused by a slight change in the hemoglobin molecule within the red blood cells. In people with sickle-cell anemia, the hemoglobin molecules have normal α polypeptide chains, but their β chains have a single amino acid that is different. At one specific

position in the chain (the sixth amino acid residue from the N-terminus), the glutamate normally present is replaced by valine. This single substitution (written as E6V) causes enough of a difference in the tertiary structure of the β chain that the hemoglobin molecules tend to crystallize, deforming the cell into a sickle shape. Not all amino acid substitutions cause such dramatic changes in structure and function, but this example underscores the crucial relationship between the amino acid sequence of a polypeptide and the final shape and biological activity of the molecule.

Although we know that the primary sequence of a protein determines its final folded shape, we still are not able to predict exactly how a given protein will fold, especially for large proteins (more than 100 amino acids). In fact, one of the most challenging unsolved problems in structural biochemistry is to predict the final folded tertiary structure of a protein from its known primary structure. Even with all our knowledge of the factors and forces involved in folding, and the availability of supercomputers to do billions of calculations per second, we cannot often predict the most stable conformation for a given protein.

In fact, in every other year since 1994, protein modelers worldwide test their predictive methods in a major modeling experiment known as CASP—the critical assessment of techniques for protein structure prediction. Their predictions are compared to subsequently released three-dimensional protein structures, and the results are published in a special issue of the journal *Proteins: Structure, Function and Bioinformatics*. One of the goals of this modeling research is for drug discovery—the ability to design therapeutic agents able to bind to specific regions of a protein involved in human disease.

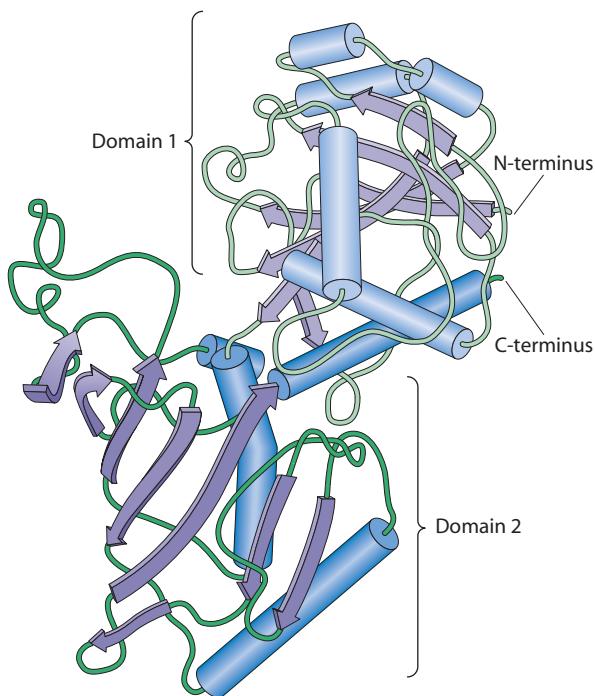

FIGURE 3-13 An Example of a Protein Containing Two Functional Domains. This model of the enzyme glyceraldehyde phosphate dehydrogenase shows a single polypeptide chain folded into two domains. One domain binds to the substance being metabolized, whereas the other domain binds to a chemical factor required for the reaction to occur. The two domains are indicated by different shadings.

Quaternary Structure. The **quaternary structure** of a protein is the level of organization concerned with subunit interactions and assembly (see Figure 3-6d). Quaternary structure therefore applies only to multimeric proteins. Many proteins are included in this category, particularly those with molecular weights above 50,000. Hemoglobin, for example, is a multimeric protein with two α chains and two β chains (see Figure 3-4). Some multimeric proteins contain identical polypeptide subunits; others, such as hemoglobin, contain two or more different kinds of polypeptides.

The bonds and forces that maintain quaternary structure are the same as those responsible for tertiary structure: hydrogen bonds, electrostatic interactions, van der Waals interactions, hydrophobic interactions, and covalent disulfide bonds. As noted earlier, disulfide bonds may be either within a polypeptide chain or between chains. When they occur within a polypeptide, they stabilize tertiary structure. When they occur between polypeptides, they help maintain quaternary structure, holding the individual polypeptides together (see Figure 3-7). As in the case of polypeptide folding, the process of subunit assembly is often, though not always, spontaneous. Most, if not all, of the requisite information is provided by the amino acid sequence of the individual polypeptides, but often molecular chaperones are required to ensure proper assembly.

In some cases a still higher level of assembly is possible in the sense that two or more proteins (often enzymes) are organized into a **multiprotein complex**, with each protein involved sequentially in a common multistep process. An example of such a complex is an enzyme system called the *pyruvate dehydrogenase complex*. This complex catalyzes the oxidative removal of a carbon atom (as CO_2) from the three-carbon compound pyruvate (or pyruvic acid), a reaction that will be of interest to us when we get to Chapter 10. Three individual enzymes and five kinds of molecules called coenzymes constitute a highly organized *multienzyme complex*. The pyruvate dehydrogenase complex is one of the best understood examples of how cells can achieve economy of function by ordering the enzymes that catalyze sequential reactions into a single multienzyme complex. Other multiprotein complexes we will encounter in our studies include ribosomes, proteasomes, the photosystems, and the DNA replication complex.

Nucleic Acids

Next, we come to the **nucleic acids**, macromolecules of paramount importance to the cell because of their role in storing, transmitting, and expressing genetic information. Nucleic acids are linear polymers of nucleotides strung together in a genetically determined order that is critical to their role as informational macromolecules. The two major types of nucleic acids are **DNA (deoxyribonucleic acid)** and **RNA (ribonucleic acid)**. DNA and RNA differ in their chemistry and their role in the cell. As the names suggest, RNA contains the five-carbon sugar **ribose** in

each of its nucleotides, whereas DNA contains the closely related sugar **deoxyribose**. Functionally, DNA serves primarily as the repository of genetic information, whereas RNA molecules play several different roles in expressing that information—that is, in protein synthesis.

The primary roles of DNA and RNA in a typical plant or animal cell are shown in **Figure 3-14**. Most of the DNA in a cell is located in the nucleus, the major site of RNA synthesis in the cell. **1 Transcription:** A specific segment of a DNA molecule known as a gene directs the synthesis of a complementary molecule of *messenger RNA (mRNA)*. Each gene contains the information to produce a specific polypeptide using this mRNA. **2 mRNA export:** Following processing to remove introns (and in some cases RNA editing to alter specific bases), the mRNA leaves the nucleus through *nuclear pores*—tiny channels in the nuclear membrane—and enters the cytoplasm. **3 Translation (polypeptide synthesis):** A ribosome, which is a complex of ribosomal proteins and *ribosomal RNA (rRNA)* molecules, attaches to the mRNA to read the coded information. As the ribosome moves down the mRNA, *transfer RNA (tRNA)* molecules bring the correct amino acids to be added to the growing polypeptide chain in the order specified by the information in the mRNA. These roles of DNA and RNA in the storage, transmission, and expression of genetic information will be considered in detail in Chapters 18–22.

In addition to these three main types of RNA, several others have been discovered in recent years. Many, if not all, eukaryotic cells contain a wide variety of *small RNAs* of 20–30 nucleotides that function as regulatory molecules. *MicroRNAs (miRNAs)* are small endogenous RNAs that down-regulate the expression of specific genes by binding to their mRNAs and either promoting mRNA degradation or inhibiting translation. They are important in regulating genes involved in embryonic development and cell proliferation, and abnormal regulation by miRNAs is associated with certain human diseases. Other small RNAs known as *small interfering RNAs (siRNAs)* are derived from exogenous sources (e.g., infection by an RNA virus) and can inhibit either transcription or translation. Use of siRNAs to target specific mRNAs for destruction is being actively explored as a way to silence genes known to contribute to human disease. These RNAs are discussed in more detail in Chapter 23, but for now we will focus on the chemistry of nucleic acids and nucleotides.

The Monomers Are Nucleotides

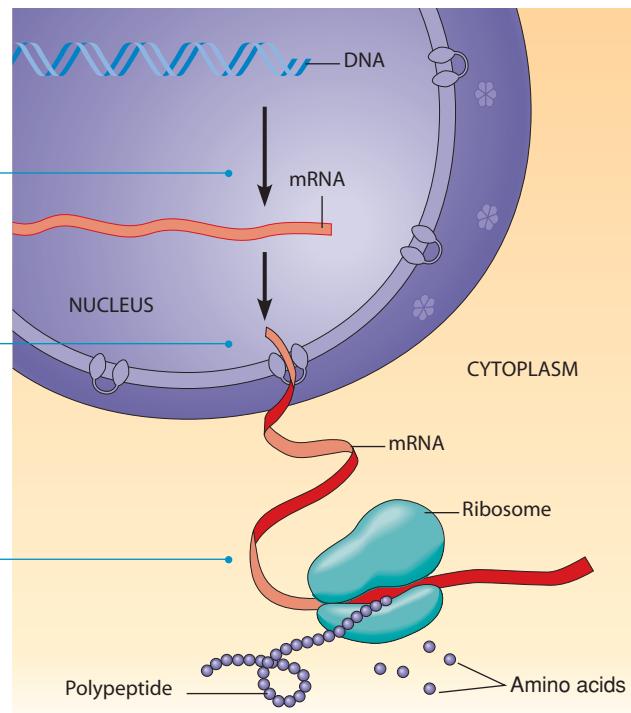

Nucleic acids are informational macromolecules and contain nonidentical monomeric units in a specified sequence. The monomeric units of nucleic acids are called **nucleotides**. Nucleotides exhibit less variety than amino acids do; DNA and RNA each contain only four different kinds of nucleotides. (Actually, there is more variety than this suggests, especially in some RNA molecules in which some nucleotides have been chemically modified after insertion into the chain.)

FIGURE 3-14 Genetic Information Is Stored in the Nucleotide Sequences of DNA Molecules. In eukaryotes, most of the DNA in a cell is located in the nucleus. This DNA contains instructions for ① the synthesis of a complementary messenger RNA (mRNA) that then ② travels to the cytoplasm, where ③ it is used by the ribosome to synthesize a protein.

① **Transcription.** Nuclear DNA directs the synthesis of specific mRNA molecules.

② **mRNA export.** mRNAs exit through nuclear pores and bind to cytoplasmic ribosomes.

③ **Translation.** A ribosome synthesizes the specific protein encoded by the mRNA.

As shown in **Figure 3-15**, each nucleotide consists of a five-carbon sugar to which is attached a phosphate group and a nitrogen-containing aromatic base. The sugar is either D-ribose (in RNA) or D-deoxyribose (in DNA). The phosphate is joined by a phosphoester bond to the 5' carbon of the sugar, and the base is attached to the 1' carbon. The base may be either a **purine** or a **pyrimidine**. DNA contains the purines **adenine** (A) and **guanine** (G) and the pyrimidines **cytosine** (C) and **thymine** (T). RNA also has adenine, guanine, and cytosine, but it contains the pyrimidine **uracil** (U) in place of thymine. Like the 20 amino acids present in proteins, these five aromatic bases are among the most common small molecules in cells (see Table 3-1).

Without the phosphate, the remaining base-sugar unit is called a **nucleoside**. Each pyrimidine and purine may therefore occur as the free base, the nucleoside, or the nucleotide. The appropriate names for these compounds are

given in **Table 3-4**. Notice that nucleotides and nucleosides containing deoxyribose are specified by a lowercase d preceding the letters identifying the base.

As the nomenclature indicates, a nucleotide can be thought of as a **nucleoside monophosphate** because it is a nucleoside with a single phosphate group attached to it. This terminology can be readily extended to molecules with two or three phosphate groups attached to the 5' carbon. For example, the nucleoside adenosine (adenine plus ribose) can have one, two, or three phosphates attached and is designated accordingly as **adenosine monophosphate (AMP)**, **adenosine diphosphate (ADP)**, or **adenosine triphosphate (ATP)**. The relationships among these compounds are shown in **Figure 3-16**.

You probably recognize ATP as the energy-rich compound used to drive various reactions in the cell, including the activation of monomers for polymer

Table 3-4 The Bases, Nucleosides, and Nucleotides of RNA and DNA

Bases	RNA		DNA	
	Nucleoside	Nucleotide	Deoxynucleoside	Deoxynucleotide
Purines				
Adenine (A)	Adenosine	Adenosine monophosphate (AMP)	Deoxyadenosine	Deoxyadenosine monophosphate (dAMP)
Guanine (G)	Guanosine	Guanosine monophosphate (GMP)	Deoxyguanosine	Deoxyguanosine monophosphate (dGMP)
Pyrimidines				
Cytosine (C)	Cytidine	Cytidine monophosphate (CMP)	Deoxycytidine	Deoxycytidine monophosphate (dCMP)
Uracil (U)	Uridine	Uridine monophosphate (UMP)	—	—
Thymine (T)	—	—	Deoxythymidine	Deoxythymidine monophosphate (dTTP)

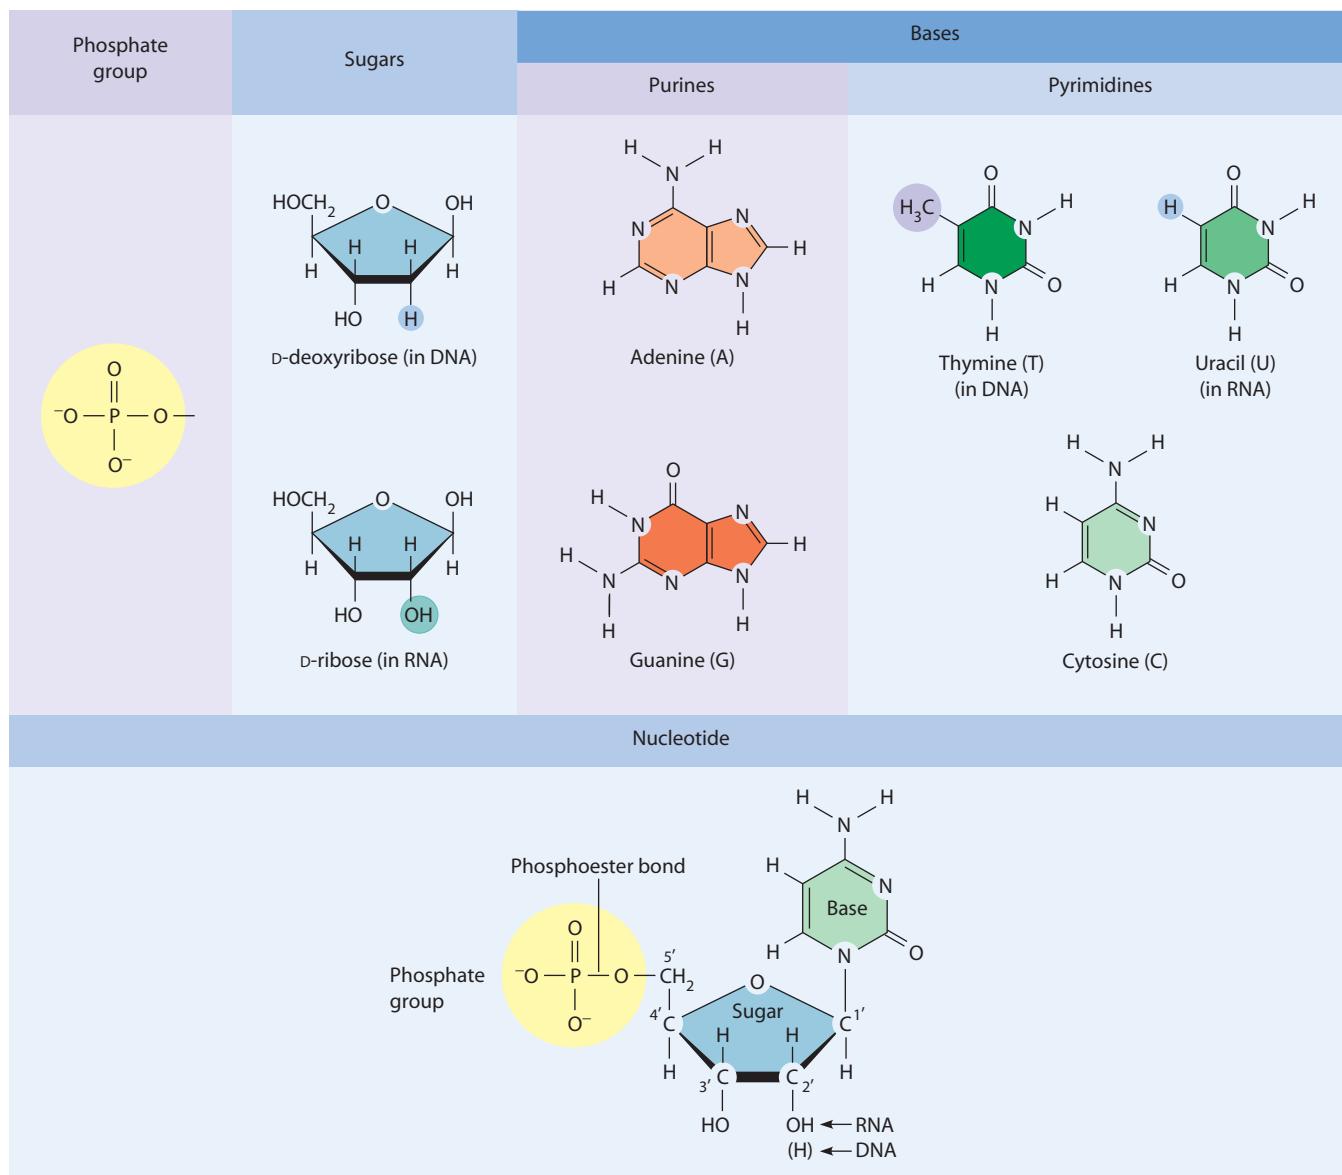

FIGURE 3-15 The Structure of a Nucleotide. In RNA, a nucleotide consists of the five-carbon sugar D-ribose with an aromatic nitrogen-containing base attached to the 1' carbon and a phosphate group linked to the 5' carbon by a phosphoester bond. (Carbon atoms in the sugar of a nucleotide are numbered from 1' to 5' to distinguish them from those in the base, which are numbered without the prime.) In DNA, the hydroxyl group on the 2' carbon is replaced by a hydrogen atom, so the sugar is D-deoxyribose. The bases in DNA are the purines adenine (A) and guanine (G) and the pyrimidines thymine (T) and cytosine (C). In RNA, thymine is replaced by the pyrimidine uracil (U).

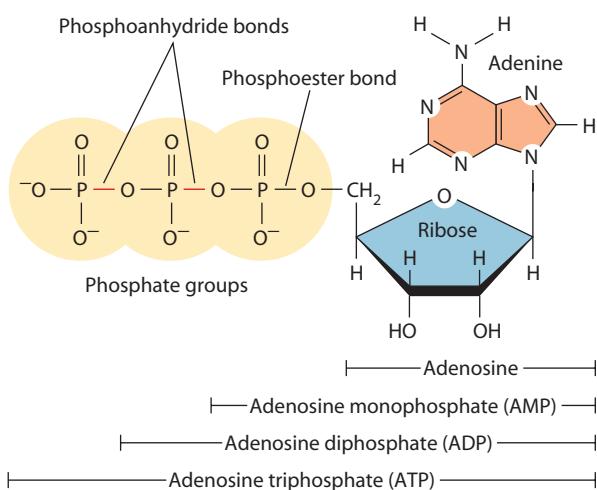

FIGURE 3-16 The Phosphorylated Forms of Adenosine.

Adenosine occurs as the free nucleoside and can also form part of the following three nucleotides: adenosine monophosphate (AMP), adenosine diphosphate (ADP), and adenosine triphosphate (ATP). The bond linking the first phosphate to the ribose of adenosine is a phosphoester bond, whereas the bonds linking the second and third phosphate groups to the molecule are phosphoanhydride bonds. As we will see in Chapter 9, the hydrolysis of a phosphoanhydride bond typically liberates two to three times as much free energy as does the hydrolysis of a phosphoester bond.

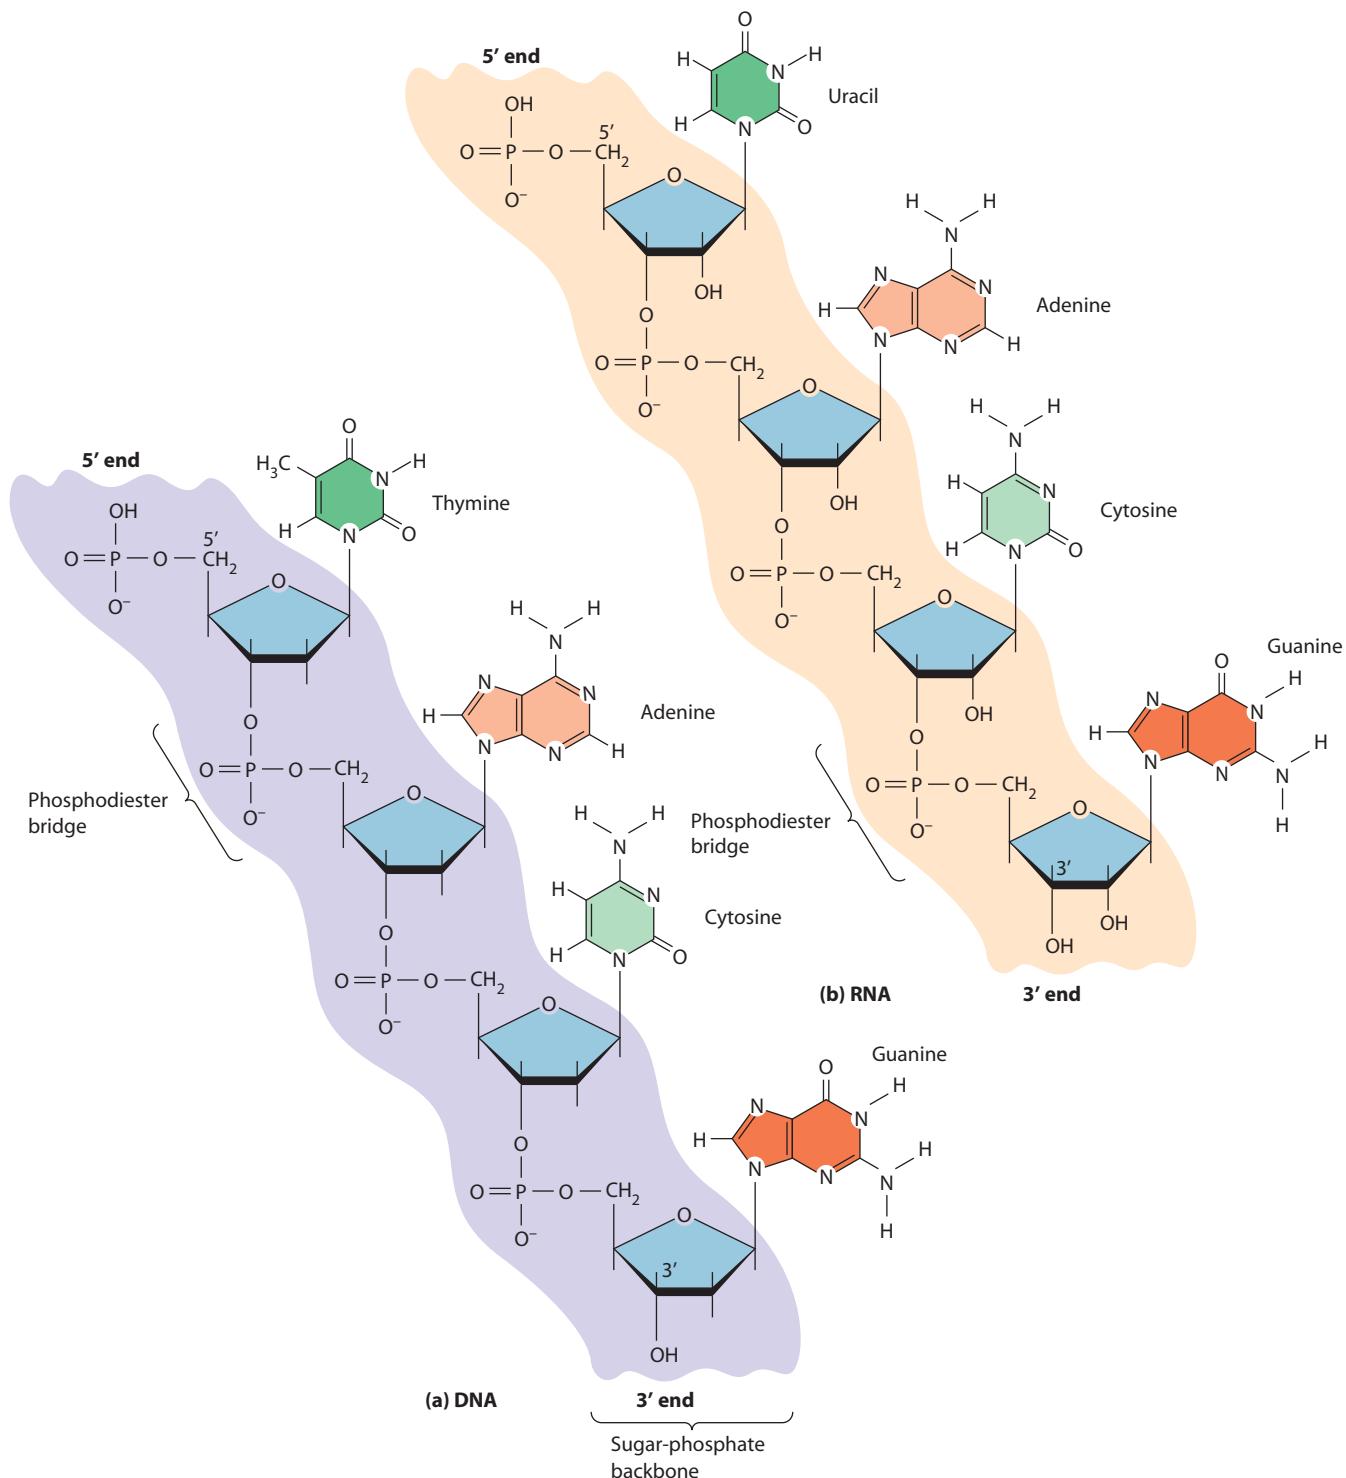

FIGURE 3-17 The Structure of Nucleic Acids. Nucleic acids consist of linear chains of nucleotides, each containing a sugar, a phosphate, and a base. The sugar is (a) deoxyribose in DNA and (b) ribose in RNA. Successive nucleotides in the chain are joined together by 3', 5' phosphodiester bridges. The resulting polynucleotide has an intrinsic directionality, with a 5' end and a 3' end. For both DNA and RNA, the backbone of the chain is an alternating sugar-phosphate sequence, from which the bases jut out.

 [ACTIVITIES](http://www.thecellplace.com) www.thecellplace.com DNA and RNA structure

formation that we encountered in the previous chapter (see Figure 2-17). As this example suggests, nucleotides play two roles in cells: They are the monomeric units of nucleic acids, and several of them—ATP most notably—serve as intermediates in various energy-transferring reactions.

The Polymers Are DNA and RNA

Nucleic acids are linear polymers formed by linking each nucleotide to the next through a phosphate group, as shown in **Figure 3-17** (see also Figure 19-7). Specifically, the phosphate group already attached by a phosphoester

bond to the 5' carbon of one nucleotide becomes linked by a second phosphoester bond to the 3' carbon of the next nucleotide. The resulting linkage is known as a **3',5' phosphodiester bridge**, which consists of a phosphate group linked to two adjacent nucleotides via two phosphoester bonds (one to each nucleotide). The **polynucleotide** formed by this process has an intrinsic directionality, with a 5' phosphate group at one end and a 3' hydroxyl group at the other end. By convention, nucleotide sequences are always written from the 5' end to the 3' end of the polynucleotide because, as we will see in Chapter 19, this is the direction of nucleic acid synthesis in cells.

Nucleic acid synthesis requires both energy and information. To provide the energy needed to form each new phosphodiester bridge, each successive nucleotide enters as

a high-energy nucleoside triphosphate. The precursors for DNA synthesis are therefore dATP, dCTP, dGTP, and dTTP. For RNA synthesis, ATP, CTP, GTP, and UTP are needed. Information is required for nucleic acid synthesis because successive incoming nucleotides must be added in a specific, genetically determined sequence. For this purpose, a preexisting molecule is used as a **template** to specify nucleotide order. For both DNA and RNA synthesis, the template is usually DNA. Template-directed nucleic acid synthesis relies on precise and predictable **base pairing** between a template nucleotide and the specific incoming nucleotide that can pair with the template nucleotide.

This recognition process depends on an important chemical feature of the purine and pyrimidine bases shown in **Figure 3-18**. These bases have carbonyl groups

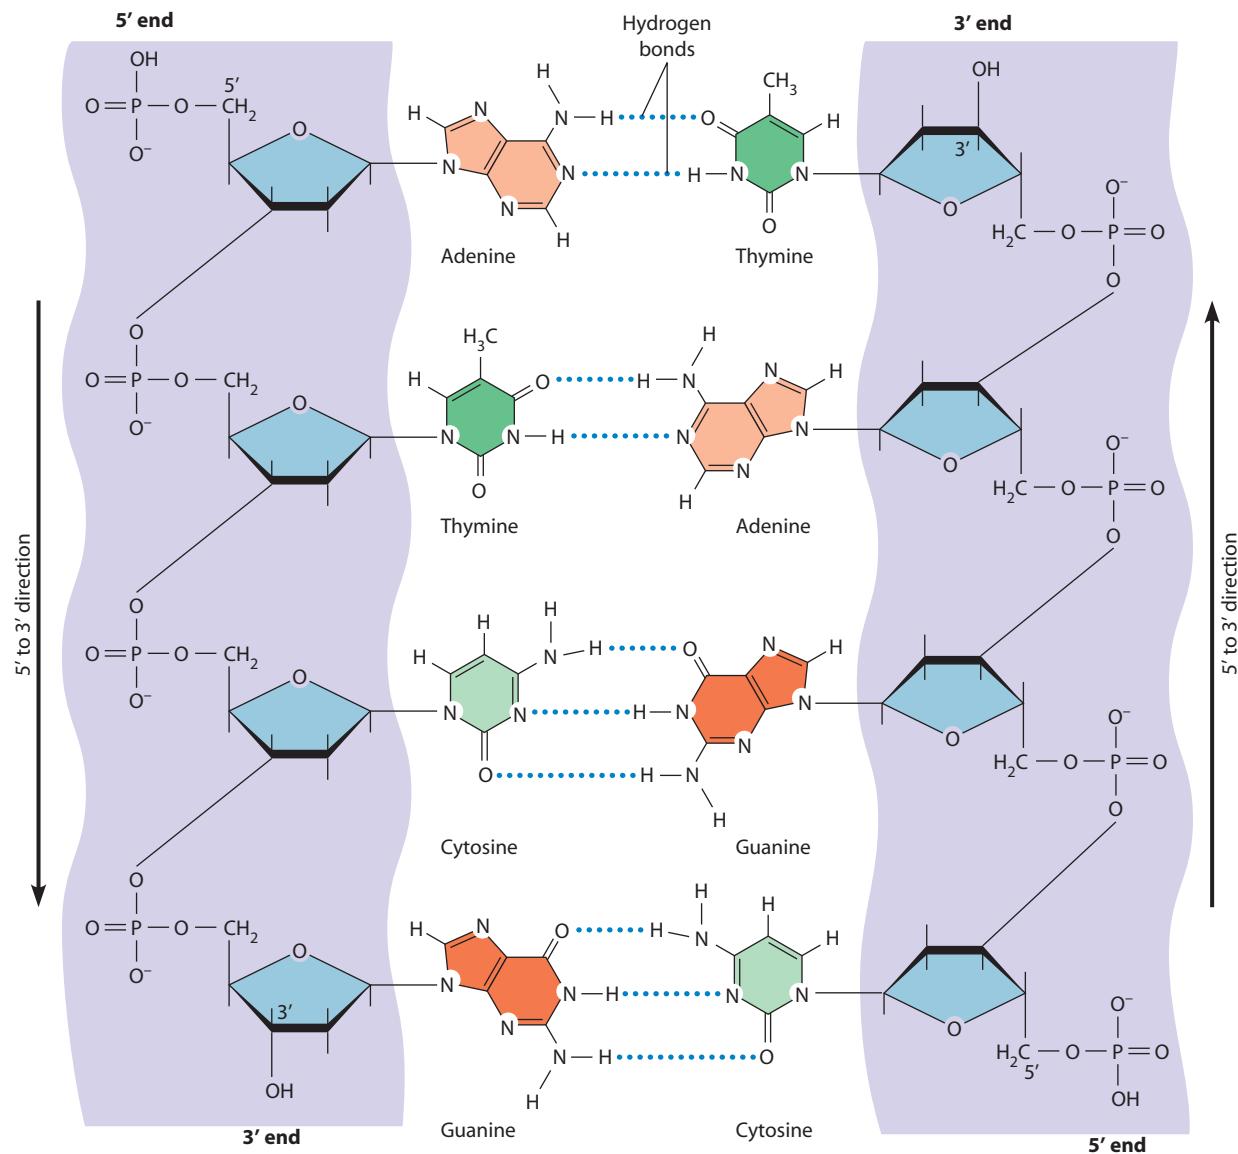

FIGURE 3-18 Hydrogen Bonding in Nucleic Acid Structure. The hydrogen bonds (blue dots) between adenine and thymine and between cytosine and guanine account for the AT and CG base pairing of DNA. Notice that the AT pair is held together by two hydrogen bonds, whereas the CG pair has three hydrogen bonds. If one or both strands were RNA instead, the pairing partner for adenine would be uracil (U).

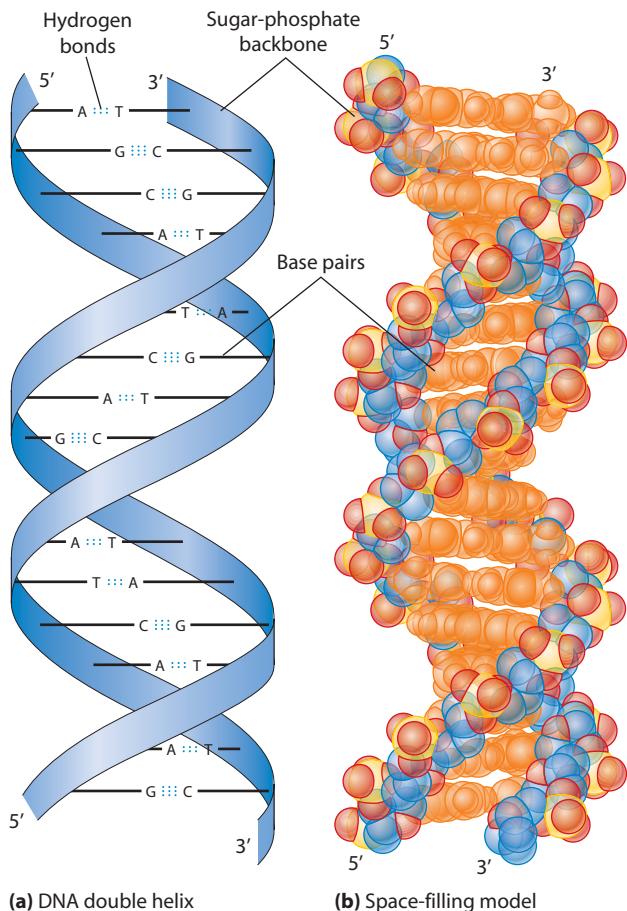

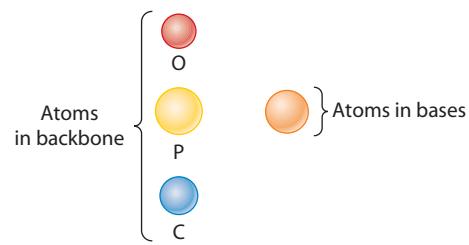

and nitrogen atoms capable of hydrogen bond formation under appropriate conditions. Complementary relationships between purines and pyrimidines allow A to form two hydrogen bonds with T (or U) and G to form three hydrogen bonds with C, as shown in Figure 3-18. This pairing of A with T (or U) and G with C is a fundamental property of nucleic acids. Genetically, this **base pairing** provides a mechanism for nucleic acids to recognize one another, as we will see in Chapter 18. For now, however, let's concentrate on the structural implications.

A DNA Molecule Is a Double-Stranded Helix

One of the most significant biological advances of the twentieth century came in 1953 in a two-page article in the scientific journal *Nature*. In the article, Francis Crick and James Watson postulated a double-stranded helical structure for DNA—the now-famous **double helix**—that not only accounted for the known physical and chemical properties of DNA but also suggested a mechanism for replication of the structure. Some highlights of this exciting chapter in the history of contemporary biology are related in **Box 3A**.

The double helix consists of two complementary chains of DNA twisted together around a common axis to form a right-handed helical structure that resembles a spiral staircase (**Figure 3-19**). The two chains are oriented in opposite directions along the helix, with one running in the $5' \rightarrow 3'$ direction and the other in the $3' \rightarrow 5'$ direction. The backbone of each chain consists of sugar molecules alternating with phosphate groups (see Figure 3-18). The phosphate groups are charged, and the sugar molecules contain polar hydroxyl groups. Therefore, it is not surprising that the sugar-phosphate backbones of the two strands are on the outside of the DNA helix, where their interaction with the surrounding aqueous environment can be maximized. The pyrimidine and purine bases, on the other hand, are aromatic compounds with less affinity for water. Accordingly, they are oriented inward, forming the base pairs that hold the two chains together.

To form a stable double helix, the two component strands must be *antiparallel* (running in opposite directions) as well as *complementary*. By complementary, we mean that each base in one strand can form specific hydrogen bonds with the base in the other strand directly across from it. From the pairing possibilities shown in Figure 3-18, this means that each A must be paired with a T, and each G with a C. In both cases, one member of the pair is a pyrimidine (T or C) and the other is a purine (A or G). The distance between the two sugar-phosphate backbones in the double helix is just sufficient to accommodate one of each kind of base. If we envision the sugar-phosphate backbones of the two strands as the sides of a circular staircase, then each step or rung of the stairway corresponds to a pair of bases held in place by hydrogen bonding (Figure 3-19).

(a) DNA double helix

(b) Space-filling model

FIGURE 3-19 The Structure of Double-Stranded DNA.

(a) A schematic representation of the double-helical structure of DNA. The continuously turning strips represent the sugar-phosphate backbones of the molecule, while the horizontal bars represent paired bases of the two strands. (b) A space-filling model of the DNA double helix, with color-coded atoms as shown at the top of the figure.

The right-handed Watson-Crick helix shown in Figure 3-19 is actually an idealized version of what is called *B-DNA*. B-DNA is the main form of DNA in cells, but two other forms may also exist, perhaps in short segments interspersed within molecules consisting mainly of B-DNA. *A-DNA* has a right-handed, helical configuration that is shorter and thicker than B-DNA. *Z-DNA*, on the other hand, is a left-handed double helix that derives its name from the zigzag pattern of its longer, thinner sugar-phosphate backbone. (For a comparison of the structures of B-DNA and Z-DNA, see Figure 18-5.)

On the Trail of the Double Helix

"I have never seen Francis Crick in a modest mood. Perhaps in other company he is that way, but I have never had reason so to judge him." With this observation as an introduction, James Watson goes on to describe, in a very personal and highly entertaining way, the events that eventually led to the discovery of the structure of DNA. The account, published in 1968 under the title *The Double Helix*, is still fascinating reading for the personal, unvarnished insights it provides into how an immense scientific discovery came about. In the preface, Watson comments on his reasons for writing the book:

There remains general ignorance about how science is "done." That is not to say that all science is done in the manner described here. This is far from the case, for styles of scientific research vary almost as much as human personalities. On the other hand, I do not believe that the way DNA came out constitutes an odd exception to a scientific world complicated by the contradictory pulls of ambition and the sense of fair play.

As portrayed in Watson's account, Crick and Watson are about as different from each other in nature and background as they could be. But there was one thing they shared, and that was an unconventional but highly productive way of "doing" science. They did little actual experimentation on DNA, choosing instead to draw heavily on the research findings of others and to use their own considerable ingenuities in building models and exercising astute insights (Figure 3A-1). Out of it all emerged, in a relatively short time, an understanding of the double-helical structure of DNA that has come to rank as one of the major scientific events of the twentieth century.

To appreciate their findings and their brilliance, we must first understand the setting in which Watson and Crick worked. The early 1950s was an exciting time in biology. It had been only a few years since Avery, MacLeod, and McCarty had published evidence on the genetic transformation of bacteria, but the work of Hershey and Chase that confirmed DNA as the genetic material had not yet appeared in print. Meanwhile, at Columbia University, Erwin Chargaff's careful chemical analyses had revealed that although the relative proportions of the four bases—A, T, C, and G—varied greatly from one species to the next, it was always the same for all members of a single species. Even more puzzling and portentous was Chargaff's second finding: For a given species, A and T always occurred in the same proportions, and so did G and C (that is, %A = %T and %C = %G).

RNA structure also depends in part on base pairing, but this pairing is usually between complementary regions within the same strand and is much less extensive than the interstrand pairing of the DNA duplex. Of the various RNA species, secondary and tertiary structures occur mainly in rRNA and tRNA, as we will see in Chapter 21. In addition, some infectious viruses consist of double-stranded RNA held together by hydrogen bonding between complementary base pairs.

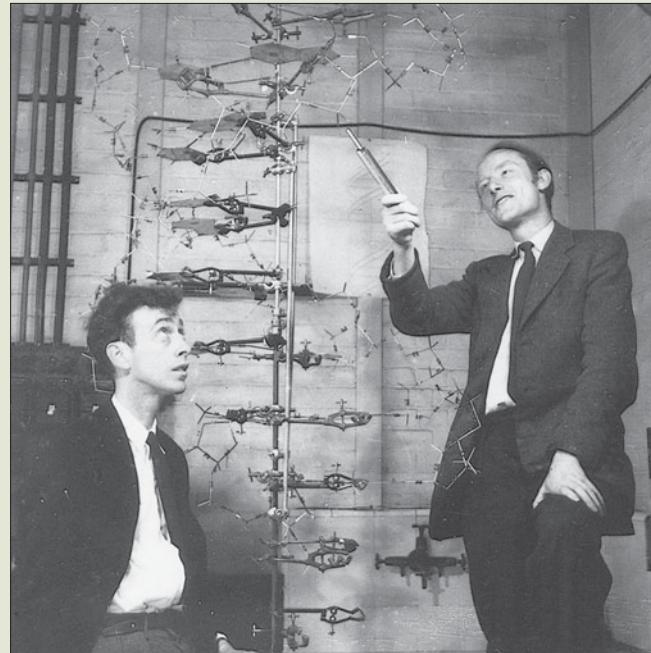

FIGURE 3A-1 James Watson (left) and Francis Crick (right) at work with their model of DNA.

Important clues came from the work of Maurice Wilkins and Rosalind Franklin at King's College in London. Wilkins and Franklin were using the technique of X-ray diffraction to study DNA structure, and they took a rather dim view of Watson and Crick's strategy of model building. X-ray diffraction is a useful tool for detecting regularly occurring structural elements in a crystalline substance because any structural feature that repeats at some fixed interval in the crystal contributes in a characteristic way to the diffraction pattern that is obtained. From Franklin's painstaking analysis of the diffraction pattern of DNA, it became clear that the molecule was long and thin, with some structural element being repeated every 0.34 nm and another being repeated every 3.4 nm. Even more intriguing, the molecule appeared to be some sort of helix.

This stirred the imaginations of Watson and Crick because they had heard only recently of Pauling and Corey's α -helical structure

Polysaccharides

The next macromolecules we will consider are the **polysaccharides**, which are long-chain polymers of sugars and sugar derivatives. Polysaccharides usually consist of a single kind of repeating unit, or sometimes an alternating pattern of two kinds, and are not informational molecules. We will see in Chapter 7, however, that shorter polymers called *oligosaccharides*, when attached to proteins on the

for proteins. Working with models of the bases cut from stiff cardboard, Watson and Crick came to the momentous insight that DNA was also a helix, but with an all-important difference: It was a *double* helix, with hydrogen-bonded pairing of purines and pyrimidines. The actual discovery is best recounted in Watson's own words:

When I got to our still empty office the following morning, I quickly cleared away the papers from my desk top so that I would have a large, flat surface on which to form pairs of bases held together by hydrogen bonds. Though I initially went back to my like-with-like prejudices, I saw all too well that they led nowhere. When Jerry [Donohue, an American crystallographer working in the same laboratory] came in I looked up, saw that it was not Francis, and began shifting the bases in and out of various other pairing possibilities. Suddenly I became aware that an adenine-thymine pair held together by two hydrogen bonds was identical in shape to a guanine-cytosine pair held together by at least two hydrogen bonds. All the hydrogen bonds seemed to form naturally; no fudging was required to make the two types of base pairs identical in shape. Quickly I called Jerry over to ask him whether this time he had any objections to my new base pairs.

When he said no, my morale skyrocketed, for I suspected that we now had the answer to the riddle of why the number of purine residues exactly equaled the number of pyrimidine residues. Two irregular sequences of bases could be regularly packed in the center of a helix if a purine always hydrogen-bonded to a pyrimidine. Furthermore, the hydrogen-bonding requirement meant that adenine would always pair with thymine, while guanine could pair only with cytosine. Chargaff's rules then suddenly stood out as a consequence of a double-helical structure for DNA. Even more exciting, this type of double helix suggested a replication scheme much more satisfactory than my briefly considered like-with-like pairing. Always pairing adenine with thymine and guanine with cytosine meant that the base sequences of the two intertwined chains were complementary to each other. Given the base sequence of one chain, that of its partner was automatically determined. Conceptually, it was thus very easy to visualize how a single chain could be the template for the synthesis of a chain with the complementary sequence.

Upon his arrival Francis did not get more than halfway through the door before I let loose that the answer to

everything was in our hands. Though as a matter of principle he maintained skepticism for a few moments, the similarly shaped AT and GC pairs had their expected impact. His quickly pushing the bases together in a number of different ways did not reveal any other way to satisfy Chargaff's rules. A few minutes later he spotted the fact that the two glycosidic bonds (joining base and sugar) of each base pair were systematically related by a dyad axis perpendicular to the helical axis. Thus, both pairs could be flip-flopped over and still have their glycosidic bonds facing in the same direction. This had the important consequence that a given chain could contain both purines and pyrimidines. At the same time, it strongly suggested that the backbones of the two chains must run in opposite directions.

The question then became whether the AT and GC base pairs would easily fit the backbone configuration devised during the previous two weeks. At first glance this looked like a good bet, since I had left free in the center a large vacant area for the bases. However, we both knew that we would not be home until a complete model was built in which all the stereochemical contacts were satisfactory. There was also the obvious fact that the implications of its existence were far too important to risk crying wolf. Thus, I felt slightly queasy when at lunch Francis winged into the Eagle to tell everyone within hearing distance that we had found the secret of life.*

The rest is history. Shortly thereafter, the prestigious journal *Nature* carried an unpretentious two-page article entitled simply "Molecular Structure of Nucleic Acids: A Structure for Deoxyribose Nucleic Acid," by James Watson and Francis Crick. Though modest in length, that paper has had far-reaching implications. In fact, near the end, this article contains what some consider to be one of the greatest scientific understatements ever: "It has not escaped our notice that the specific pairing that we have postulated immediately suggests a possible copying mechanism for the genetic material."† The double-stranded model that Watson and Crick worked out in 1953 has proved to be correct in all its essential details, unleashing a revolution in the field of biology.

cell surface, play important roles in cellular recognition of extracellular signal molecules and of other cells. As noted earlier, polysaccharides include the storage polysaccharides starch and glycogen and the structural polysaccharide cellulose. Each of these polymers contains the six-carbon sugar glucose as its single repeating unit, but they differ in the nature of the bond between successive glucose units as well as in the presence and extent of side branches on the chains.

The Monomers Are Monosaccharides

The repeating units of polysaccharides are simple sugars called **monosaccharides** (from the Greek *mono*, meaning "single," and *sakkharon*, meaning "sugar"). A sugar can be defined as an aldehyde or ketone that has two or more hydroxyl groups. Thus, there are two categories of sugars: the *aldosugars*, with a terminal carbonyl group (**Figure 3-20a**), and the *ketosugars*, with an internal

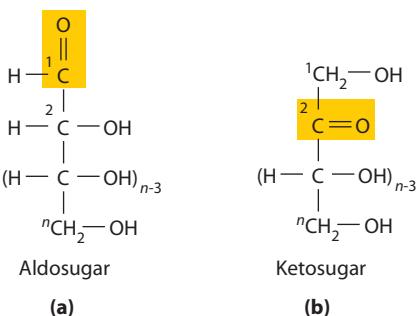

FIGURE 3-20 Structures of Monosaccharides. (a) Aldosugars have a carbonyl group on carbon atom 1. (b) Ketosugars have a carbonyl group on carbon atom 2. The number of carbon atoms in a monosaccharide (n) varies from three to seven.

carbonyl group (Figure 3-20b). Within these categories, sugars are named generically according to the number of carbon atoms they contain. Most sugars have between three and seven carbon atoms and thus are classified as *trioses* (three carbons), *tetroses* (four carbons), *pentoses* (five carbons), *hexoses* (six carbons), or *heptoses* (seven carbons). We have already encountered two pentoses—the ribose of RNA and the deoxyribose of DNA.

The single most common monosaccharide in the biological world is the aldohexose D-glucose, represented by the formula $C_6H_{12}O_6$ and by the structure shown in Figure 3-21. The formula $C_nH_{2n}O_n$ is characteristic of sugars and gave rise to the general term **carbohydrate** because compounds of this sort were originally thought of as “hydrates of carbon”— $C_n(H_2O)_n$. Although carbohydrates are not simply hydrated carbons, we will see in Chapter 11 that, for every CO_2 molecule incorporated

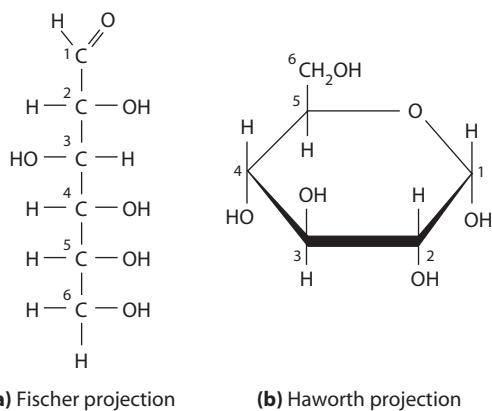

FIGURE 3-21 The Structure of D-Glucose. The D-glucose molecule can be represented by (a) the Fischer projection of the straight-chain form or (b) the Haworth projection of the ring form. In the Fischer projection, the —H and —OH groups are intended to project slightly out of the plane of the paper. In the Haworth projection, carbon atoms 2 and 3 are intended to jut out of the plane of the paper, and carbon atoms 5 and 6 are behind the plane of the paper. The —H and —OH groups then project upward or downward, as indicated. Notice that the carbon atoms are numbered from the more oxidized end of the molecule.

into sugar, one water molecule is consumed (see Reaction 11–2 on page 295).

In keeping with the general rule for numbering carbon atoms in organic molecules, the carbons of glucose are numbered beginning with the more oxidized end of the molecule, the carbonyl group. Because glucose has four asymmetric carbon atoms (carbon atoms 2, 3, 4, and 5), there are $2^4 = 16$ different possible stereoisomers of the aldohexose $C_6H_{12}O_6$. Here, we will concern ourselves only with D-glucose, which is the most stable of the 16 isomers.

Figure 3-21a illustrates D-glucose as it appears in what chemists call a **Fischer projection**, with the —H and —OH groups intended to project slightly out of the plane of the paper. This structure depicts glucose as a linear molecule, and it is often a useful representation of glucose for teaching purposes. In reality, however, glucose exists in the cell in a dynamic equilibrium between the linear (or straight-chain) configuration of Figure 3-21a and the ring form shown in Figure 3-21b. This ring forms when the oxygen atom of the hydroxyl group on carbon atom 5 forms a bond with carbon atom 1. Although the bonding of this oxygen atom to carbon atoms 1 and 5 seems unlikely from the Fischer projection, it is actually favored by the tetrahedral nature of each carbon atom in the chain. This ring form is the predominant structure, because it is energetically more stable.

Therefore, the more satisfactory representation of glucose is the **Haworth projection** shown in Figure 3-21b. This shows the spatial relationship of different parts of the molecule and makes the spontaneous formation of a bond between an oxygen atom and carbon atoms 1 and 5 appear more likely. Either of the representations of glucose shown in Figure 3-21 is valid, but the Haworth projection is generally preferred because it indicates both the ring form and the spatial relationship of the carbon atoms.

Notice that formation of the ring structure results in the generation of one of two alternative forms of the molecule, depending on the spatial orientation of the hydroxyl group on carbon atom 1. These alternative forms of glucose are designated α and β . As shown in Figure 3-22, α -D-glucose has the hydroxyl group on carbon atom 1

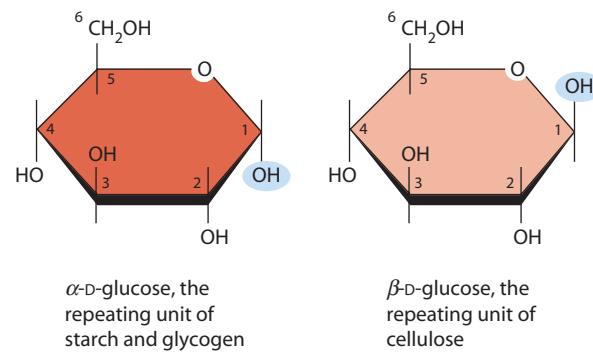

FIGURE 3-22 The Ring Forms of D-Glucose. The hydroxyl group on carbon atom 1 (blue oval) points downward in the α form and upward in the β form.

pointing downward in the Haworth projection, and β -D-glucose has the hydroxyl group on carbon atom 1 pointing upward. Starch and glycogen both have α -D-glucose as their repeating unit, whereas cellulose consists of strings of β -D-glucose.

In addition to the free monosaccharide and the long-chain polysaccharides, glucose also occurs in **disaccharides**, which consist of two monosaccharide units linked covalently. Three common disaccharides are shown in **Figure 3-23**. **Maltose** (malt sugar) consists of two glucose units linked together, whereas **lactose** (milk sugar) contains a glucose linked to a galactose and **sucrose** (common table sugar) has a glucose linked to a fructose. Both galactose and fructose will be discussed in more detail in Chapter 9, where the chemistry and metabolism of several sugars are considered.

Each of these disaccharides is formed by a condensation reaction in which two monosaccharides are linked together by the elimination of water. The resulting

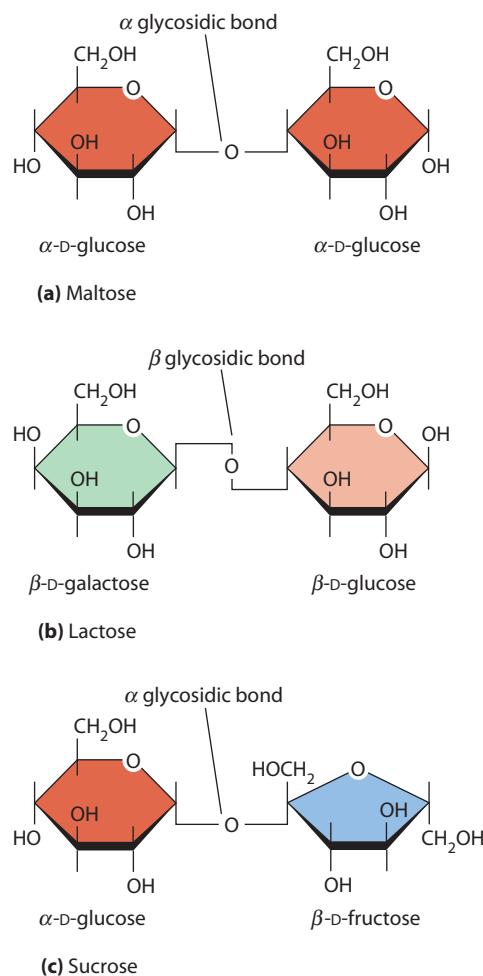

FIGURE 3-23 Some Common Disaccharides. (a) Maltose (malt sugar) consists of two molecules of α -D-glucose linked by an α glycosidic bond. (b) Lactose (milk sugar) consists of a molecule of β -D-galactose linked to a molecule of β -D-glucose by a β glycosidic bond. (c) Sucrose (table sugar) consists of a molecule of α -D-glucose linked to a molecule of β -D-fructose by an α glycosidic bond.

glycosidic bond is characteristic of linkages between sugars. In the case of maltose, both of the constituent glucose molecules are in the α form, and the glycosidic bond forms between carbon atom 1 of one glucose and carbon atom 4 of the other. This is called an α *glycosidic bond* because it involves a carbon atom 1 with its hydroxyl group in the α configuration. Lactose, on the other hand, is characterized by a β *glycosidic bond* because the hydroxyl group on carbon atom 1 of the galactose is in the β configuration. Some people lack the enzyme needed to hydrolyze this β glycosidic bond and are considered *lactose intolerant* due to their difficulty in metabolizing this disaccharide. The distinction between α and β again becomes critical when we get to the polysaccharides because both the three-dimensional configuration and the biological role of the polymer depend critically on the nature of the bond between the repeating monosaccharide units.

The Polymers Are Storage and Structural Polysaccharides

Polysaccharides typically perform either storage or structural roles in cells. The most familiar *storage polysaccharides* are **starch**, found in plant cells (**Figure 3-24a**), and **glycogen**, found in animal cells and bacteria (Figure 3-24b). Both of these polymers consist of α -D-glucose units linked together by $\alpha(1 \rightarrow 4)$ bonds. In addition to $\alpha(1 \rightarrow 4)$ bonds that link carbon atoms 1 and 4 of adjacent glucose units, these polysaccharides may contain occasional $\alpha(1 \rightarrow 6)$ linkages along the backbone, giving rise to side chains (Figure 3-24c). Storage polysaccharides can therefore be branched or unbranched polymers, depending on the presence or absence of $\alpha(1 \rightarrow 6)$ linkages.

Glycogen is highly branched, with $\alpha(1 \rightarrow 6)$ linkages occurring every 8 to 10 glucose units along the backbone and giving rise to short side chains of about 8 to 12 glucose units (Figure 3-24b). In our bodies, glycogen is stored mainly in the liver and in muscle tissue. In the liver, it is used as a source of glucose to maintain blood sugar levels. In muscle, it serves as a fuel source to generate ATP for muscle contraction. Bacteria also commonly store glycogen as a glucose reserve.

Starch, the glucose reserve commonly found in plant tissue, occurs both as unbranched **amylose** and as branched **amylopectin**. Like glycogen, amylopectin has $\alpha(1 \rightarrow 6)$ branches, but these occur less frequently along the backbone (once every 12 to 25 glucose units) and give rise to longer side chains (lengths of 20 to 25 glucose units are common; Figure 3-24a). Starch deposits are usually 10–30% amylose and 70–90% amylopectin. Starch is stored in plant cells as *starch grains* within the plastids—either within the *chloroplasts* that are the sites of carbon fixation and sugar synthesis in photosynthetic tissue or within the *amyloplasts*, which are specialized plastids for starch storage. The potato tuber, for example, is filled with starch-laden amyloplasts.

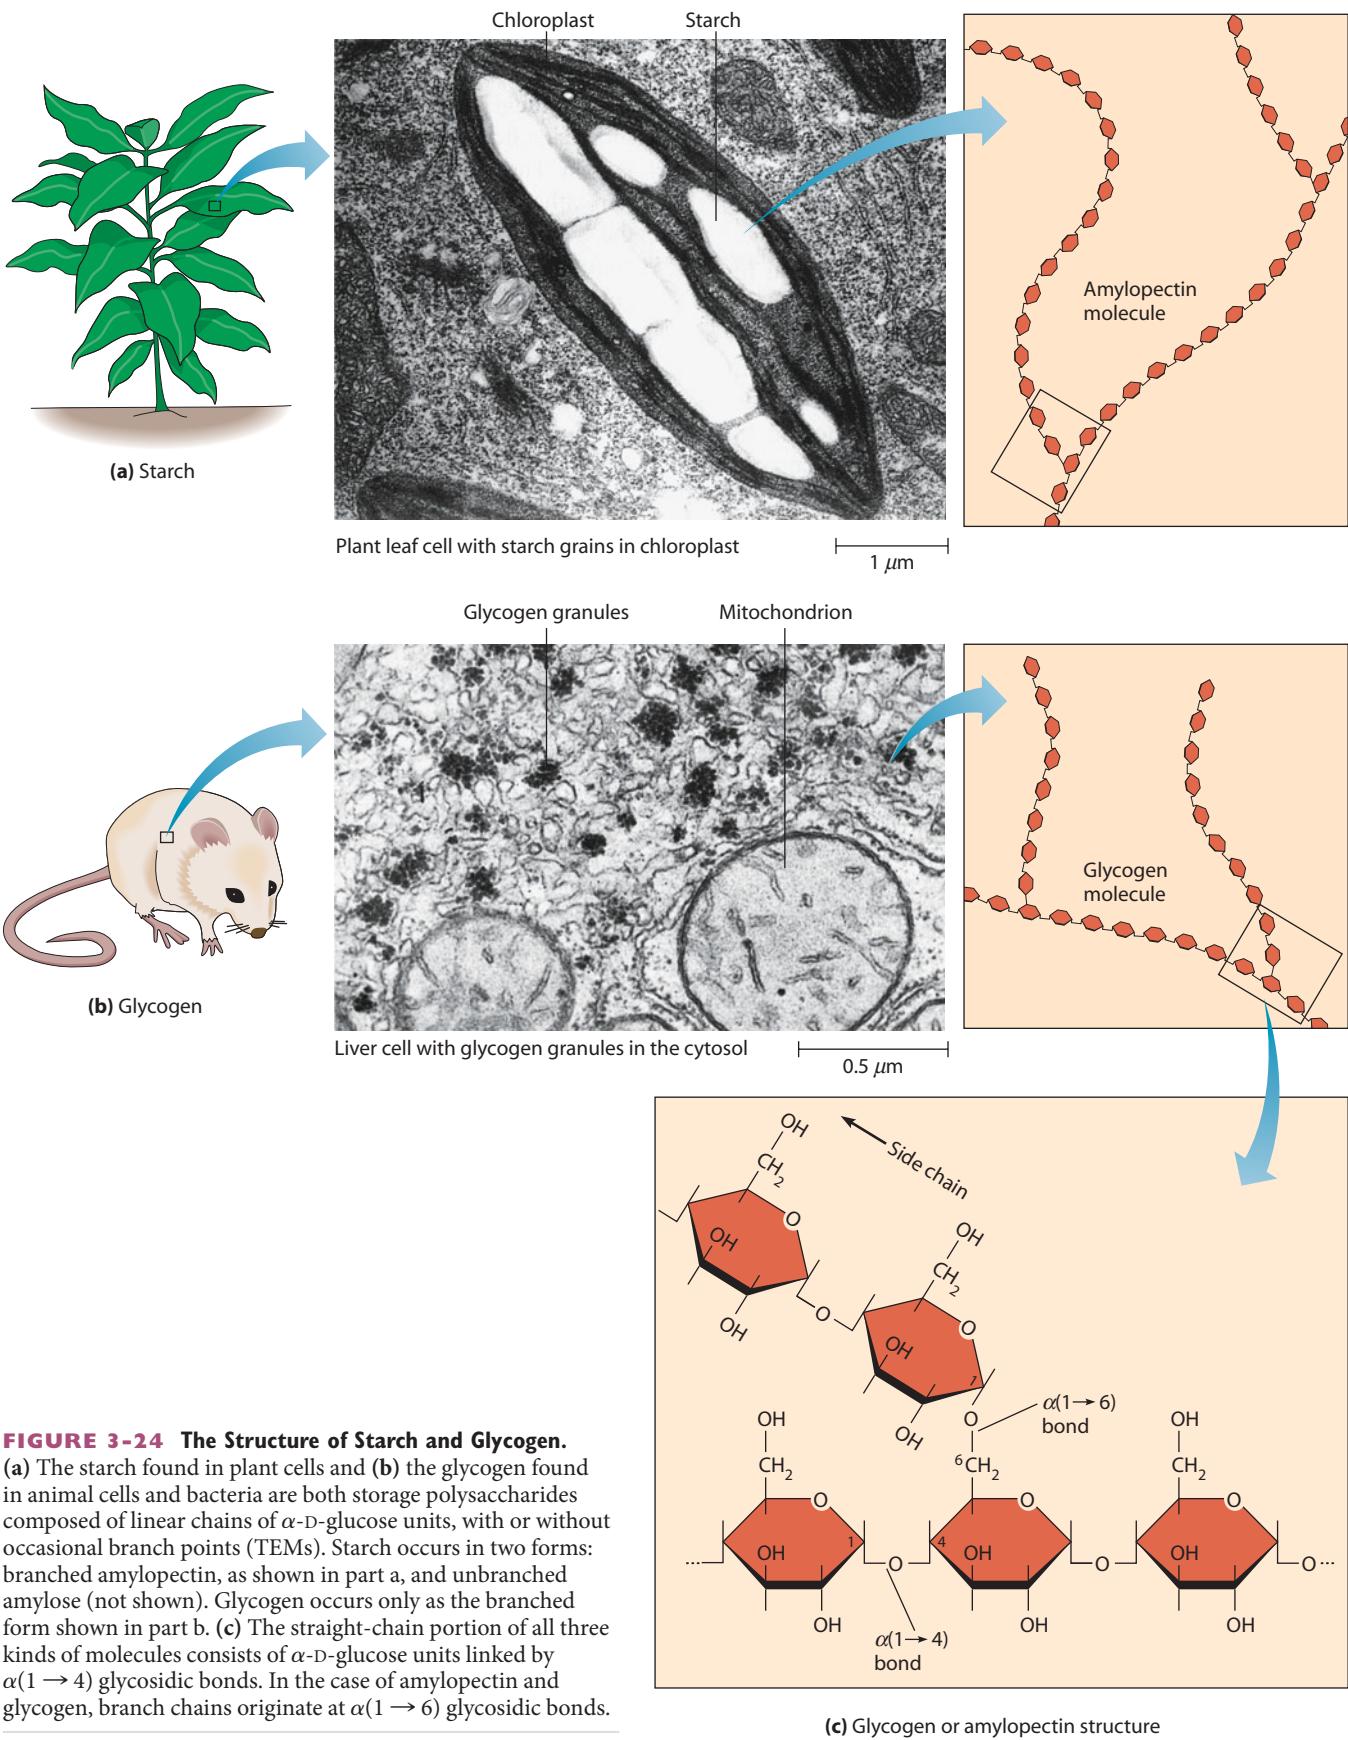

FIGURE 3-24 The Structure of Starch and Glycogen.
 (a) The starch found in plant cells and (b) the glycogen found in animal cells and bacteria are both storage polysaccharides composed of linear chains of α -D-glucose units, with or without occasional branch points (TEMs). Starch occurs in two forms: branched amylopectin, as shown in part a, and unbranched amylose (not shown). Glycogen occurs only as the branched form shown in part b. (c) The straight-chain portion of all three kinds of molecules consists of α -D-glucose units linked by $\alpha(1 \rightarrow 4)$ glycosidic bonds. In the case of amylopectin and glycogen, branch chains originate at $\alpha(1 \rightarrow 6)$ glycosidic bonds.

The best-known example of a *structural polysaccharide* is the **cellulose** found in plant cell walls (**Figure 3-25**). Cellulose is an important polymer quantitatively—more than half of the carbon in many plants is typically present in cellulose. Like starch and glycogen, cellulose is a polymer of glucose; however, the repeating monomer is β -D-glucose, and the linkage is therefore $\beta(1 \rightarrow 4)$. This bond has structural consequences that we will get to shortly, but it also has nutritional implications. Mammals do not possess an enzyme that can hydrolyze this $\beta(1 \rightarrow 4)$ bond and therefore cannot utilize cellulose as food. As a result, you can digest potatoes (starch) but not grass and wood (cellulose).

Animals such as cows and sheep might seem to be exceptions because they do eat grass and similar plant products. But they cannot cleave β glycosidic bonds either; they rely on microorganisms (bacteria and protozoa) in their digestive systems to do this for them. The microorganisms digest the cellulose, and the host animal then obtains the end-products of microbial digestion, now in a form the animal can use (glucose). Even termites do not actually digest wood. They simply chew it into small pieces that are then hydrolyzed to glucose monomers by microorganisms in their digestive tracts.

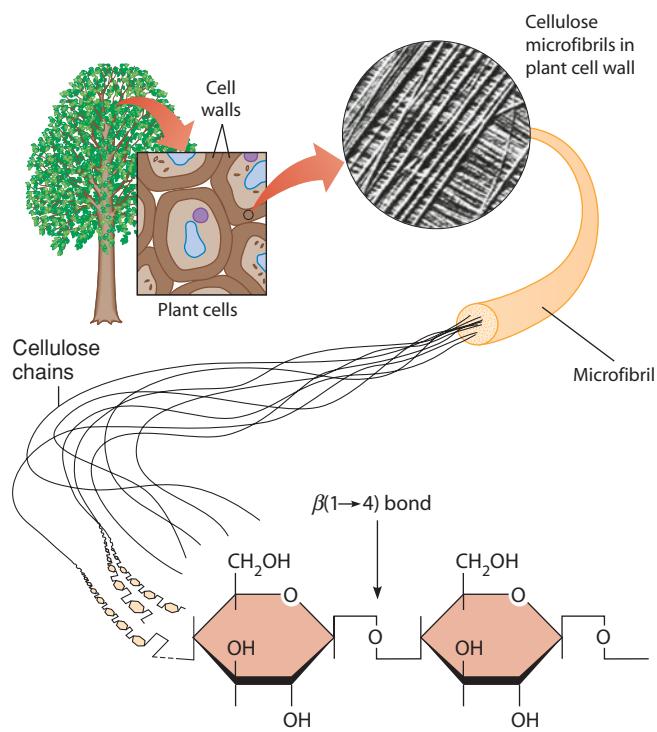

FIGURE 3-25 **The Structure of Cellulose.** Cellulose consists of long, unbranched chains of β -D-glucose units linked together by $\beta(1 \rightarrow 4)$ glycosidic bonds. Many such chains associate laterally and are held together by hydrogen bonds to form microfibrils. Individual microfibrils can be seen in the micrograph of a primary plant cell wall shown here (TEM). The $\beta(1 \rightarrow 4)$ glycosidic bonds cannot be hydrolyzed by most higher animals.

 [ACTIVITIES www.thecellplace.com](http://www.thecellplace.com) Carbohydrate structure and function

Although $\beta(1 \rightarrow 4)$ -linked cellulose is the most abundant structural polysaccharide, others are also known. The celluloses of fungal cell walls, for example, contain either $\beta(1 \rightarrow 4)$ or $\beta(1 \rightarrow 3)$ linkages, depending on the species. The cell wall of most bacteria is somewhat more complex and contains two kinds of sugars, *N-acetylglucosamine* (GlcNAc) and *N-acetylmuramic acid* (MurNAc). As shown in **Figure 3-26a**, GlcNAc and MurNAc are derivatives of β -glucosamine, a glucose molecule with the hydroxyl group on carbon atom 2 replaced by an amino group. GlcNAc is formed by acetylation of the amino group, and MurNAc requires the further addition of a three-carbon lactyl group to carbon atom 3. The cell wall polysaccharide is then formed by the linking of GlcNAc and MurNAc in a strictly alternating sequence with $\beta(1 \rightarrow 4)$ bonds (Figure 3-26b). Figure 3-26c shows the structure of yet another structural polysaccharide, the **chitin** found in insect exoskeletons, crustacean shells, and fungal cell walls. Chitin consists of GlcNAc units only, joined by $\beta(1 \rightarrow 4)$ bonds.

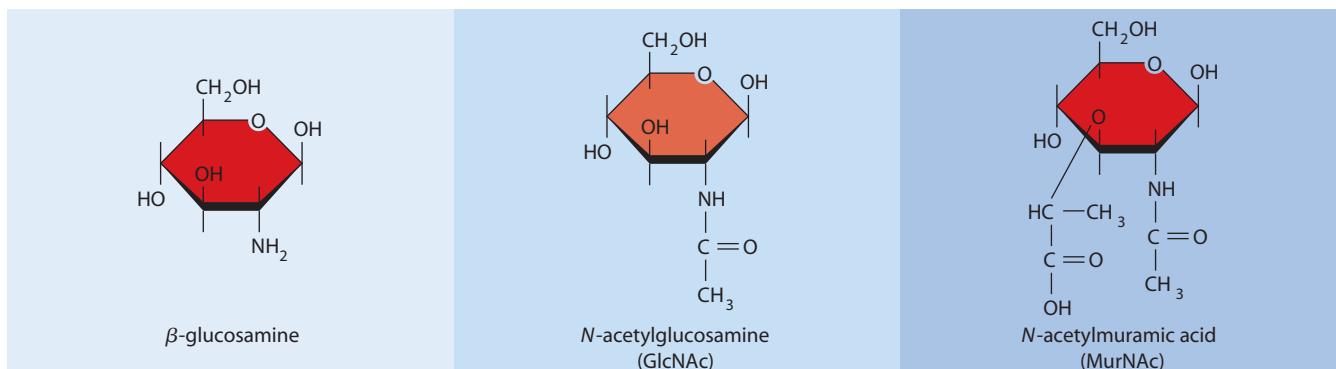

Polysaccharide Structure Depends on the Kinds of Glycosidic Bonds Involved

The distinction between the α and β glycosidic bonds of storage and structural polysaccharides has more than just nutritional significance. Because of the difference in linkages and therefore in the spatial relationship between successive glucose units, the two classes of polysaccharides differ markedly in secondary structure. The helical shape already established as a characteristic of both proteins and nucleic acids is also found in polysaccharides. Both starch and glycogen coil spontaneously into loose helices, but often the structure is not highly ordered due to the numerous side chains of amylopectin and glycogen.

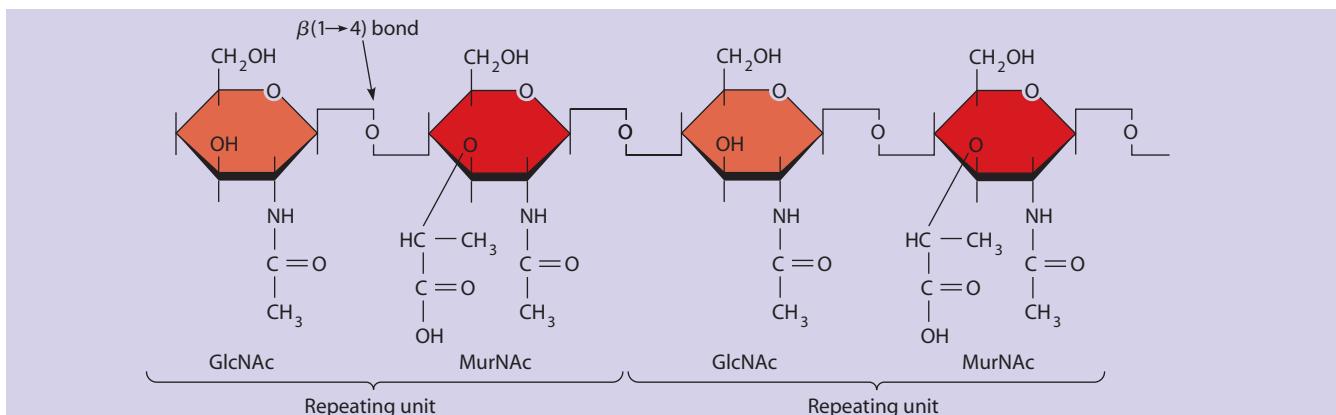

Cellulose, by contrast, forms rigid, linear rods. These in turn aggregate laterally into *microfibrils* (see Figure 3-25). Microfibrils are about 5–20 nm in diameter and are composed of about 36 cellulose chains. Plant and fungal cell walls consist of these rigid microfibrils of cellulose embedded in a *noncellulosic matrix* containing a rather variable mixture of several other polymers (*hemicellulose* and *pectin*, mainly) and a protein called *extensin* that occurs only in the cell wall. Cell walls have been aptly compared to reinforced concrete, in which steel rods are embedded in the cement before it hardens to add strength. In cell walls, the cellulose microfibrils are the “rods” and the noncellulosic matrix is the “cement.”

Lipids

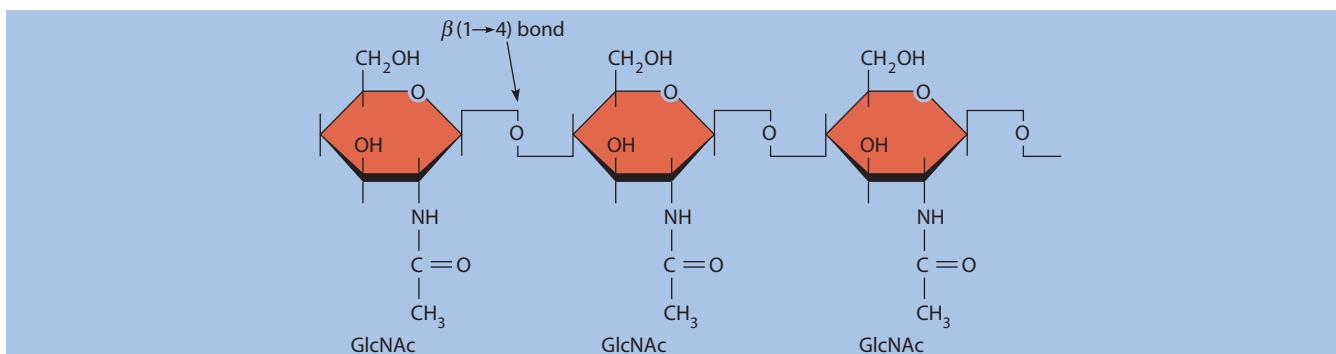

Strictly speaking, **lipids** differ from the macromolecules we have discussed so far in this chapter because they are not formed by the kind of linear polymerization that gives rise to proteins, nucleic acids, and polysaccharides. However, they are commonly regarded as macromolecules because of their high molecular weights and their presence in important cellular structures, particularly membranes. Also, the final steps in the synthesis of triglycerides, phospholipids,

and other large lipid molecules involve condensation reactions similar to those used in polymer synthesis.

Lipids constitute a rather heterogeneous category of cellular components that resemble one another more in their solubility properties than in their chemical structures. *The distinguishing feature of lipids is their hydrophobic nature.* Although they have little, if any, affinity for water, they are readily soluble in nonpolar solvents such as chloroform or ether. Accordingly, we can expect to find that they are rich in nonpolar hydrocarbon regions and have relatively few polar groups. Some lipids, however, are *amphipathic*, having both

a polar and a nonpolar region. As we have already seen in Figures 2-11 and 2-12, this characteristic has important implications for membrane structure.

Because they are defined in terms of solubility characteristics rather than chemical structure, we should not be surprised to find that lipids as a group include molecules that are quite diverse in terms of structure, chemistry, and function. Functionally, lipids play at least three main roles in cells. Some serve as forms of *energy storage*, others are involved in *membrane structure*, and still others have *specific biological functions*, such as the transmission of

chemical signals into and within the cell. We will discuss lipids in terms of six main classes, based on their chemical structure: *fatty acids*, *triacylglycerols*, *phospholipids*, *glycolipids*, *steroids*, and *terpenes*. Note that, because of the wide variety of lipids and the fact that members of different classes sometimes share structural and chemical similarities,

this is only one of several different ways to classify lipids. The six main classes of lipids as we will discuss them are illustrated in **Figure 3-27**, which includes representative examples of each class. We will look briefly at each of these six kinds of lipids, pointing out their functional roles in the process.

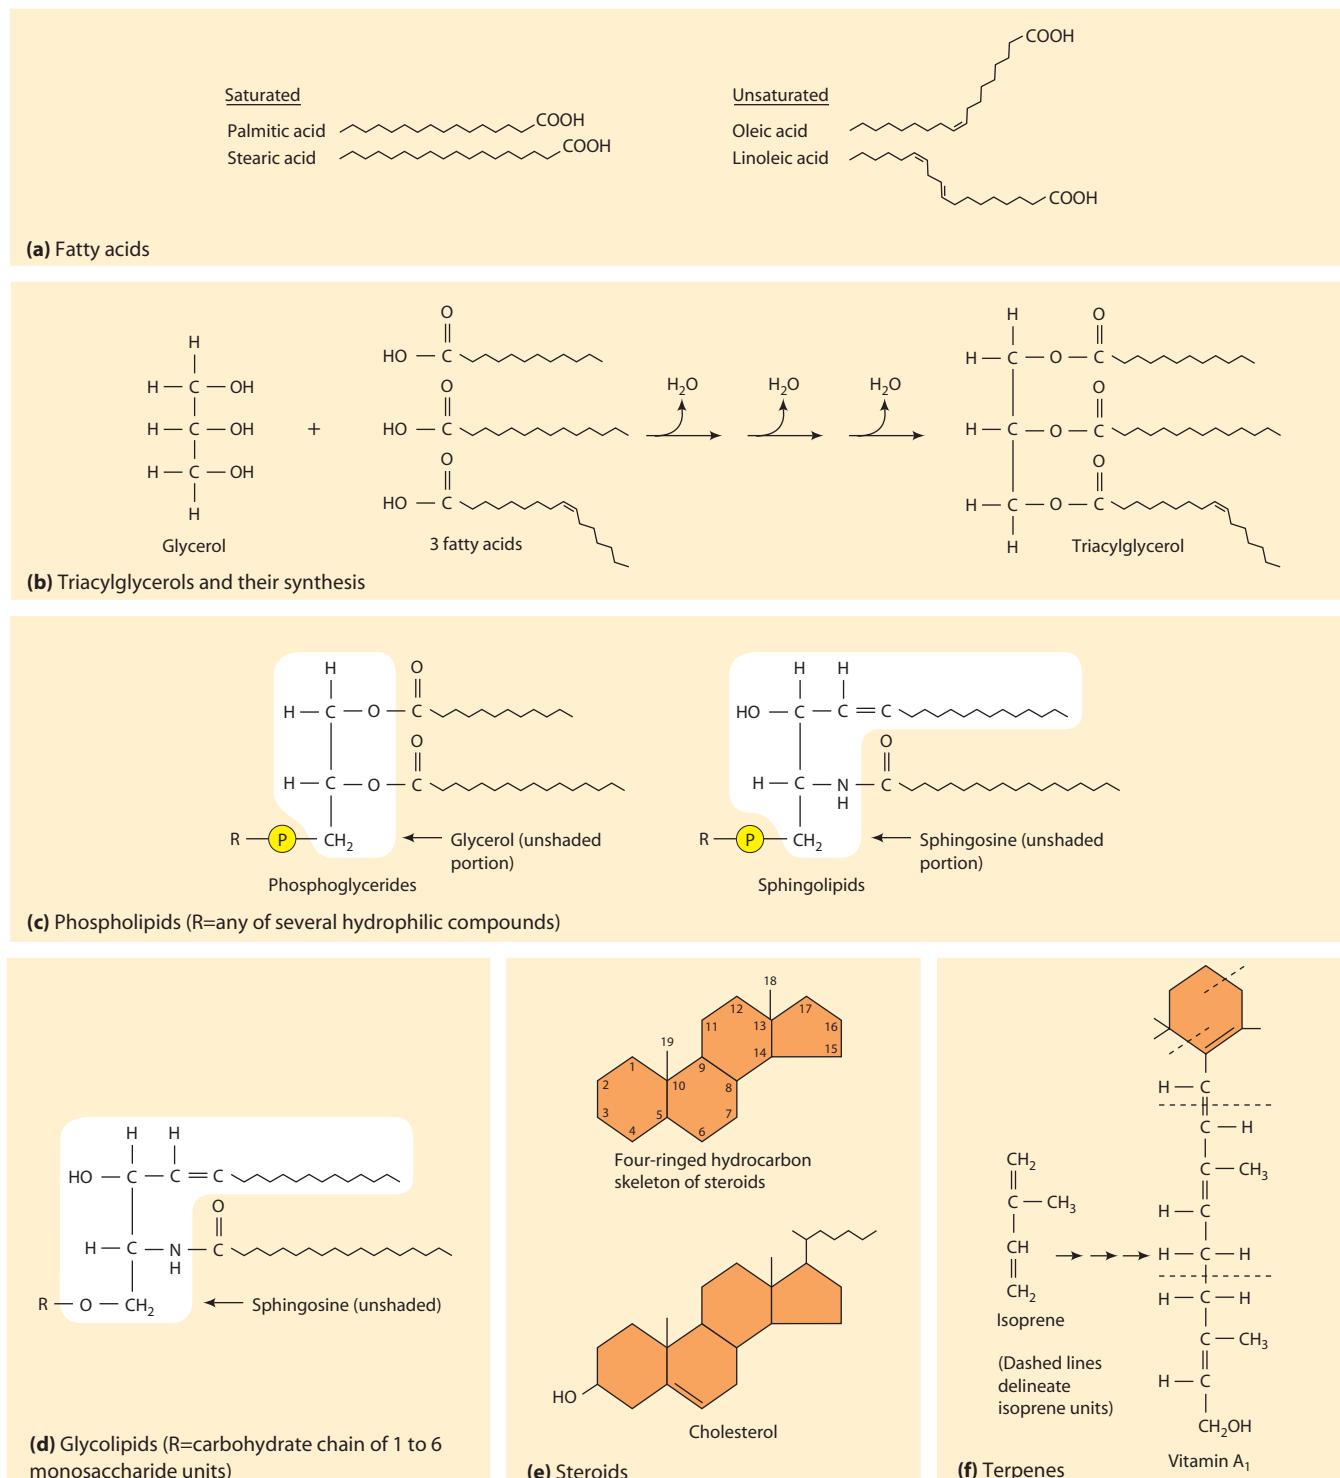

FIGURE 3-27 The Main Classes of Lipids. The zigzag lines in parts a-d represent the long hydrocarbon chains of fatty acids. Each corner of the zigzag lines represents a methylene ($-\text{CH}_2-$) group.

Table 3-5

Some Common Fatty Acids in Cells

Number of Carbons	Number of Double Bonds	Common Name*
12	0	Laurate
14	0	Myristate
16	0	Palmitate
18	0	Stearate
20	0	Arachidate
16	1	Palmitoleate
18	1	Oleate
18	2	Linoleate
18	3	Linolenate
20	4	Arachidonate

*Shown are the names for the ionized forms of the fatty acids as they exist at the near-neutral pH of most cells. For the names of the free fatty acids, simply replace the *-ate* ending with *-ic acid*.

Fatty Acids Are the Building Blocks of Several Classes of Lipids

We will begin our discussion with **fatty acids** because they are components of several other kinds of lipids. A fatty acid is a long, unbranched hydrocarbon chain with a carboxyl group at one end (Figure 3-27a). The fatty acid molecule is therefore amphipathic; the carboxyl group renders one end (often called the “head”) polar, whereas the hydrocarbon “tail” is nonpolar. Fatty acids contain a variable, but usually even, number of carbon atoms. The usual range is from 12 to 20 carbon atoms per chain, with 16- and 18-carbon fatty acids especially common.

Table 3-5 lists some common fatty acids. Fatty acids with even numbers of carbon atoms are greatly favored because fatty acid synthesis involves the stepwise addition of two-carbon units to a growing fatty acid chain. Because they are highly reduced, having many hydrogen atoms but few oxygen atoms, fatty acids yield a great deal of energy upon oxidation and are therefore efficient forms of energy storage—a gram of fat contains more than twice as much usable energy as a gram of sugar or polysaccharide.

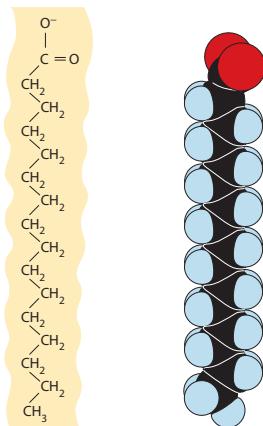

Table 3-5 also shows the variability in fatty acids due to the presence of double bonds between carbons. Fatty acids without double bonds are referred to as **saturated fatty acids** because every carbon atom in the chain has the maximum number of hydrogen atoms attached to it (Figure 3-28a). The general formula for a saturated fatty acid with n carbon atoms is $C_nH_{2n}O_2$. Saturated fatty acids have long, straight chains that pack together well. By contrast, **unsaturated fatty acids** contain one or more double bonds, resulting in a bend or kink in the chain that prevents tight packing (Figure 3-28b; also see Figure 7-14). Structures and models of several of these fatty acids are shown in Table 7-2, page 168.

There has been much recent concern about a particular type of unsaturated fatty acid known as a *trans fat*. *Trans fats* contain unsaturated fatty acids with a particular type of double bond that causes less of a bend in the fatty acid chain (see page 171). This causes them to resemble saturated fatty acids both in their shape and in their ability to pack together more tightly than typical unsaturated fatty acids. While naturally present in small amounts in meat and dairy products, *trans fats* are produced artificially during the commercial production of shortening and margarine. *Trans fats* have been linked to changes in blood cholesterol that are associated with increased risk of heart disease.

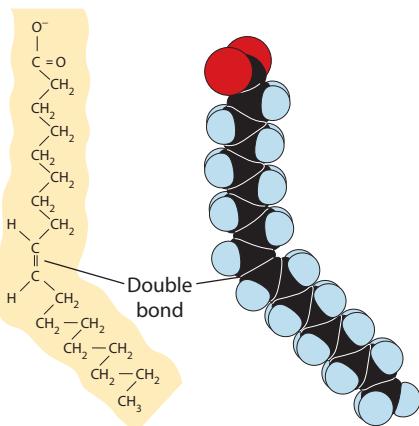

Triacylglycerols Are Storage Lipids

The **triacylglycerols**, also called *triglycerides*, consist of a glycerol molecule with three fatty acids linked to it. As shown in Figure 3-27b, **glycerol** is a three-carbon alcohol with a hydroxyl group on each carbon. Fatty acids are linked to glycerol by *ester bonds*, which are formed by the removal of water. Triacylglycerols are synthesized stepwise, with one fatty acid added at a time. *Monoacylglycerols* contain a single fatty acid, *diacylglycerols* have two, and *triacylglycerols* have three. The three fatty acids of a given triacylglycerol need not be identical. They can—and generally do—vary in chain length, degree of unsaturation, or both. Each fatty acid in a triacylglycerol is linked to a carbon atom of glycerol by means of a condensation reaction.

FIGURE 3-28 Structures of Saturated and Unsaturated Fatty Acids. (a) The saturated 16-carbon fatty acid palmitate. (b) The unsaturated 18-carbon fatty acid oleate. The space-filling models are intended to emphasize the overall shape of the molecules. Notice the kink that the double bond creates in the oleate molecule.

(a) Palmitate (saturated)

(b) Oleate (unsaturated)

The main function of triacylglycerols is to store energy, which will be of special interest to our discussion of energy metabolism in Chapter 10. In some animals, triacylglycerols also provide insulation against low temperatures. Animals such as walruses, seals, and penguins that live in very cold climates store triacylglycerols under their skin and depend on the insulating properties of this fat for survival.

Triacylglycerols containing mostly saturated fatty acids are usually solid or semisolid at room temperature and are called *fats*. Fats are prominent in the bodies of animals, as evidenced by the fat that comes with most cuts of meat, by the large quantity of lard that is obtained as a by-product of the meat-packing industry, and by the widespread concern people have that they are “getting fat.” In plants, most triacylglycerols are liquid at room temperature, as the term *vegetable oil* suggests. Because the fatty acids of oils are predominantly unsaturated, their hydrocarbon chains have kinks that prevent an orderly packing of the molecules. As a result, vegetable oils have lower melting temperatures than most animal fats do. Soybean oil and corn oil are two familiar vegetable oils. Vegetable oils can be converted into solid products such as margarine and shortening by hydrogenation (saturation) of the double bonds, a process explored further in Problem 3-15 at the end of the chapter.

Phospholipids Are Important in Membrane Structure

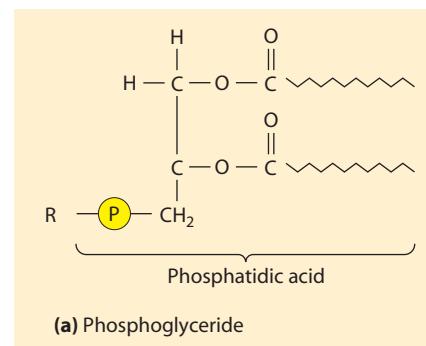

Phospholipids make up a third class of lipids (see Figure 3-27c). They are similar to triacylglycerols in some chemical details but differ strikingly in their properties and their role in the cell. First and foremost, phospholipids are important in membrane structure due to their amphipathic nature. In fact, as we saw in Chapter 2, they are critical to the bilayer structure found in all membranes (see Figure 2-12). Based on their chemistry, phospholipids are classified as *phosphoglycerides* or *sphingolipids* (see Figure 3-27c).

Phosphoglycerides are the predominant phospholipids present in most membranes. Like triacylglycerols, a phosphoglyceride consists of fatty acids that are esterified to a glycerol molecule. However, the basic component of a phosphoglyceride is **phosphatidic acid**, which has just two fatty acids and a phosphate group attached to a glycerol backbone (Figure 3-29a). Phosphatidic acid is a key intermediate in the synthesis of other phosphoglycerides but is itself not at all prominent in membranes. Instead, membrane phosphoglycerides invariably have, in addition, a small hydrophilic alcohol linked to the phosphate by an ester bond and represented in Figure 3-29a as an R group. The alcohol is usually *serine*, *ethanolamine*, *choline*, or *inositol* (see Figure 3-29b), groups that contribute to the polar nature of the phospholipid head group.

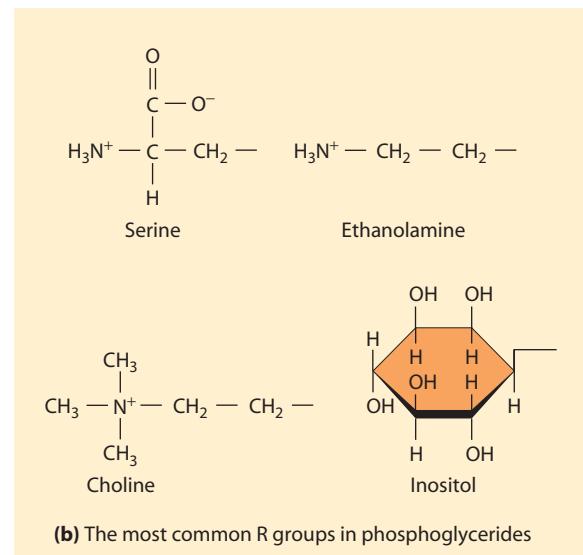

The combination of a highly polar head and two long nonpolar chains gives phosphoglycerides the characteristic amphipathic nature that is so critical to their role in membrane structure. As we saw earlier, the fatty acids can vary considerably in both length and the presence and position

of sites of unsaturation. In membranes, 16- and 18-carbon fatty acids are most common, and a typical phosphoglyceride molecule is likely to have one saturated and one unsaturated fatty acid. The length and the degree of unsaturation of fatty acid chains in membrane phospholipids profoundly affect membrane fluidity and can, in fact, be regulated by the cells of some organisms.

In addition to the phosphoglycerides, some membranes contain another class of phospholipid called **sphingolipids**, which are important in membrane structure and cell signaling. When sphingolipids were first discovered by Johann Thudicum in the late nineteenth century, their biological role seemed as enigmatic as the Sphinx, after which he named them. As the name suggests, these lipids are based not on glycerol but on the amine alcohol **sphingosine**. As shown in Figure 3-27c, sphingosine has a long hydrocarbon chain with a single site of unsaturation near the polar end. Through its amino group, sphingosine can form an amide bond to a long-chain fatty acid (up to 34 carbons). The resulting molecule is called a *ceramide* and

(a) Phosphoglyceride

(b) The most common R groups in phosphoglycerides

FIGURE 3-29 Structures of Common Phosphoglycerides.

(a) A phosphoglyceride consists of a molecule of phosphatidic acid (glycerol esterified to two fatty acids and a phosphate group) with a small polar alcohol, represented as R, also esterified to the phosphate group. (b) The four most common R groups found in phosphoglycerides are serine, ethanolamine, choline, and inositol, the first three of which contain a positively charged amino group or nitrogen atom.

consists of a polar region flanked by two long, nonpolar tails, giving it a shape approximating that of the phospholipids.

The hydroxyl group on carbon atom 1 of sphingosine juts out from what is effectively the head of this hairpin molecule. A sphingolipid is formed when any of several polar groups becomes linked to this hydroxyl group. A whole family of sphingolipids exists, differing only in the chemical nature of the polar group attached to the hydroxyl group of the ceramide (the R group of Figure 3-27c). Sphingolipids are present predominantly in the outer leaflet of the plasma membrane bilayer, where they often are found in *lipid rafts*, which, as we will see in Chapter 7, are localized microdomains within a membrane that facilitate communication with the external environment of the cell.

Glycolipids Are Specialized Membrane Components

Glycolipids are lipids containing a carbohydrate group instead of a phosphate group and are typically derivatives of sphingosine or glycerol (see Figure 3-27d). Those containing sphingosine are called *glycosphingolipids*. The carbohydrate group attached to a glycolipid may contain one to six sugar units, which can be D-glucose, D-galactose, or N-acetyl-D-galactosamine. These carbohydrate groups, like phosphate groups, are hydrophilic, giving the glycolipid an amphipathic nature. Glycolipids are specialized constituents of some membranes, especially those found in certain plant cells and in the cells of the nervous system. Glycolipids occur largely in the outer monolayer of the plasma membrane, and the glycosphingolipids are often sites of biological recognition on the surface of the plasma membrane, a topic we will consider further in Chapter 14.

Steroids Are Lipids with a Variety of Functions

The **steroids** constitute yet another distinctive class of lipids. Steroids are derivatives of a four-ringed hydrocarbon skeleton (see Figure 3-27e), which makes them structurally distinct from other lipids. In fact, the only property linking them to the other classes of lipids is that they are relatively nonpolar and therefore hydrophobic. As **Figure 3-30** illustrates, steroids differ from one another in the number and positions of double bonds and functional groups.

Steroids are found almost exclusively in eukaryotic cells. The most common steroid in animal cells is **cholesterol**, the structure of which is shown in Figure 3-27e. Cholesterol is an amphipathic molecule, with a polar head group (the hydroxyl group at position 3) and a nonpolar hydrocarbon body and tail (the four-ringed skeleton and the hydrocarbon side chain at position 17). Because most of the molecule is hydrophobic, cholesterol is insoluble and is found primarily in membranes. It occurs in the plasma membrane of animal cells and in most of the membranes of organelles, except the inner membranes of mitochondria and chloroplasts. Similar membrane steroids also occur in other cells, including *stigmasterol* and *sitosterol* in plant cells, *ergosterol* in fungal cells, and related sterols in *Mycoplasma* bacteria.

Cholesterol is the starting point for the synthesis of all the **steroid hormones** (Figure 3-30), which include the male and female *sex hormones*, the *glucocorticoids*, and the *mineralocorticoids*. The sex hormones include the *estrogens* produced by the ovaries of females (*estradiol*, for example) and the *androgens* produced by the testes of males (*testosterone*, for example). The glucocorticoids (*cortisol*, for example) are a family of hormones that promote gluconeogenesis (synthesis of glucose) and suppress inflammation reactions. Mineralocorticoids such as *aldosterone* regulate ion balance by promoting the reabsorption of sodium, chloride, and bicarbonate ions in the kidney.

Terpenes Are Formed from Isoprene

The final class of lipids shown in Figure 3-27 consists of the **terpenes**. Terpenes are synthesized from the five-carbon compound *isoprene* and are therefore also called *isoprenoids*. Isoprene and its derivatives are joined together in various combinations to produce such substances as *vitamin A* (see Figure 3-27f), a required nutrient in our bodies, and *carotenoid pigments*, which are involved in light harvesting in plants during photosynthesis. Other isoprene-based compounds are *dolichols*, which are involved in activating sugar derivatives, and electron carriers such as *coenzyme Q* and *plastoquinone*, which we will encounter when we study respiration and photosynthesis in detail in Chapters 10 and 11. Finally, polymers of isoprene units known as polyisoprenoids are found in the cell membranes of Archaea, a unique domain of organisms distinct from eukaryotes and bacteria that we will encounter in Chapter 4.

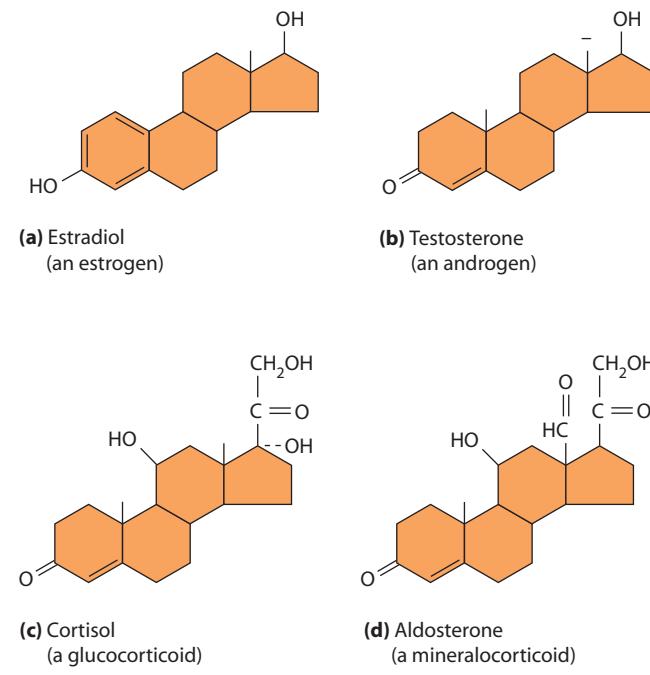

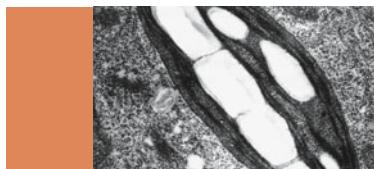

FIGURE 3-30 Structures of Several Common Steroid Hormones.

Among the many steroids that are synthesized from cholesterol are the hormones (a) estradiol, an estrogen; (b) testosterone, an androgen; (c) cortisol, a glucocorticoid; and (d) aldosterone, a mineralocorticoid.

SUMMARY OF KEY POINTS

The Macromolecules of the Cell

- Three classes of macromolecular polymers are prominent in cells: proteins, nucleic acids, and polysaccharides. Lipids are not long, polymeric macromolecules, but they are included in this chapter because of their general importance as constituents of cells (especially membranes) and because their synthesis involves condensation reactions between smaller constituents.
- Proteins and nucleic acids are macromolecules in which the particular ordering of monomers is critical to their roles in the cell. Polysaccharides, on the other hand, usually contain only one or a few kinds of repeating units and play storage or structural roles instead.

Proteins

- All of the thousands of different proteins in a cell are linear chains of amino acid monomers. Each of the 20 different amino acids found in proteins has a different R group, which can be either hydrophobic, hydrophilic uncharged, or hydrophilic charged. These amino acids can be linked together in any sequence via peptide bonds to form the wide variety of polypeptides that make up monomeric and multimeric proteins.
- The amino acid sequence of a polypeptide (its primary structure) usually contains all of the information necessary to specify local folding into α helices and β sheets (secondary structure), overall three-dimensional shape (tertiary structure), and, for multimeric proteins, association with other polypeptides (quaternary structure).
- Major forces influencing polypeptide folding and stability are covalent disulfide bond formation and several types of noncovalent interactions: hydrogen bonds, ionic bonds, van der Waals interactions, and hydrophobic interactions.
- Despite extensive knowledge of the forces involved in protein folding, we are still not able to predict the final folded tertiary structure of a protein from its primary amino acid sequence, except in the case of peptides and relatively small proteins.

Nucleic Acids

- The nucleic acids DNA and RNA are informational macromolecules composed of nucleotide monomers linked together by phosphodiester bridges in a specific order. Each nucleotide is composed of a deoxyribose or ribose sugar, a phosphate, and a purine or pyrimidine base.
- The base sequence of the nucleotides in a particular segment of DNA known as a gene determines the sequence of the amino acids in the protein encoded by that gene. DNA is the carrier of genetic information in a cell, while mRNA, tRNA, and rRNA function mainly in expression of the information in DNA by their involvement in protein synthesis.

- While RNA is mainly single stranded, DNA forms a double-stranded helix based on complementary base pairing (A with T and C with G) that is stabilized by hydrogen bonding. Elucidation of the double-helical structure of DNA was a defining biological breakthrough of the twentieth century.
- In addition to mRNA, tRNA, and rRNA, several other types of RNAs have been discovered in cells, including microRNA (miRNA) and small interfering RNA (siRNA). These RNAs regulate gene expression either by inhibiting translation or by promoting mRNA degradation.

Polysaccharides

- In contrast to nucleic acids and proteins, polysaccharides show little variation in sequence and serve storage or structural roles. They typically consist either of a single type of monosaccharide or of two alternating monosaccharides linked together by either α or β glycosidic bonds. The type of glycosidic bond determines whether the polysaccharide serves as energy storage or as a structural polysaccharide.
- The α linkages are readily digestible by animals and are found in storage polysaccharides such as starch and glycogen, which consist solely of glucose monomers. In contrast, the β glycosidic bonds of cellulose and chitin are not digestible by animals and give these molecules a rigid shape suitable to their functions as structural molecules.

Lipids

- Lipids are not true polymers but are often considered macromolecules due to their high molecular weight and their frequent association with macromolecules, particularly proteins. Lipids vary substantially in chemical structure but are grouped together because they share the common property of being hydrophobic and thus are nearly insoluble in water.
- Fatty acids are lipids consisting of a long hydrocarbon chain of 12–20 carbon atoms with a carboxylic acid group at one end. They are energy-rich molecules found in the triacylglycerols that make up animal fats and vegetable oils, as well as in the phospholipids found in all cellular membranes.
- Phosphoglycerides and sphingolipids are types of phospholipids that make up the lipid bilayer of biological membranes. They are amphipathic molecules with two hydrophobic fatty acid chains and a polar phosphate-containing head group.
- Glycolipids are similar to phospholipids but contain a polar carbohydrate group instead of phosphate. They are often found on the outer surface of membranes, where they play a role in cell recognition.
- Other important cellular lipids are the steroids (including cholesterol and several sex hormones) and the terpenes (including vitamin A and some important coenzymes).

MAKING CONNECTIONS

Now that you are familiar with the types of macromolecules in cells, where in our upcoming studies do you suppose we will see proteins, nucleic acids, polysaccharides, and lipids again? Not to sound repetitive, but—as with chemistry in Chapter 2—again the simple answer is “everywhere.” For example, in the next chapter we will survey the main structures and organelles of the cell, all of which are composed of macromolecules important to their functions. In the next few chapters, we will see how proteins act as enzyme catalysts in cellular reactions that provide both energy and usable biochemical compounds for the cell. We will also study the structure of phospholipid membranes and the mechanisms

used by transport proteins to move material into and out of the cell across these membranes. In subsequent chapters, we will see how proteins are involved in motility, muscle contraction, structural support, and cell-to-cell communication. Polysaccharides, as you know, serve as storage and structural molecules in cells. Soon, we will see them as components of glycoproteins and glycolipids that have important roles in cell recognition and protein trafficking. Finally, in later chapters, we will study the unique importance of nucleic acids as the carriers of genetic information, and we will see how they interact with proteins in controlling gene expression and cell division in both normal cells and cancer cells.

PROBLEM SET

More challenging problems are marked with a •.

3-1 Polymers and Their Properties. For each of the six biological polymers listed, indicate which of the properties apply. Each polymer has multiple properties, and a given property may be used more than once.

Polymers

- (a) Cellulose
- (b) Messenger RNA
- (c) Globular protein
- (d) Amylopectin
- (e) DNA
- (f) Fibrous protein

Properties

1. Branched-chain polymer
2. Extracellular location
3. Glycosidic bonds
4. Informational macromolecule
5. Peptide bond
6. β linkage
7. Phosphodiester bridge
8. Nucleoside triphosphates
9. Helical structure possible
10. Synthesis requires a template

3-2 Stability of Protein Structure. Several different kinds of bonds or interactions are involved in generating and maintaining the structure of proteins. List five such bonds or interactions, give an example of an amino acid that might be involved in each, and indicate which level(s) of protein structure might be generated or stabilized by that particular kind of bond or interaction.

3-3 Amino Acid Localization in Proteins. Amino acids tend to be localized either in the interior or on the exterior of a globular protein molecule, depending on their relative affinities for water.

- (a) For each of the following pairs of amino acids, choose the one that is more likely to be found in the interior of a protein molecule, and explain why:

alanine; glycine glutamate; aspartate
tyrosine; phenylalanine methionine; cysteine

(b) Explain why cysteine residues with free sulphydryl groups tend to be localized on the exterior of a protein molecule, whereas those involved in disulfide bonds are more likely to be buried in the interior of the molecule.

3-4 Sickle-Cell Anemia. Sickle-cell anemia (see page 52) is a striking example of the drastic effect a single amino acid substitution can have on the structure and function of a protein.

- (a) Given the chemical nature of glutamate and valine, can you suggest why substitution of valine for glutamate at position 6 of the β chain would be especially deleterious?
- (b) Suggest several amino acids that would be much less likely than valine to cause impairment of hemoglobin function if substituted for the glutamate at position 6 of the β chain.
- (c) Can you see why, in some cases, two proteins could differ at several points in their amino acid sequence and still be very similar in structure and function? Explain.

3-5 Hair Versus Silk. The α -keratin of human hair is a good example of a fibrous protein with extensive α -helical structure. Silk fibroin is also a fibrous protein, but it consists primarily of β -sheet structure. Fibroin is essentially a polymer of alternating glycines and alanines, whereas α -keratin contains most of the common amino acids and has many disulfide bonds.

- (a) If you were able to grab onto both ends of an α -keratin polypeptide and pull, you would find it to be both extensible (it can be stretched to about twice its length in moist heat) and elastic (when you let go, it will return to its normal length). In contrast, a fibroin polypeptide has essentially no extensibility, and it has great resistance to breaking. Explain these differences.
- (b) Can you suggest why fibroin assumes a pleated sheet structure, whereas α -keratin exists as an α helix and even reverts spontaneously to a helical shape when it has been stretched artificially?

3-6 The “Permanent” Wave That Isn’t. The “permanent” wave that your local beauty parlor offers depends critically on rearrangements in the extensive disulfide bonds of keratin that give your hair its characteristic shape. To change the shape of

your hair (that is, to give it a wave or curl), the beautician first treats your hair with a sulphydryl reducing agent, then uses curlers or rollers to impose the desired artificial shape, and follows this by treatment with an oxidizing agent.

- (a) What is the chemical basis of a permanent? Be sure to include the use of a reducing agent and an oxidizing agent in your explanation.
- (b) Why do you suppose a permanent isn't permanent? (Explain why the wave or curl is gradually lost during the weeks following your visit to the beautician.)
- (c) Can you suggest an explanation for naturally curly hair?

3-7 Features of Nucleic Acids. For each of the following features of nucleic acids, indicate whether it is true of DNA only (D), of RNA only (R), of both DNA and RNA (DR), or of neither (N).

- (a) Contains the base adenine.
- (b) Contains the nucleotide deoxythymidine monophosphate.
- (c) Occurs only in single-stranded form.
- (d) Is involved in the process of protein synthesis in the cytoplasm of the cells in the liver.
- (e) Is synthesized by a process that involves base pairing.
- (f) Is an inherently directional molecule, with an N-terminus on one end and a C-terminus on the other end.

3-8 Wrong Again. For each of the following false statements, change the statement to make it true, and explain why it was false:

- (a) Proteins, nucleic acids, polysaccharides, and lipids are all very long polymers that are synthesized by condensation of individual monomer units.
- (b) The amino acid proline is not found in α helices because its R group is too large to fit into the α helix.
- (c) While a protein can be denatured by high-temperature treatment, extremes of pH generally have no effect on tertiary structure.
- (d) Nucleic acids are synthesized from monomers that are activated by linking them to a carrier molecule in an energy-requiring reaction.
- (e) α -D-glucose and β -D-glucose are stereoisomers.
- (f) Fatty acids are important components of all cellular lipids.
- (g) It is easy to predict the final folded structure of a protein from its amino acid sequence using today's powerful supercomputers.
- (h) Most cells contain only three types of RNA: mRNA, tRNA, and rRNA.

3-9 Storage Polysaccharides. The only common examples of branched-chain polymers in cells are the storage polysaccharides glycogen and amylopectin. Both are degraded exolytically, which means by stepwise removal of terminal glucose units.

- (a) Why might it be advantageous for a storage polysaccharide to have a branched-chain structure instead of a linear structure?
- (b) Can you foresee any metabolic complications in the process of glycogen degradation? How do you think the cell handles this?
- (c) Can you see why cells that degrade amylose instead of amylopectin have enzymes capable of endolytic (internal) as well as exolytic cleavage of glycosidic bonds?
- (d) Why do you suppose the structural polysaccharide cellulose does not contain branches?

3-10 Carbohydrate Structure. From the following descriptions of gentiobiose, raffinose, and a dextran, draw Haworth projections of each:

- (a) *Gentiobiose* is a disaccharide found in gentians and other plants. It consists of two molecules of β -D-glucose linked to each other by a $\beta(1 \rightarrow 6)$ glycosidic bond.
- (b) *Raffinose* is a trisaccharide found in sugar beets. It consists of one molecule each of α -D-galactose, α -D-glucose, and β -D-fructose, with the galactose linked to the glucose by an $\alpha(1 \rightarrow 6)$ glycosidic bond and the glucose linked to the fructose by an $\alpha(1 \rightarrow 2)$ bond.
- (c) *Dextrans* are polysaccharides produced by some bacteria. They are polymers of α -D-glucose linked by $\alpha(1 \rightarrow 6)$ glycosidic bonds, with frequent $\alpha(1 \rightarrow 3)$ branching. Draw a portion of a dextran, including one branch point.

3-11 Telling Them Apart. For each of the following pairs of molecules, specify a property that would distinguish between them, and indicate two different chemical tests or assays that could be used to make that distinction:

- (a) The protein insulin and the DNA in the gene that encodes insulin
- (b) The DNA that encodes insulin and the messenger RNA for insulin
- (c) Starch and cellulose
- (d) Amylose and amylopectin
- (e) The monomeric protein myoglobin and the tetrameric protein hemoglobin
- (f) A triacylglycerol and a phospholipid with a very similar fatty acid content
- (g) A glycolipid and a sphingolipid
- (h) A bacterial cell wall polysaccharide and chitin

• 3-12 Find an Example. For each of the following classes of proteins, give two examples of specific proteins, briefly state how each one is important in cells, and mention a type of cell in which each protein would be found. You may use any available resources: later chapters in the text, your notes from other classes, or the Internet. Try to find examples that your professor may not be familiar with. (We love when our students can educate us!)

- (a) Enzymes
- (b) Structural proteins
- (c) Motility proteins
- (d) Regulatory proteins
- (e) Transport proteins
- (f) Hormonal proteins
- (g) Receptor proteins
- (h) Defensive proteins
- (i) Storage proteins

3-13 Cotton and Potatoes. A cotton fiber consists almost exclusively of cellulose, whereas a potato tuber contains mainly starch. Cotton is tough, fibrous, and virtually insoluble in water. The starch present in a potato tuber, on the other hand, is neither tough nor fibrous and can be dispersed in hot water to form a turbid solution. Yet both the cotton fiber and the potato tuber consist primarily of polymers of D-glucose in $(1 \rightarrow 4)$ linkage.

- (a) How can two polymers consisting of the same repeating subunit have such different properties?
- (b) What is the advantage of the respective properties in each case?
- **3-14 Thinking About Lipids.** You should be able to answer each of the following questions based on the properties of lipids discussed in this chapter:
- (a) How would you define a lipid? In what sense is the operational definition different from that of proteins, nucleic acids, or carbohydrates?
 - (b) Arrange the following lipids in order of decreasing polarity: cholesterol, estradiol, fatty acid, phosphatidyl choline, and triglyceride. Explain your reasoning.
 - (c) Which would you expect to resemble a sphingomyelin molecule more closely: a molecule of phosphatidyl choline containing two molecules of palmitate acid as its fatty acid side chains or a phosphatidyl choline molecule with one molecule of palmitate and one molecule of oleate as its fatty acid side chains? Explain your reasoning.
 - (d) Assume you and your lab partner Mort determined the melting temperature for each of the following fatty acids:

arachidic, linoleic, linolenic, oleic, palmitic, and stearic acids. Mort recorded the melting points of each but neglected to note the specific fatty acid to which each value belongs. Assign each of the following melting temperatures (in °C) to the appropriate fatty acid, and explain your reasoning: –11, 5, 16, 63, 70, and 76.5.

- (e) For each of the following amphipathic molecules, indicate which part of the molecule is hydrophilic: phosphatidyl serine, sphingomyelin, cholesterol, and triacylglycerol.

3-15 Shortening. A popular brand of shortening has a label on the can that identifies the product as “partially hydrogenated soybean oil, palm oil, and cottonseed oil.”

- (a) What does the process of partial hydrogenation accomplish chemically?
- (b) What did the product in the can look like before it was partially hydrogenated?
- (c) What is the physical effect of partial hydrogenation?
- (d) Why would it be misleading to say that the shortening is “made from 100% polyunsaturated oils”?

4

Cells and Organelles

In the previous two chapters, we encountered the major kinds of molecules found in cells, as well as some principles governing the assembly of these molecules into the supramolecular structures that make up cells and their organelles (see Figure 2-14). Now we are ready to focus our attention on cells and organelles directly.

Properties and Strategies of Cells

As we begin to consider what cells are and how they function, several general characteristics of cells quickly emerge. These include the organizational complexity and molecular components of cells, the sizes and shapes of cells, and the specializations that cells undergo.

All Organisms Are Bacteria, Archaea, or Eukaryotes

With improvements in microscopy, biologists came to recognize two fundamentally different types of cellular organization: a simpler one characteristic of bacteria and a more complex one found in all other kinds of cells. Based on the structural differences of their cells, organisms have been traditionally divided into two broad groups, the **prokaryotes** (bacteria) and the **eukaryotes** (plants, animals, fungi, algae, and protozoa). The most fundamental distinction between the two groups is that eukaryotic cells have a true, membrane-bounded nucleus (*eu-* is Greek for “true” or “genuine”; *-karyon* means “nucleus”), whereas prokaryotic cells do not (*pro-* means “before,” suggesting an evolutionarily earlier form of life).

Recently, however, the term *prokaryote* is becoming less satisfactory to describe these non-nucleated cells, partly because this is a negative classification based on what cells do not have and partly because it wrongly implies a fundamental similarity among all organisms whose cells lack a nucleus. The fact that two organisms lack a particular gross structural feature does not necessarily imply evolutionary

relatedness—cells of humans and *Mycoplasma*, a type of bacterium, both lack cell walls but are not at all closely related. Likewise, sharing a gross structural feature does not necessarily mean a close relationship. Although plants and most bacteria have cell walls, they are only distantly related.

Molecular and biochemical criteria are proving to be more reliable than structural criteria in describing evolutionary relationships among organisms. The more closely related two different organisms are, the more similarities we see in their sequences of particular DNA, RNA, and protein molecules. Especially useful for comparative studies are molecules common to all living organisms that are necessary for universal, basic processes, in which even slight changes in component molecules are not well tolerated. This includes molecules such as the ribosomal RNAs used in protein synthesis and the cytochrome proteins used in energy metabolism.

Based on the pioneering ribosomal RNA sequencing work of Carl Woese, Ralph Wolfe, and coworkers, we now recognize that the group traditionally called the prokaryotes actually includes two widely divergent groups—the **bacteria** and the **archaea**, which are as different from each other as we are from bacteria! Rather than the prokaryote-eukaryote dichotomy, it is more biologically correct to describe all organisms as belonging to one of three *domains*—the bacteria, the archaea, or the **eukarya** (eukaryotes). As shown in **Table 4-1**, cells of each of these domains share some characteristics with cells of the other domains, but all three domains have some unique characteristics.

The bacteria include most of the commonly encountered single-celled, non-nucleated organisms that we have traditionally referred to as bacteria—for example, *Escherichia coli*, *Pseudomonas*, and *Streptococcus*. The archaea (which were called *archaeabacteria* before investigators realized how different they are from bacteria) include many species that live in extreme habitats on Earth and have very diverse metabolic strategies. Members of the archaea include the

Table 4-1

A Comparison of Some Properties of Bacterial, Archaeal, and Eukaryotic Cells*

Property	Prokaryotes			Refer to:
	Bacteria	Archaea	Eukaryotes	
Typical size	Small (1–5 μm)	Small (1–5 μm)	Large (10–100 μm)	—
Nucleus and organelles	No	No	Yes	Table 4-2
Microtubules and microfilaments	Actin-like and tubulin-like proteins	Actin-like and tubulin-like proteins	Actin and tubulin proteins	Chapter 15
Exocytosis and endocytosis	No	No	Yes	Chapter 12
Cell wall	Peptidoglycan	Varies from proteinaceous to peptidoglycan-like	Cellulose in plants, fungi; none in animals, protozoa	Chapter 17
Mode of cell division	Binary fission	Binary fission	Mitosis or meiosis plus cytokinesis	Chapter 19
Typical form of chromosomal DNA	Circular, few associated proteins	Circular, associated with histone-like proteins	Linear, associated with histone proteins	Chapter 18
RNA processing	Minimal	Moderate	Extensive	Chapter 21
Transcription initiation	Bacterial type	Eukaryotic type	Eukaryotic type	Chapter 21
RNA polymerase	Bacterial type	Some features of both bacterial, eukaryotic types	Eukaryotic type	Chapter 21
Ribosome size and number of proteins	70S with 55 proteins	70S with 65 proteins	80S with 78 proteins	Chapter 22
Ribosomal RNAs	Bacterial type	Archaeal type	Eukaryotic type	Chapter 21
Translation initiation	Bacterial type	Eukaryotic type	Eukaryotic type	Chapter 22
Membrane phospholipids	Glycerol-3-phosphate + linear fatty acids	Glycerol-1-phosphate + branched polyisoprenoids	Glycerol-3-phosphate + linear fatty acids	Chapter 7

*This table lists many features that we have not yet discussed in detail. Its main purpose is to point out that, despite some sharing of characteristics, each of the three main cell types has a unique set of properties.

methanogens, which obtain energy from hydrogen while converting carbon dioxide into methane; the *halophiles*, which can grow in extremely salty environments; and the *thermacidophiles*, which thrive in acidic hot springs where the pH can be as low as 2 and the temperature can exceed 100°C! Rather than being considered as an evolutionarily ancient form of prokaryote (*archae-* is a Greek prefix meaning “ancient”), archaea are now considered to be descended from a common ancestor that also gave rise to the eukaryotes long after diverging from the bacteria, as shown here:

While resembling bacteria in many ways, archaea possess many unique features, as well as features that are found in eukaryotes. They resemble bacteria in cell size and gross structure, in their method of cell division, and in many aspects of basic metabolism and enzyme content. However, they are much more similar to eukaryotes regarding many details of DNA replication, transcription, RNA processing, and initiation of protein synthesis. Unique features of archaea include their ribosomal RNAs and their membrane phospholipids (Table 4-1).

Limitations on Cell Size

Cells come in various sizes and shapes. Some of the smallest bacterial cells, for example, are only about 0.2–0.3 μm in diameter—so small that about 50,000 such cells could fit side by side on your thumbnail. At the other extreme are highly elongated nerve cells, which may extend one or more meters. The nerve cells running the length of a giraffe’s neck or legs are especially dramatic examples. So are bird eggs, which are extremely large single cells, although much of their internal volume is occupied by the yolk that nourishes the developing embryo.

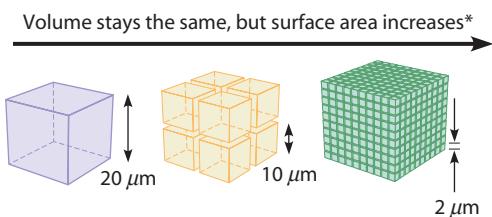

Despite these extremes, most cells fall into a rather narrow and predictable range of sizes. Bacterial and archaeal cells, for example, are usually about 1–5 μm in diameter, while most cells of higher plants and animals have dimensions in the range of 10–100 μm . Why are cells so small? Several factors limit cell size, but the three most important are (1) the requirement for an adequate surface area/volume ratio, (2) the rates at which molecules diffuse, and (3) the need to maintain adequate local concentrations of the specific substances and enzymes involved in necessary cellular processes. Let’s now look at each of these three factors in turn.

Surface Area/Volume Ratio. In most cases, the main limitation on cell size is set by the need to maintain an adequate **surface area/volume ratio**. Surface area is critical because it

is at the cell surface that the needful exchanges between a cell and its environment take place. The cell's internal volume determines the amount of nutrients that will have to be imported and the quantity of waste products that must be excreted. The surface area effectively represents the amount of cell membrane available for such uptake and excretion.

The problem of maintaining adequate surface area arises because the volume of a cell increases with the cube of the cell's length or diameter, whereas its surface area increases only with the square. Thus, large cells have a lower ratio of surface area to volume than small cells do, as illustrated in **Figure 4-1**. This comparison illustrates a major constraint on cell size: As a cell increases in size, its surface area does not keep pace with its volume, and the necessary exchange of substances between the cell and its surroundings becomes more and more problematic. Cell size, therefore, can increase only as long as the membrane surface area is still adequate for the passage of materials into and out of the cell.

Some cells, particularly those that play a role in absorption, have characteristics that maximize their surface area. Effective surface area is most commonly increased by the inward folding or outward protrusion of the cell membrane. The cells lining your small intestine, for example, contain many fingerlike projections called *microvilli* that greatly increase the effective membrane surface area and therefore the nutrient-absorbing capacity of these cells (**Figure 4-2**).

Number of cells	1	8	1000
Length of one side	20 μm	10 μm	2 μm
Total volume	$8000 \mu\text{m}^3$	$8000 \mu\text{m}^3$	$8000 \mu\text{m}^3$
Total surface area	$2400 \mu\text{m}^2$	$4800 \mu\text{m}^2$	$24,000 \mu\text{m}^2$
Surface area to volume ratio	0.3	0.6	3.0

*For a cube having a side with length s , volume = s^3 and surface area = $6s^2$.

FIGURE 4-1 The Effect of Cell Size on the Surface Area/Volume Ratio.

The single large cell on the left, the eight smaller cells in the center, and the 1000 tiny cells on the right all have the same total volume ($8000 \mu\text{m}^3$), but the total surface area increases as the cell size decreases. The surface area/volume ratio therefore increases from left to right as the linear dimension of the cell decreases. Note how the eight small cells in the center have the same total volume as the large cell on the left but twice the surface area. Likewise, the 1000 small bacterial cells on the right have the same total volume but a total surface area ten times that of the single large eukaryotic cell on the left.

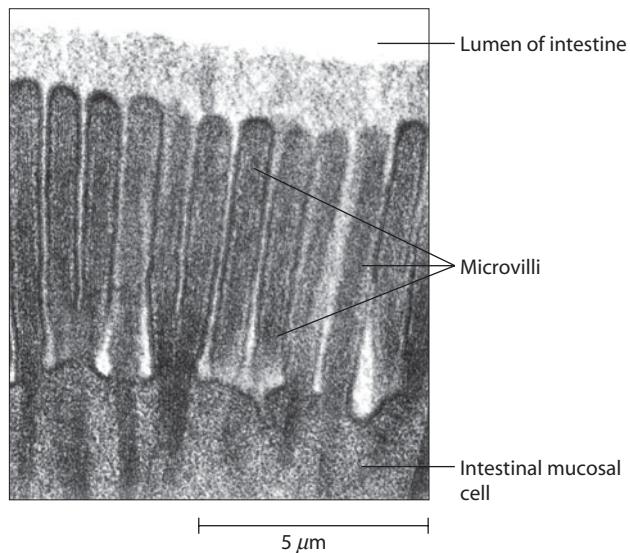

FIGURE 4-2 The Microvilli of Intestinal Mucosal Cells.

Microvilli are fingerlike projections of the cell membrane that greatly increase the absorptive surface area of intestinal mucosal cells, such as those lining the inner surface of your small intestine (TEM).

Diffusion Rates of Molecules. Cell size is also limited by how rapidly molecules can move around in the cell to reach sites of specific cellular activities. Many molecules move through the cell by **diffusion**, which is the free, unassisted movement of a substance from a region of high concentration to a region of low concentration. Molecular movement can therefore be limited by the diffusion rates for molecules of various sizes. And because the rate of diffusion decreases as the size of the molecule increases, this limitation is most significant for macromolecules such as proteins and nucleic acids.

Recent work shows that many eukaryotic cells may be able to bypass this limitation by actively transporting ions, macromolecules, and other materials through the cytoplasm using special carrier proteins. Some cells of higher organisms get around this limitation to some extent by *cytoplasmic streaming* (also called *cyclosis* in plant cells), a process that involves active movement and mixing of cytoplasmic contents rather than diffusion. Other cells move specific molecules through the cell using vesicles that are transported along microtubules, as we will see shortly. In the absence of these mechanisms, however, the size of a cell is limited by the diffusion rates of the molecules it contains.

The Need for Adequate Concentrations of Reactants and Catalysts. A third limitation on cell size is the need to maintain adequate concentrations of the essential compounds and enzymes needed for the various processes that cells must carry out. For a chemical reaction to occur in a cell, the appropriate reactants must collide with and bind to a particular enzyme. The frequency of such collisions will be greatly increased by higher concentrations of the reactants and the enzyme. To maintain the concentration

of a specific molecule, the number of molecules must increase proportionately with cell volume. Every time each of the three dimensions of the cell doubles, there is an eightfold increase in cell volume, and thus eight times as many molecules are required to maintain the original concentration. In the absence of a concentrating mechanism, this obviously taxes the cell's synthetic capabilities.

Eukaryotic Cells Use Organelles to Compartmentalize Cellular Function

An effective solution to the concentration problem is the *compartmentalization of activities* within specific regions of the cell. If all the enzymes and compounds necessary for a particular process are localized within a specific region, high concentrations of those substances are needed only in that region rather than throughout the whole cell.

To compartmentalize activities, most eukaryotic cells have a variety of **organelles**, which are membrane-bound compartments that are specialized for specific functions. For example, the cells in a plant leaf have most of the enzymes, compounds, and pigments needed for photosynthesis compartmentalized together into structures called *chloroplasts*. Such a cell can therefore maintain appropriately high concentrations of everything it requires for photosynthesis within its chloroplasts without having to maintain correspondingly high concentrations of these substances elsewhere in the cell. In a similar way, other processes are localized within other compartments.

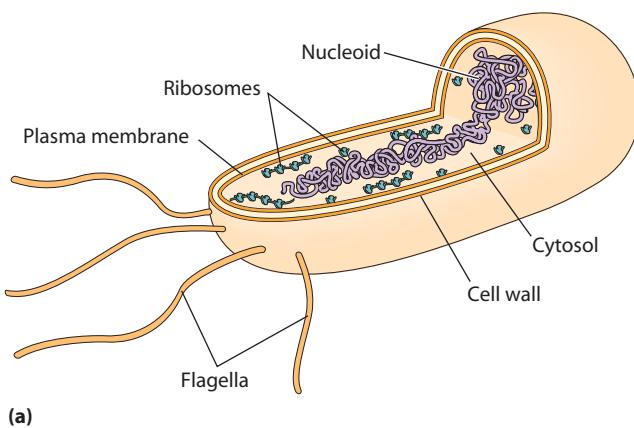

Bacteria, Archaea, and Eukaryotes Differ from Each Other in Many Ways

Returning to the distinction between bacteria, archaea, and eukaryotes, we recognize many important structural, biochemical, and genetic differences among these groups. Some of these differences are summarized in Table 4-1 and are discussed here briefly—others will be discussed in

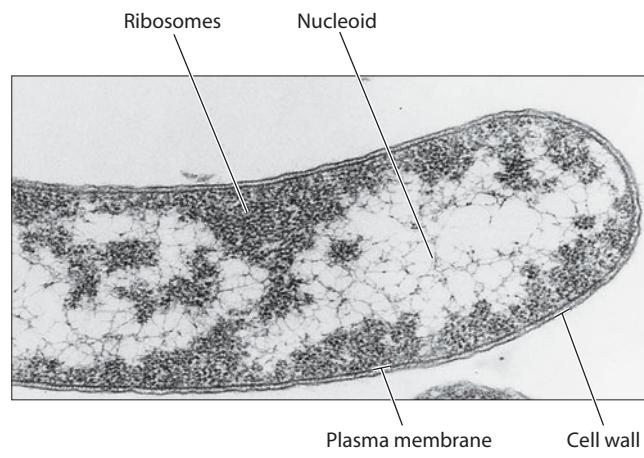

later chapters. For now, it is important to realize that, despite some sharing of characteristics among cells of each of these three domains, each type of cell has a unique set of distinguishing properties.

Presence of a Membrane-Bounded Nucleus. As already noted, a structural distinction has traditionally been made between eukaryotes and prokaryotes (bacteria and archaea) and is reflected in the nomenclature itself. However, as we learn more about the cellular details of the three domains of living organisms, this distinction is becoming less important than other aspects of structure and function. A eukaryotic cell has a true, membrane-bounded nucleus, whereas a prokaryotic cell does not. Instead of being enveloped by a membrane, the genetic information of a bacterial or archaeal cell is folded into a compact structure known as the *nucleoid*, which is attached to the cell membrane in a particular region of the cytoplasm (**Figure 4-3**). Within a eukaryotic cell, on the other hand, most of the genetic information is localized to the nucleus, which is surrounded not by a single membrane but by a *nuclear envelope* consisting of two membranes (**Figure 4-4**). The nucleus also includes the *nucleolus*, which is the site of ribosomal RNA synthesis and ribosome subunit assembly, and it contains the DNA-bearing *chromosomes*, which are dispersed as chromatin throughout the semifluid *nucleoplasm* that fills the internal volume of the nucleus.

Use of Internal Membranes to Segregate Function. As Figure 4-3 illustrates, bacterial (and archaeal) cells generally do not contain internal membranes; most cellular functions occur either in the cytoplasm or on the plasma membrane. However, there is a group of photosynthetic bacteria known as *cyanobacteria* that have extensive internal membranes on which photosynthetic reactions are carried out (see Figure 11-4). Also, some bacteria have membrane-bound structures that resemble organelles, while others have protein-lined compartments that serve

(a)

FIGURE 4-3 Structure of a Rod-Shaped Bacterial Cell. (a) A three-dimensional model showing the components of a bacterium. (b) An electron micrograph of a bacterial cell with several of the same components labeled. Notice that the nucleoid refers to the folded bacterial chromosome, not a membrane-bounded compartment (TEM).

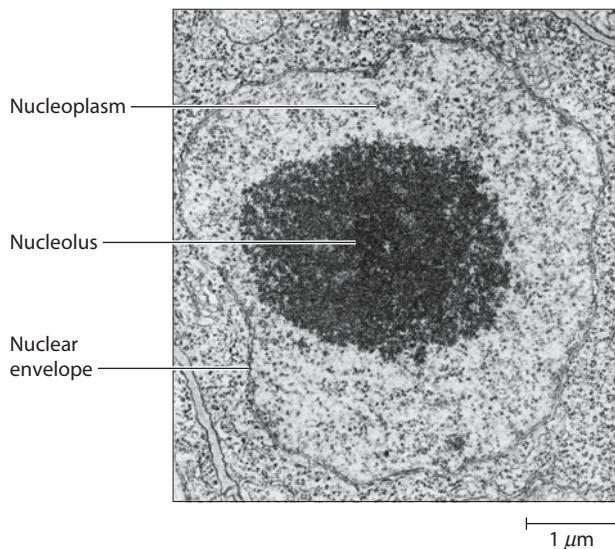

FIGURE 4-4 The Nucleus of a Eukaryotic Cell. The nucleus is enclosed by a pair of membranes called the nuclear envelope. Because this cell is between divisions, the chromosomes are dispersed as chromatin in the nucleoplasm within the nucleus and are not visible. The nucleolus is involved in the synthesis of ribosomal components (TEM).

as organelles by isolating groups of enzymes involved in specific metabolic pathways. In contrast, nearly all eukaryotic cells make extensive use of internal membranes to compartmentalize specific functions (**Figure 4-5** and **Figure 4-6**), and they often have numerous organelles.

Examples of internal membrane systems in eukaryotic cells include the *endoplasmic reticulum*, the *Golgi complex*, and the membranes surrounding and delimiting organelles such as *mitochondria*, *chloroplasts*, *lysosomes*, and *peroxisomes*, as well as various kinds of *vacuoles* and *vesicles*. Each of these organelles is surrounded by its own characteristic membrane (or pair of membranes) that may be similar to other membranes in basic structure but can have a distinctive chemical composition. Localized within each such organelle is the molecular machinery needed to carry out the particular cellular functions for which the structure is specialized. We will meet each of these organelles later in this chapter and then return to each one in its appropriate context in succeeding chapters.

The Cytoskeleton. Also found in the cytoplasm of eukaryotic cells are several nonmembranous, proteinaceous structures that are involved in cellular contraction, motility, and the establishment and support of cellular architecture. These include the *microtubules* found in the cilia and flagella of many cell types, the *microfilaments* found in muscle fibrils and other structures involved in motility, and the *intermediate filaments*, which are especially prominent in cells that are subject to stress. Microtubules, microfilaments, and intermediate filaments are key components of the *cytoskeleton*, which imparts structure and elasticity to almost all eukaryotic cells, as we will learn shortly and explore in more detail in Chapter 15. In addition, the cytoskeleton can provide a scaffolding for

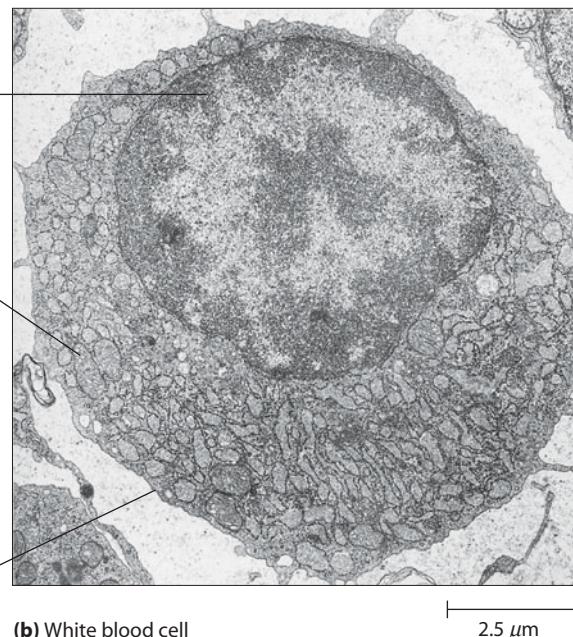

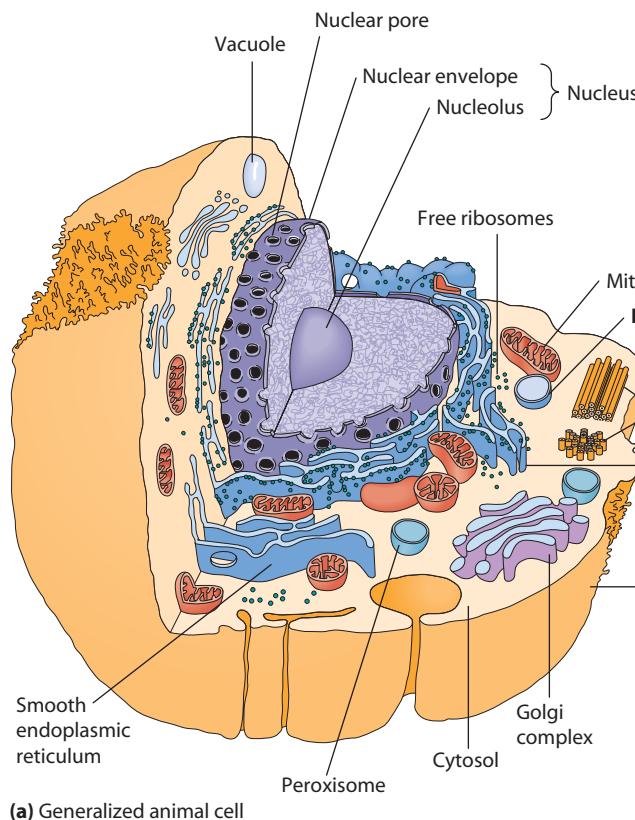

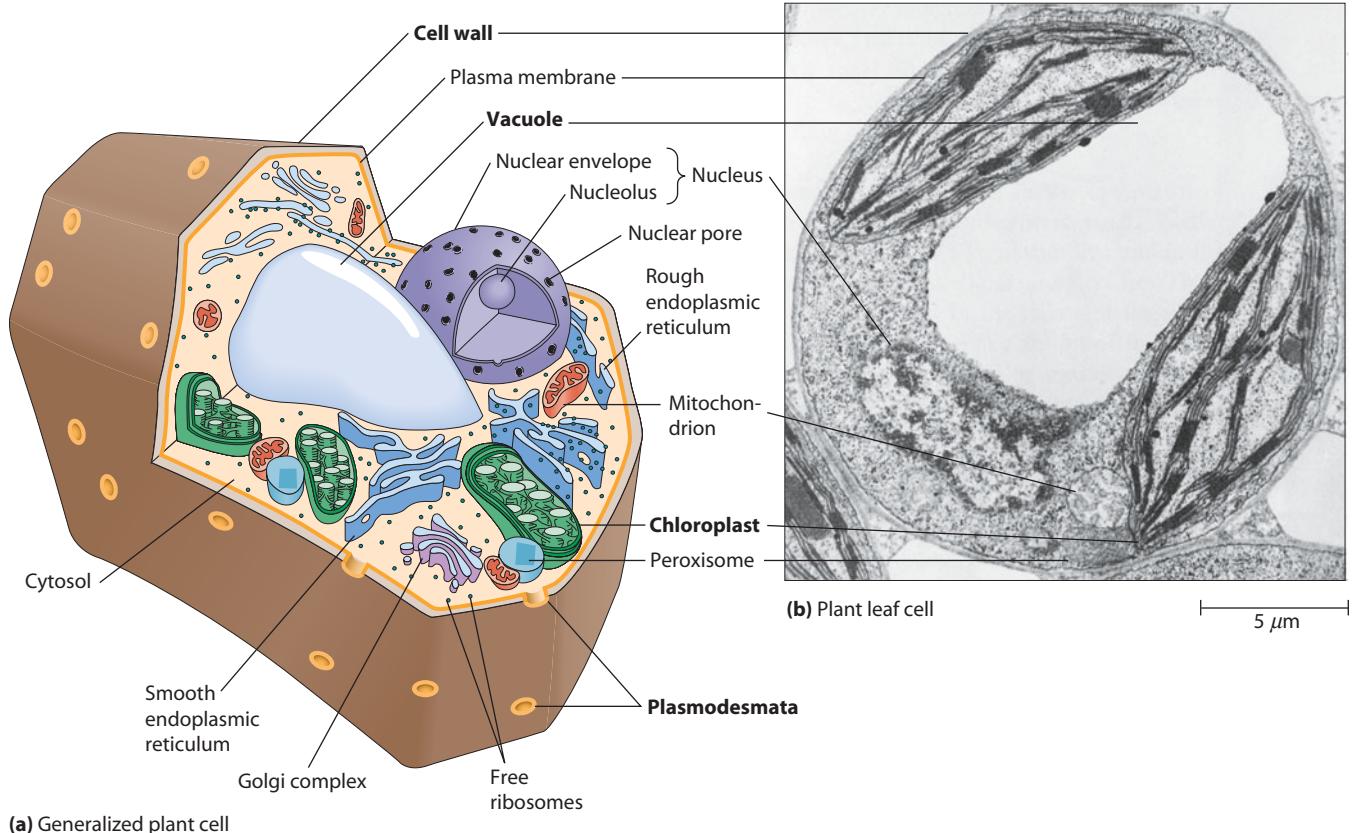

FIGURE 4-5 An Animal Cell. (a) A schematic drawing of an animal cell to provide perspective on the relative sizes and shapes of organelles and other subcellular structures. intracellular transport of vesicles to places in the cell where their contents are needed (**Figure 4-7**). Recently, proteins similar to cytoskeleton proteins have been found in bacteria and appear to have a role in maintaining cell shape.

Exocytosis and Endocytosis. A further feature of eukaryotic cells is their ability to exchange materials between the membrane-bounded compartments within the cell and the exterior of the cell. This exchange is possible because of *exocytosis* and *endocytosis*, processes involving membrane fusion events that are unique to eukaryotic cells. In endocytosis, portions of the plasma membrane invaginate and are pinched off to form membrane-bounded cytoplasmic vesicles containing substances that were previously on the outside of the cell. Exocytosis is essentially the reverse of this process: Membrane-bounded vesicles inside the cell fuse with the plasma membrane and release their contents to the outside of the cell.

Organization of DNA. Another distinction among bacteria, archaea, and eukaryotes is the amount and organization of the genetic material. Bacterial DNA is usually present in the cell as a circular molecule associated with relatively few proteins. On the other hand, eukaryotic

DNA exists in the cell as multiple linear molecules that are complexed with large amounts of proteins known as *histones*. Archaeal DNA is typically circular and is complexed with moderate amounts of proteins that resemble the eukaryotic histone proteins.

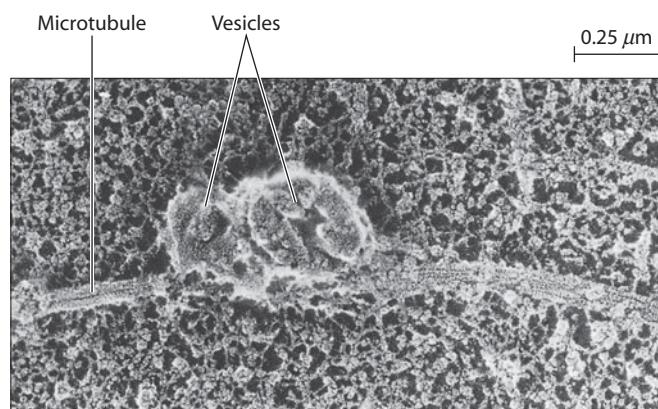

FIGURE 4-7 Vesicle Transport. This SEM of a squid giant axon shows two neurotransmitter-containing vesicles attached to a microtubule. The microtubule provides a “track” to move the molecules in these vesicles through the cell to the axon tips, where they will aid in nerve cell signaling.

The circular DNA molecule of a bacterial or archaeal cell is much longer than the cell itself. It therefore has to be folded and packed together tightly to fit into the cell. For example, the common intestinal bacterium *Escherichia coli* is only about a micrometer or two long, yet it has a circular DNA molecule about 1300 μm in circumference. Clearly, a great deal of folding and packing is necessary to fit that much DNA into such a small cell. By way of analogy, it is roughly equivalent to packing about 60 feet (18 m) of very thin thread into a typical thimble.

But if DNA appears to pose a packaging problem for prokaryotic cells, consider the case of the eukaryotic cell. Most eukaryotic cells have at least 1000 times as much DNA as *E. coli* has but encode only 5–10 times as many proteins. Because scientists did not know the function of the excess, noncoding DNA, it had been often referred to as “junk DNA.”

Now, however, it appears that much of this excess DNA may have important functions other than encoding cellular proteins. Some of it is involved in production of regulatory miRNAs, other regions appear to be involved in generation of species diversity during evolution, and some contains repetitive sequences that appear to serve as binding sites for regulatory proteins. A recent study showed that up to 33% of the binding sites for transcription factors with roles in cancer development are found in these regions of repetitive DNA. Thus, we must be careful not to assume that there is no function for certain cellular components just because we currently do not understand their roles in the cell.

Whatever the function of such large amounts of DNA, the problem of packaging all this material is clearly acute. It is solved universally among eukaryotes by the organization of DNA into complex structures called **chromosomes**, which contain at least as much histone protein as DNA (see Figure 18-22). It is as chromosomes that the DNA of eukaryotic cells is packaged, segregated during cell division, and transmitted to daughter cells. **Figure 4-8** shows a chromosome from an animal cell as seen by high-voltage electron microscopy.

Segregation of Genetic Information. A further contrast between prokaryotes and eukaryotes is the way they allocate genetic information to daughter cells upon division. Bacterial and archaeal cells merely replicate their DNA and divide by a relatively simple process called *binary fission*, with one molecule of the replicated DNA and half of the cytoplasm going to each daughter cell. Following DNA replication in eukaryotic cells, the chromosomes are distributed equally to the daughter cells by the more complex processes of *mitosis* and *meiosis*, followed by *cytokinesis*, the division of the cytoplasm.

Expression of DNA. The differences among bacterial, archaeal, and eukaryotic cells extend to the expression of genetic information. Eukaryotic cells tend to transcribe genetic information in the nucleus into large RNA molecules and depend on later processing and transport

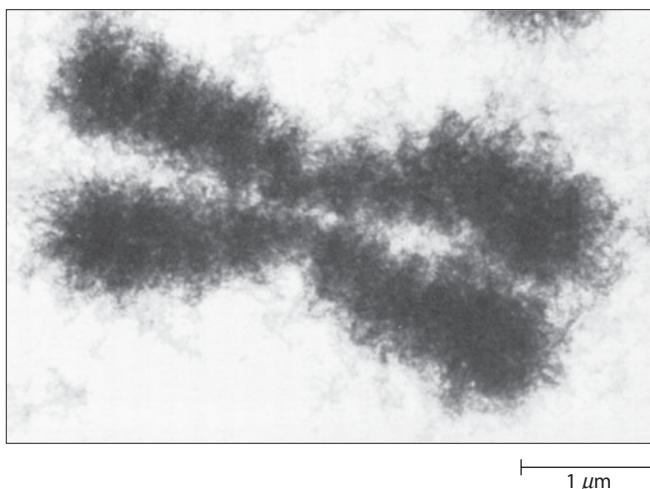

FIGURE 4-8 A Eukaryotic Chromosome. This chromosome was obtained from a cultured Chinese hamster cell and visualized by high-voltage electron microscopy (HVEM). The cell was undergoing mitosis, and the chromosome is therefore highly coiled and condensed.

processes to deliver RNA molecules of the proper sizes to the cytoplasm for protein synthesis. Each RNA molecule typically encodes one polypeptide.

By contrast, bacteria transcribe very specific segments of genetic information into RNA messages, and often a single RNA molecule contains the information to produce several polypeptides. In bacteria, little or no processing of RNA occurs; a moderate amount is seen in archaea, though less than in eukaryotes. The absence of a nuclear membrane in bacteria and archaea makes it possible for messenger RNA molecules to become involved in the process of protein synthesis even before they are completely synthesized. Bacteria, archaea, and eukaryotes also differ in the size and composition of the ribosomes and ribosomal RNAs used to synthesize proteins (see Table 4-1). We will explore this distinction in more detail later in the chapter.

Cell Specialization Demonstrates the Unity and Diversity of Biology

In their structure and function, cells are characterized by both unity and diversity, as you can see in the generalized animal and plant cells shown in Figures 4-5 and 4-6. By unity and diversity, we simply mean that all cells resemble one another in fundamental ways, yet they differ from one another in other important ways. In upcoming chapters we will concentrate on those aspects of structure and function common to most cell types. We will find, for example, that virtually all cells oxidize sugar molecules for energy, transport ions across membranes, transcribe DNA into RNA, and undergo division to generate daughter cells.

Much the same is true for structural features. All cells are surrounded by a selectively permeable plasma membrane, all cells have ribosomes for protein synthesis, and all contain double-stranded DNA as their genetic

information. Clearly, we can be confident that we are dealing with fundamental aspects of cellular organization and function when we consider processes and structures common to most, if not all, cells.

But sometimes our understanding of cellular biology is enhanced by considering not just the unity but also the diversity of cells—the features that are especially prominent in a particular cell type. For example, to understand how the process of protein secretion works, it is advantageous to consider a cell that is highly specialized for that particular function. Cells from the human pancreas are a good choice for studying this process because they secrete large amounts of digestive enzymes.

Similarly, to study functions known to occur in mitochondria, it is clearly an advantage to select a cell type that is highly specialized in the energy-releasing processes occurring in the mitochondrion. Such a cell would likely have a lot of well-developed, highly active mitochondria. In fact, it was for this very reason—to study a cell that is highly specialized for a particular function—that Hans Krebs chose the flight muscle of the pigeon as the tissue for carrying out the now-classic studies on the cyclic pathway of oxidative reactions that we know as the *tricarboxylic acid (TCA), or Krebs, cycle*.

In general, the single cell of unicellular organisms must be capable of carrying out any and all of the functions necessary for survival, growth, and reproduction. It typically does not overemphasize any single function at the expense of others. Multicellular organisms, on the other hand, are characterized by a division of labor among tissues and organs that not only allows for but also depends on specialization of structure and function. Whole groups of cells become highly specialized for a particular task, which then becomes their specific role in the overall functioning of the organism.

The Eukaryotic Cell in Overview: Pictures at an Exhibition

From the preceding discussion, it should be clear that all cells carry out many of the same basic functions and have some of the same basic structural features. However, the cells of eukaryotic organisms are far more complicated structurally than bacterial or archaeal cells, primarily because of the organelles and other intracellular structures that eukaryotes use to compartmentalize various functions. The structural complexity of eukaryotic cells is illustrated by the typical animal and plant cells shown in Figures 4-5 and 4-6.

In reality, of course, there is no such thing as a truly “typical” cell; nearly all eukaryotic cells have features that distinguish them from the generalized cells shown in Figures 4-5 and 4-6. Nonetheless, most eukaryotic cells are sufficiently similar to warrant a general overview of their structural features.

As we have seen, a typical eukaryotic cell has at least four major structural features: an external *plasma membrane* to define its boundary and retain its contents, a *nucleus* to

Table 4-2

house the DNA that directs cellular activities, *membrane-bounded organelles* in which various cellular functions are localized, and the *cytosol* interlaced by a *cytoskeleton* of microtubules and microfilaments. In addition, plant and fungal cells have a rigid *cell wall* external to the plasma membrane. Animal cells do not have a cell wall; they are usually surrounded by an *extracellular matrix* consisting primarily of proteins that provide structural support.

Our intention here is to look at each of these structural features in overview, as an introduction to cellular architecture. For now, we will simply look at each structure as we might look at pictures at an exhibition, moving through the gallery rather quickly just to get a feel for the overall display. Keep in mind, however, that these introductory “pictures” are only static representations of a dynamic cell that can adapt and respond to its environment. We will study each structure in detail in later chapters when we consider the dynamic cellular processes in which these organelles and other structures are involved (**Table 4-2**).

The Plasma Membrane Defines Cell Boundaries and Retains Contents

Our tour begins with the **plasma membrane** that surrounds every cell (**Figure 4-9**). The plasma membrane defines the boundaries of the cell, ensuring that its contents are retained. The plasma membrane consists of phospholipids, other lipids, and proteins and is organized into two layers (Figure 4-9b). Typically, each phospholipid molecule consists of two hydrophobic “tails” and a hydrophilic “head” and is therefore an *amphipathic molecule* (see

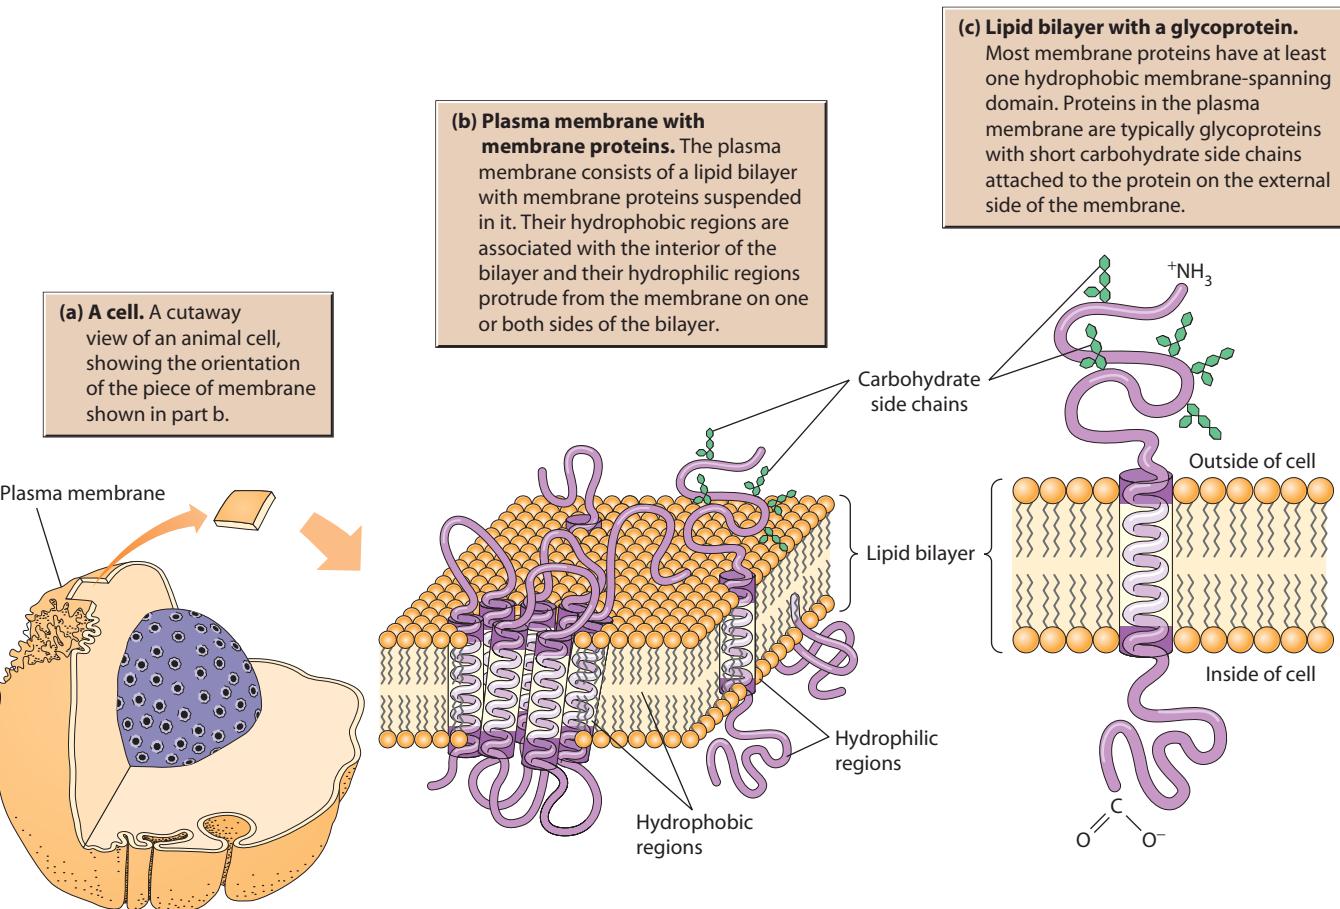

FIGURE 4-9 Organization of the Plasma Membrane. This figure shows successively more detail (a)–(c) in a section of the plasma membrane that surrounds all cells.

Figures 2-11 and 2-12). The phospholipid molecules orient themselves in the two layers of the membrane such that the hydrophobic, hydrocarbon tails of each molecule face inward and the hydrophilic, phosphate-containing heads of the molecules face outward (Figure 4-9c). The resulting **lipid bilayer** is the basic structural unit of virtually all membranes and serves as a permeability barrier to most water-soluble substances. Some members of Archaea, however, have an unusual phospholipid membrane that has long hydrophobic tails (twice the normal length) linked to a polar head group on both ends, forming a monolayer.

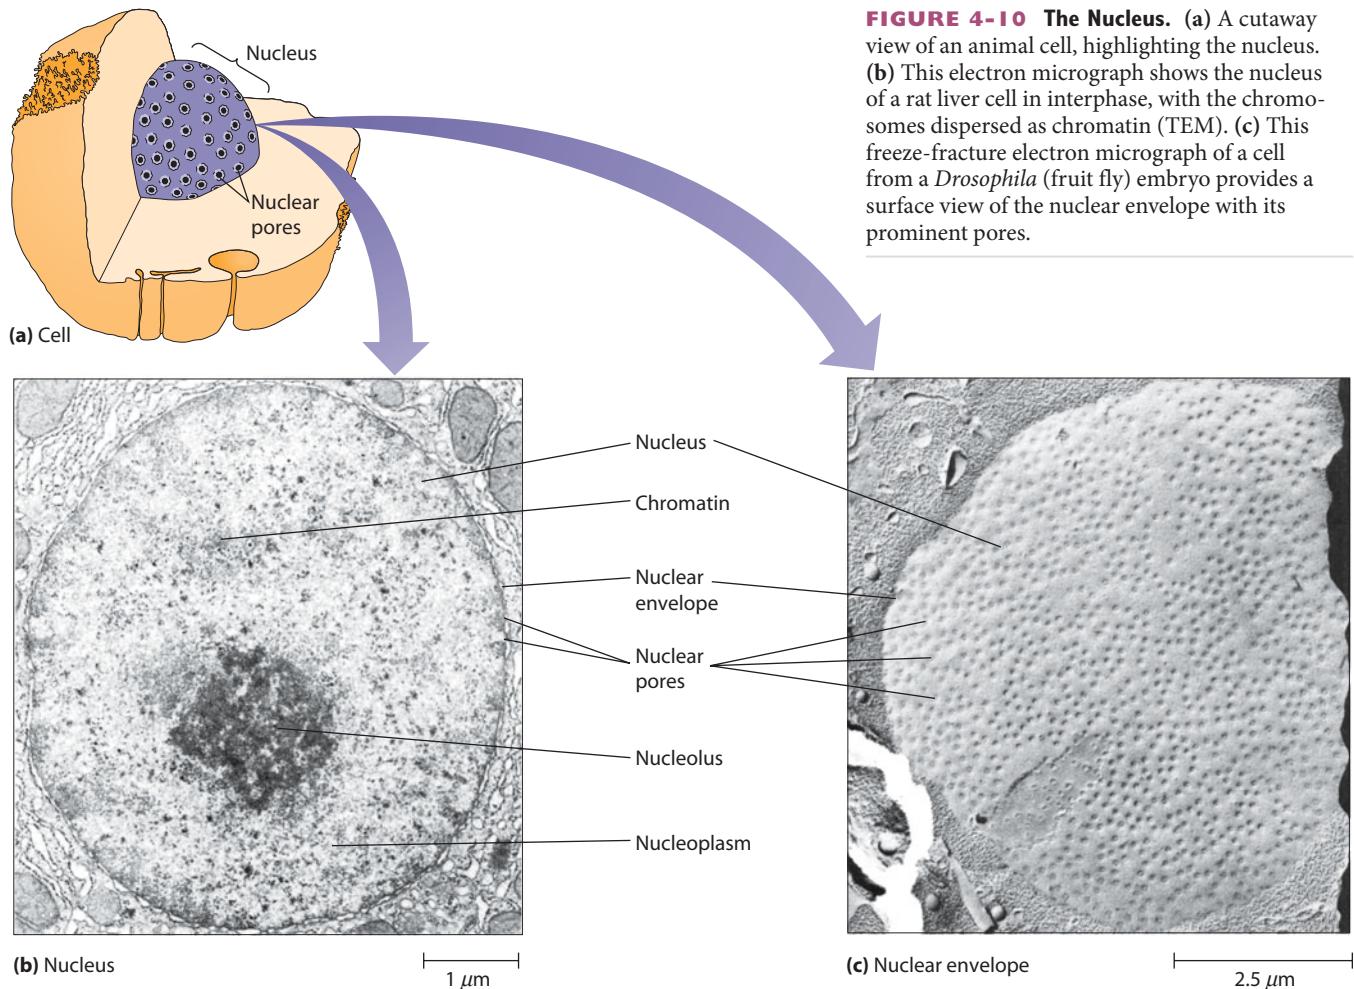

Membrane proteins are also amphipathic, with both hydrophobic and hydrophilic regions on their surfaces. They orient themselves in the membrane such that hydrophobic regions of the protein are located within the hydrophobic interior of the membrane, whereas hydrophilic regions protrude into the aqueous environment at the surfaces of the membrane. Many of the proteins with hydrophilic regions exposed on the external side of the plasma membrane have carbohydrate side chains known as oligosaccharides attached to them and are therefore called **glycoproteins** (Figure 4-9c).

The proteins present in the plasma membrane play a variety of roles. Some are *enzymes*, which catalyze reactions known to be associated with the membrane—reactions such

as cell wall synthesis. Others serve as *anchors* for structural elements of the cytoskeleton that we will encounter later in the chapter. Still others are *transport proteins*, responsible for moving specific substances (ions and hydrophilic solutes, usually) across the membrane. Membrane proteins are also important as *receptors* for external chemical signals that trigger specific processes within the cell. Transport proteins, receptor proteins, and most other membrane proteins are *transmembrane proteins* that have hydrophilic regions protruding from both sides of the membrane. These hydrophilic regions are connected by one or more hydrophobic, membrane-spanning domains.

The Nucleus Is the Information Center of the Eukaryotic Cell

Perhaps the most prominent structure we encounter in a eukaryotic cell is the **nucleus** (Figure 4-10). The nucleus serves as the cell's information center. Here, separated from the rest of the cell by a membrane boundary, are the DNA-bearing chromosomes of the cell. Actually, the boundary around the nucleus consists of two membranes, called the *inner* and *outer nuclear membranes*. Taken together, the two membranes make up the **nuclear envelope**. Unique to the membranes of the nuclear envelope are numerous small

openings called *pores* (Figure 4-10). Each pore is a channel through which water-soluble molecules and supramolecular complexes can move between the nucleus and cytoplasm. This channel is lined with transport machinery known as a *pore complex* that regulates the movement of macromolecules through the nuclear envelope and is shown in close-up detail in Figures 18-28 and 18-29. Ribosomal subunits, messenger RNA molecules, chromosomal proteins, and enzymes needed for nuclear activities are transported across the nuclear envelope through these nuclear pores.

The number of chromosomes within the nucleus is characteristic of the species. It can be as low as two (in the sperm and egg cells of some grasshoppers, for example), or it can run into the hundreds. Chromosomes are most readily visualized during mitosis, when they are highly condensed and can easily be stained (see Figure 4-8). During the *interphase* between divisions, on the other hand, chromosomes are dispersed as DNA-protein fibers called **chromatin** and are not easy to visualize (Figure 4-10b).

Also present in the nucleus are **nucleoli** (singular: **nucleolus**), structures responsible for synthesizing and assembling some of the RNA and protein components needed to form the ribosomes. Nucleoli are usually associated with specific regions of particular chromosomes that contain the genes encoding ribosomal RNAs.

FIGURE 4-10 The Nucleus. (a) A cutaway view of an animal cell, highlighting the nucleus. (b) This electron micrograph shows the nucleus of a rat liver cell in interphase, with the chromosomes dispersed as chromatin (TEM). (c) This freeze-fracture electron micrograph of a cell from a *Drosophila* (fruit fly) embryo provides a surface view of the nuclear envelope with its prominent pores.

Intracellular Membranes and Organelles Define Compartments

The internal volume of the cell exclusive of the nucleus is called the *cytoplasm* and is occupied by *organelles* and by the semifluid *cytosol* in which they are suspended. By “semifluid,” we mean that the cytosol is not a thin, watery liquid. Instead, it is believed to be a more viscous material with a consistency closer to that of honey or soft gelatin. In this section, we will look at each of the major eukaryotic organelles. In a typical animal cell, these compartments make up almost half of the cell’s total internal volume.

As we continue on our tour of the eukaryotic cell and begin to explore its organelles, you may find it helpful to view these subcellular structures from a human perspective by reading **Box 4A** and acquainting yourself with some of the heritable human diseases that are associated with malfunctions of specific organelles. In most cases, these disorders are caused by genetic defects in specific proteins—enzymes and transport proteins, most commonly—that are localized to particular organelles.

The Mitochondrion. Our tour of the eukaryotic organelles begins with a prominent organelle—the **mitochondrion** (plural: **mitochondria**), shown in **Figure 4-11**. Mitochondria

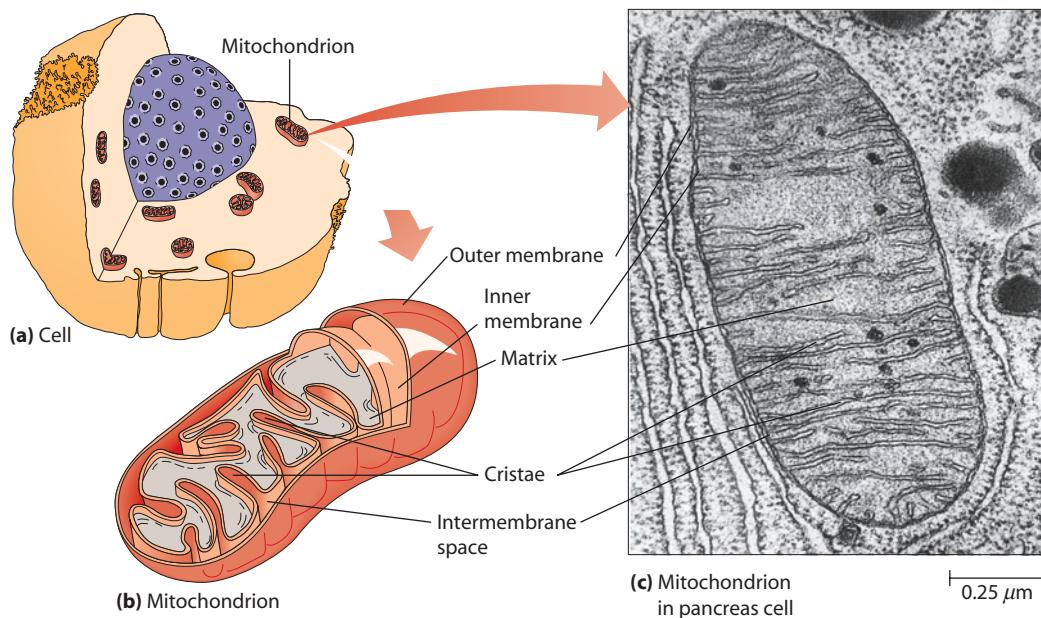

FIGURE 4-11 The Mitochondrion. (a) A cutaway view showing the relative numbers and size of the mitochondria within a typical animal cell. Remember that plant cells and all other eukaryotic cells also have mitochondria. (b) A schematic illustration of mitochondrial structure. (c) A mitochondrion in a rat pancreas cell (TEM).

[VIDEOS www.thecellplace.com](http://www.thecellplace.com) Mitochondria in 3-D

are found in all eukaryotic cells and are the site of aerobic respiration, the topic of Chapter 10. Mitochondria are large by cellular standards—up to a micrometer across and usually a few micrometers long. A mitochondrion is therefore comparable in size to a whole bacterial cell. Most eukaryotic cells contain hundreds of mitochondria, and each mitochondrion is surrounded by two membranes, designated the *inner* and *outer mitochondrial membranes*. Also found in mitochondria are small, circular molecules of DNA that encode some of the RNAs and proteins needed in mitochondria, along with the ribosomes involved in protein synthesis. In humans and most animals, mitochondria are inherited only through the mother. Therefore, analysis of mitochondrial DNA sequences has been quite useful in tracing genetic lineages in order, for example, to determine the geographic region(s) of origin and subsequent dispersal of modern humans.

Oxidation of sugars and other cellular “fuel” molecules to carbon dioxide in mitochondria extracts energy from food molecules and conserves it as *adenosine triphosphate* (ATP). It is within the mitochondrion that the cell localizes most of the enzymes and intermediates involved in such important cellular processes as the TCA cycle, fat oxidation, and ATP generation. Most of the intermediates involved in transporting electrons from oxidizable food molecules to oxygen are located in or on the **cristae** (singular: **crista**), infoldings of the inner mitochondrial membrane. Other reaction sequences, particularly those of the TCA cycle and those involved in fat oxidation, occur in the semifluid **matrix** that fills the inside of the mitochondrion.

The number and location of mitochondria within a cell can often be related directly to their role in that cell.

Tissues with an especially heavy demand for ATP as an energy source can be expected to have cells that are well endowed with mitochondria, and the organelles are usually located within the cell just where the energy need is greatest. This localization is illustrated by the sperm cell in **Figure 4-12**. As the drawing indicates, a sperm cell often

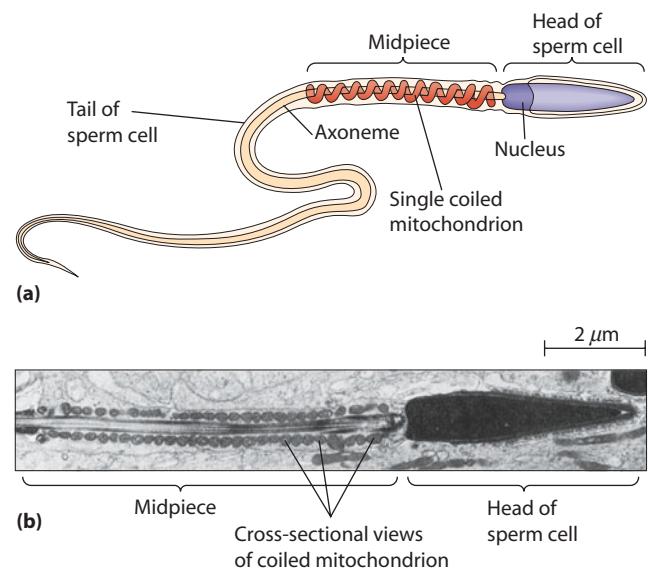

FIGURE 4-12 Localization of the Mitochondrion Within a Sperm Cell. The single mitochondrion present in a sperm cell is coiled tightly around the axoneme of the tail, reflecting the localized need of the sperm tail for energy. (a) A schematic drawing of a sperm. (b) An electron micrograph of the head and the midpiece of a sperm cell from a marmoset monkey (TEM).

Organelles and Human Diseases

Although we may not often acknowledge it—indeed, we may not even be aware of it—many human diseases are actually caused by molecular malfunctions within specific organelles. In fact, several of the organelles that we have encountered on our tour of the “picture exhibition” in this chapter—and that we will encounter in more detail in later chapters—are the sites of a variety of human genetic disorders. Most of them are rare but very serious when they occur. The list of organelle-linked diseases is lengthy, including such diverse mitochondrial disorders as *myopathies* (diseases or disorders of muscle cells), *Leigh syndrome* (a devastating neurodegenerative disorder), and *fatal infantile respiratory defects*. Also included are peroxisomal disorders such as *Zellweger syndrome* and *neonatal adrenoleukodystrophy*, as well as more than 40 *lysosomal storage diseases*, each marked by the harmful accumulation of specific substances. We will consider several of these diseases here, though only at an introductory level. In the process we will anticipate discussions of the functions localized to several organelles, including mitochondria (Chapter 10) as well as peroxisomes and lysosomes (Chapter 12).

Mitochondrial Disorders

Most of the diseases associated with mitochondrial defects are characteristic of either muscle or nerve tissue. This is not surprising, given the high rates of ATP consumption by these tissues and the essential role of the mitochondrion in ATP synthesis. The list includes at least 35 myopathies, as well as a variety of disorders affecting nerve function. Depending on the specific defect, these disorders range greatly in severity. Some lead to infant death; others result in blindness, deafness, seizures, or stroke-like episodes. Milder forms, on the other hand, are characterized by muscular weakness, intolerance of exercise, muscle deterioration, and, in some cases, infertility due to nonmotile sperm.

These are all genetic disorders; and to understand them, we need to know that mitochondria have a limited amount of their own DNA. The mitochondrion encodes some, though by no means all, of its own proteins. Human mitochondrial DNA (mtDNA) consists of 16,568 base pairs and contains 37 genes: 22 specify transfer RNAs (tRNAs), 2 specify ribosomal RNAs (rRNAs), and the remaining 13 encode polypeptides, all of which are components of the respiratory complexes that carry out oxygen-dependent ATP synthesis. An extensive amount of information regarding mitochondrial DNA, including mutations associated with human diseases, has been compiled by the MITOMAP project at the University of California–Irvine.

Although the respiratory complexes also contain about 70 nuclear-encoded polypeptides, most of the known mitochondrial myopathies are due to defects in mitochondrial rather than in nuclear genes, involving either the deletion or mutation of specific mitochondrial genes. Most of these defects occur in the genes that

encode mitochondrial tRNAs, which are required for the synthesis of all 13 mitochondrially encoded polypeptides. Examples of these diseases include *mitochondrial encephalomyopathy* and *hypertrophic cardiomyopathy*, which affect the brain and heart, respectively, and are due to defects in the tRNAs for the amino acids leucine and isoleucine, respectively.

Mitochondrial disorders follow what is called *maternal inheritance*, which means that they come exclusively from the mother. Since all human mitochondria are derived from the mitochondria that were present in the egg at the time of fertilization, the sperm cell provides its half of the nuclear genome but makes little or no mitochondrial contribution. A further distinction between nuclear and mitochondrial genes is that a typical human cell contains hundreds of mitochondria, each with 2 to 10 copies of mtDNA, so the cell contains thousands of copies of mtDNA. As a result, mtDNAs can be quite heterogeneous within specific tissues, and mitochondrial disorders are likely to arise only when most of the mitochondria within a given tissue contain a particular mutant gene.

Peroxisomal Disorders

Most of the human diseases associated with peroxisomes are due to the absence of a single peroxisomal protein. Considering the variety of cellular functions that are localized to this organelle, it is not surprising that many disorders are known in which specific peroxisomal proteins are either defective or absent. Unlike mitochondria, peroxisomes contain no DNA; thus, all of these defects are due to mutations in nuclear genes.

There are several well-studied peroxisomal disorders: *Zellweger syndrome* (ZS), *neonatal adrenoleukodystrophy* (NALD), *X-linked adrenoleukodystrophy* (X-ALD), and *infantile Refsum disease* (IRD). ZS is characterized by a variety of severe neurological, visual, and liver disorders that lead to death during early childhood, often by age one or two. NALD (autosomal recessive) and X-ALD (sex-linked, typically male-only) are less severe than ZS but eventually lead to neurological impairment and death. Patients with NALD or X-ALD usually begin to display symptoms of adrenal failure and neurological debilitation during early childhood. The symptoms of IRD are similar to, but less severe than, those of ZS and NALD.

Although these diseases were discovered independently and not initially considered to be related, we now know that each of these disorders is caused by mutations in any of 11 different human genes. The most severe mutations in these genes cause ZS, moderately severe mutations cause NALD, and the least severe mutations cause IRD.

In some forms of NALD, the defective gene product is a membrane protein involved in the transport of very-long-chain fatty acids into the peroxisomes, where such fatty acids are broken

has a single spiral mitochondrion wrapped around the central shaft, or *axoneme*, of the cell. Notice how tightly the mitochondrion coils around the axoneme, just where the ATP is actually needed to propel the sperm cell. Muscle cells and cells that specialize in the transport of ions also have numerous mitochondria located strategically to meet the special energy needs of such cells (**Figure 4-13**).

The Chloroplast. The next organelle we encounter on our gallery tour is the **chloroplast**, the site of photosynthesis in plants and algae (**Figure 4-14**). Chloroplasts are large organelles, typically a few micrometers in diameter and 5–10 μm long, and can be quite numerous in the leaves of green plants. They are therefore substantially bigger than mitochondria and larger than any other structure in a

down to shorter chain lengths that can be handled by the mitochondrion. When this transport mechanism is impaired or non-functional, the very-long-chain fatty acids accumulate in cells and tissues. That accumulation is particularly devastating in the brain, where the very-long-chain fatty acids destroy the myelin sheaths that provide essential insulation for nerve cells, thereby profoundly impairing transmission of neural signals.

Similarly, X-ALD is caused by mutation of a gene encoding a peroxisomal transporter, *ABCD-1*. This transporter is involved in recycling of myelin, a component of the sheath that surrounds neurons. Its deficiency leads to demyelination and neurodegeneration and is typically fatal before adolescence. However, in late 2009, early results of a gene therapy trial showed significant promise: neural degeneration was halted in two X-ALD patients who received an infusion of their own blood cells that had been treated with a modified viral vector containing a functional gene encoding *ABCD-1*.

In ZS, the missing or defective gene product can be any of several proteins that are essential for targeting peroxisomal enzymes for uptake by the organelle. As we will learn in Chapter 12, peroxisomal proteins are encoded by nuclear genes, synthesized on cytoplasmic ribosomes, and then imported into the peroxisome. Individuals with ZS can typically synthesize all of the requisite enzymes, but they have a deficiency in any of several membrane proteins involved in transporting these enzymes into the organelle. As a result, the proteins remain in the cytosol, where they cannot perform their intended functions. Peroxisomes can be detected in the cells of such individuals, but the organelles are empty “ghosts”—membrane-bound structures without the normal complement of enzymes. Not surprisingly, afflicted individuals develop various neurological, visual, and liver disorders that lead inevitably to death during early childhood.

Lysosomal Disorders

Another organelle subject to a variety of genetic defects is the lysosome, which plays an essential role in the digestion of food molecules and in the recycling of cellular components that are no longer needed. Over 40 heritable *lysosomal storage diseases* are known, each characterized by the harmful accumulation of a specific substance or class of substances—most commonly polysaccharides or lipids—that would normally be catabolized by the hydrolytic enzymes present within the lysosome. In some cases, the defective protein is either a key enzyme in degrading the substance or a protein involved in transporting the degradation products out of the lysosome. In other cases, the requisite enzymes are synthesized in normal amounts but are secreted into the extracellular medium rather than being targeted to the lysosomes.

An example of this latter type of disorder is *I-cell disease*, which is due to a defect in an enzyme called N-acetylglucosamine phospho-

transferase. This enzyme is required to correctly process the portion of the protein that targets, or signals, lysosomal enzymes for import into the organelle. Without the necessary signal, the hydrolytic enzymes are not transported into the lysosomes. Thus, the lysosomes become engorged with undegraded polysaccharides, lipids, and other material. This causes irreversible damage to the cells and tissues.

A well-known example is *Tay-Sachs disease*, which is quite rare in the general population but has a higher incidence among Ashkenazi Jews of eastern European ancestry. After about six months, children who are homozygous for this defect show rapid mental and motor deterioration as well as skeletal, cardiac, and respiratory dysfunction. This is followed by dementia, paralysis, blindness, and death, usually within three years. The disease results from the accumulation in nervous tissue of a particular glycolipid called *ganglioside G_{M2}*. (For the structure of gangliosides, see Figure 7-6.) The missing or defective lysosomal enzyme is β -N-acetylhexosaminidase A, which cleaves the terminal N-acetylgalactosamine from the “glyco” (carbohydrate) portion of the ganglioside. *G_{M2}* is a prominent component of the membranes in brain cells. Not surprisingly, lysosomes from children afflicted with Tay-Sachs disease are filled with membrane fragments containing undigested gangliosides.

All of the known lysosomal storage diseases can be diagnosed prenatally. Even more significant are the prospects for *enzyme replacement therapy* and *gene therapy*. Enzyme replacement therapy has been shown to be effective with a particular lysosomal disorder called *Gaucher disease*, characterized by the absence or deficiency of a specific hydrolase called *glucocerebrosidase*. In the absence of this enzyme, lipids called *glucocerebrosides* accumulate in the lysosomes of macrophages, which are the white blood cells that engulf and digest foreign material or invasive microorganisms as well as cellular debris and whole damaged cells. (The structure of cerebrosides is also shown in Figure 7-6.) Glucocerebroside accumulation typically leads to liver and spleen enlargement, anemia, and mental retardation. In the past, treatment depended on the ability to purify glucocerebrosidase from human placental material, treat it so that it could be taken up by macrophages, and infuse it into the bloodstream. Recently, however, a synthetic form has been produced using recombinant DNA technology, simplifying the treatment protocol. Macrophages that take up this enzyme are able to degrade glucocerebrosides as needed, thereby effectively treating what would otherwise be a fatal disease.

Gene therapy is a somewhat more futuristic prospect for the treatment of lysosomal storage diseases as well as other heritable disorders. This approach involves inserting the genes for the missing enzymes into the appropriate cells, thereby effectively curing the disease rather than simply treating it. For a further consideration of gene therapy, see the discussion in Chapter 20.

typical plant cell except the nucleus. (However, in some algae, there is a single large chloroplast that can be larger than the nucleus.) Like mitochondria, chloroplasts are surrounded by both an inner and an outer membrane. Inside the chloroplast there is a third membrane system consisting of flattened sacs called **thylakoids** and the membranes (**stroma thylakoids**), that interconnect them. Thylakoids

are stacked together to form the **grana** (singular: **granum**) that characterize most chloroplasts (Figure 4-14c, d).

Chloroplasts are the site of *photosynthesis*, the light-driven process that uses solar energy and carbon dioxide to manufacture the sugars and other organic compounds from which all life is ultimately fabricated. Chloroplasts are found in leaves and other photosynthetic tissues of higher plants,

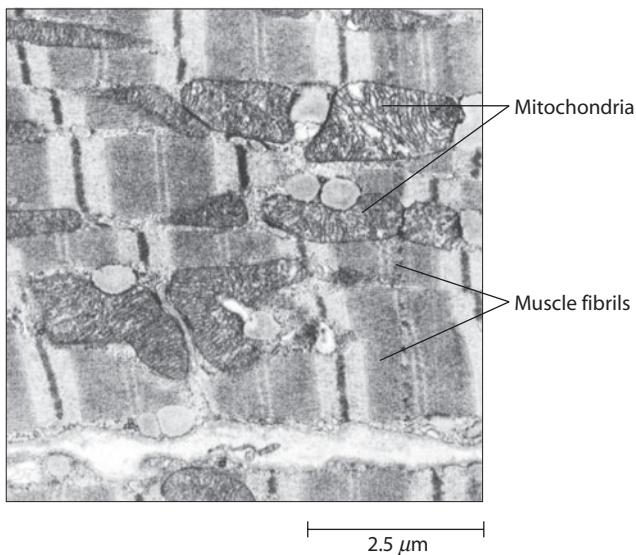

FIGURE 4-13 Localization of Mitochondria Within a Muscle Cell. This electron micrograph of a muscle cell from a cat heart shows the intimate association of mitochondria with the muscle fibrils that are responsible for muscle contraction (TEM).

as well as in the algae. Located within this organelle are most of the enzymes, intermediates, and light-absorbing pigments needed for photosynthesis—the enzymatic reduction of carbon dioxide to sugar, an energy-requiring process. (Note

that this reduction process is the reverse of the energy-producing oxidation reactions in mitochondria that convert sugar to carbon dioxide.) Reactions that depend directly on solar energy are localized in or on the thylakoid membrane system. Reactions involved in the reduction of carbon dioxide to sugar molecules occur within the semifluid **stroma** that fills the interior of the chloroplast. Also found in the stroma are chloroplast ribosomes along with small, circular molecules of DNA that encode some of the RNAs and proteins needed in the chloroplast.

Although known primarily for their role in photosynthesis, chloroplasts are also involved in a variety of other chemical processes. They contain enzymes that reduce nitrogen from the oxidation level of soil-derived nitrate ions (NO_3^-) to ammonia (NH_3), the form of nitrogen required for protein synthesis. Enzymes in the chloroplast also catalyze the reduction of sulfate ions (SO_4^{2-}) to hydrogen sulfide (H_2S), which can be incorporated into the amino acid cysteine for use in protein synthesis. Furthermore, the chloroplast is the most prominent example of a class of plant organelles known as the **plastids**. Plastids other than chloroplasts perform a variety of functions in plant cells. *Chromoplasts*, for example, are pigment-containing plastids that are responsible for the characteristic coloration of flowers, fruits, and other plant parts. *Amyloplasts* are plastids that are specialized for the storage of starch (amylose and amylopectin).

Chloroplast structure

The Endosymbiont Theory: Did Mitochondria and Chloroplasts Evolve from Ancient Bacteria? Having just met the mitochondrion and chloroplast as eukaryotic organelles, we pause here for a brief digression concerning the possible evolutionary origins of these organelles. Both mitochondria and chloroplasts contain their own DNA and ribosomes, which enable them to carry out the synthesis of both RNA and proteins (although most of the proteins present in these organelles are in fact encoded by nuclear genes). As molecular biologists studied nucleic acid and protein synthesis in these organelles, they were struck by the many similarities between these processes in mitochondria and chloroplasts and the comparable processes in bacterial cells. Both have circular DNA molecules without associated histones, and both show similarities in rRNA sequences, ribosome size, sensitivity to inhibitors of RNA and protein synthesis, and the type of protein factors used in protein synthesis. In addition to these molecular features, mitochondria and chloroplasts resemble bacterial cells in size and shape, and they have a double membrane in which the inner membrane has bacterial-type lipids.

These similarities led to the **endosymbiont theory** for the evolutionary origins of mitochondria and chloroplasts.

This theory, which is described more fully in Box 11A, pages 298–299, proposes that both of these organelles originated from prokaryotes that gained entry to, and established a symbiotic relationship within, the cytoplasm of ancient single-celled organisms called *protoeukaryotes*. The endosymbiont theory proposes that protoeukaryotes ingested bacteria and cyanobacteria by a process known as *phagocytosis* (“cell eating”). Following phagocytosis, these cells were not digested; instead, they took up residence in the cytoplasm and eventually evolved into mitochondria and chloroplasts, respectively.

The Endoplasmic Reticulum. Extending throughout the cytoplasm of almost every eukaryotic cell is a network of membranes called the **endoplasmic reticulum**, or ER (**Figure 4-15**). The name sounds complicated, but *endoplasmic* just means “within the plasm” (of the cell), and *reticulum* is simply a fancy word for “network.” The endoplasmic reticulum consists of tubular membranes and flattened sacs, or **cisternae** (singular: **cisterna**), that are interconnected. The internal space enclosed by the ER membranes is called the **lumen**. The ER is continuous with the outer membrane of the nuclear envelope (Figure 4-15a).

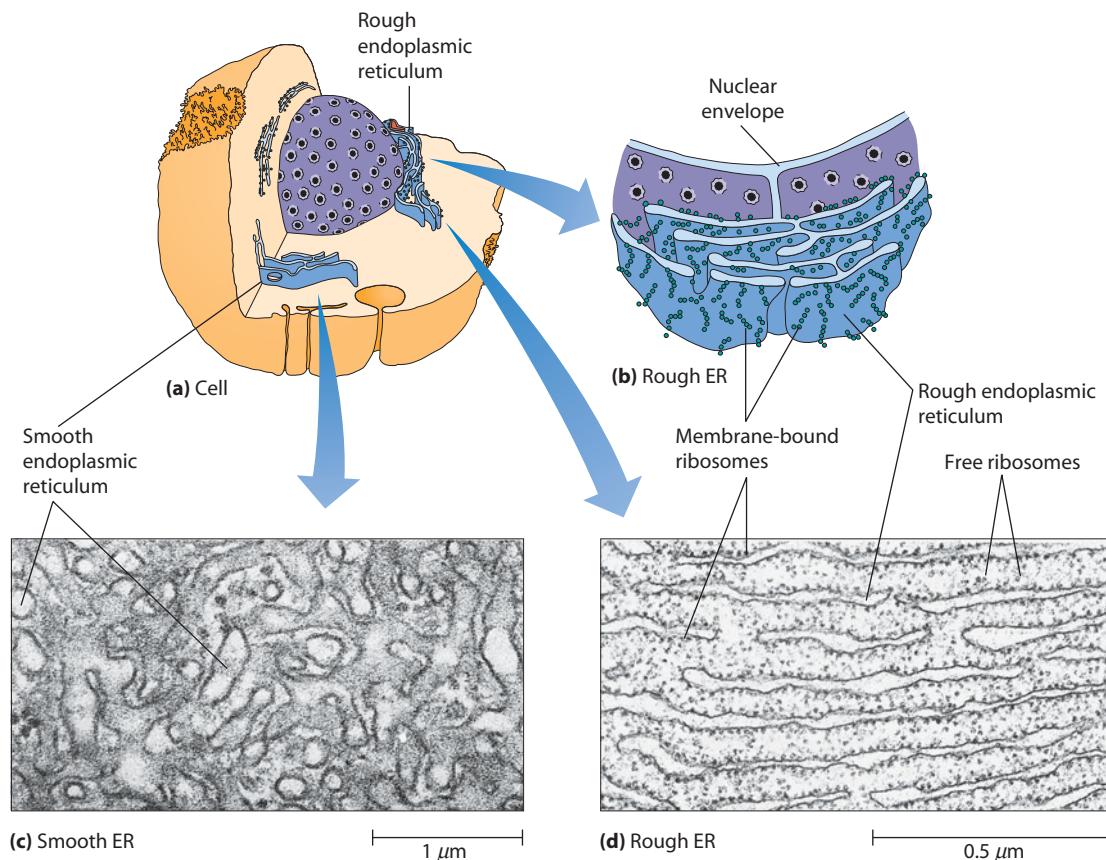

FIGURE 4-15 The Endoplasmic Reticulum. (a) A cutaway view of a typical animal cell showing the location and relative size of the endoplasmic reticulum (ER). (b) A schematic illustration depicting the organization of the rough ER as layers of flattened membranes. Rough ER membranes are studded on their outer surface with ribosomes and are continuous with the nuclear envelope. (c) An electron micrograph of smooth ER in a cell from guinea pig testis (TEM). (d) An electron micrograph of rough ER in a rat pancreas cell (TEM); notice that ribosomes are either attached to the ER or free in the cytosol.

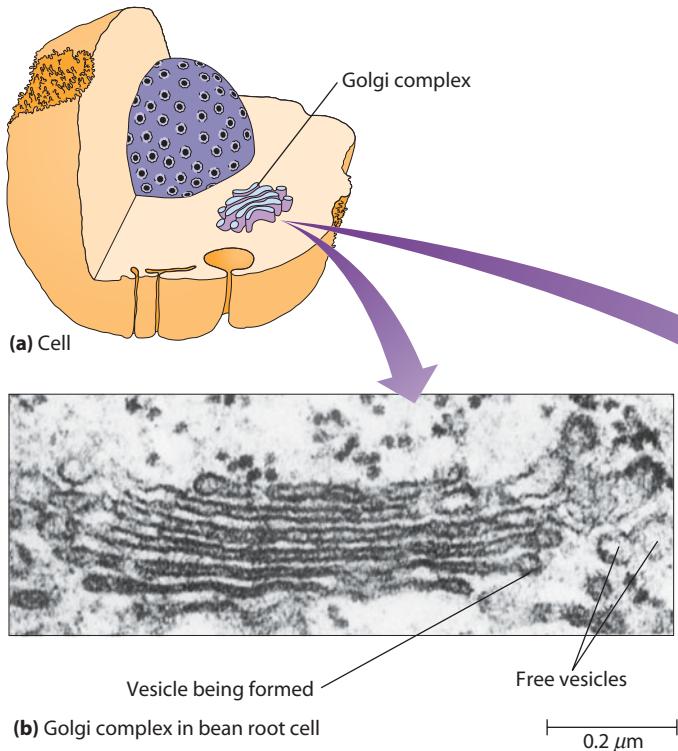

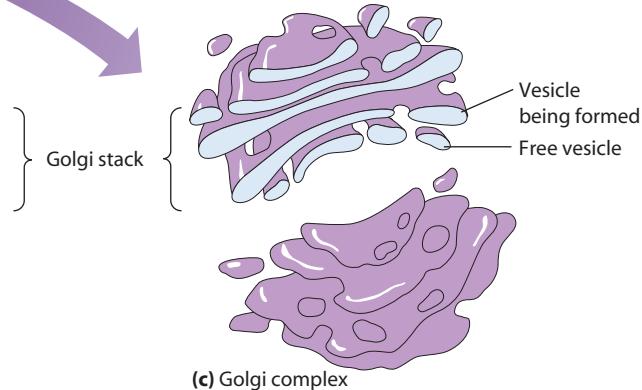

FIGURE 4-16 The Golgi Complex. (a) A cutaway view showing the relative orientation and size of a Golgi complex within a cell. (b) An electron micrograph of a Golgi complex in a cell from a bean root tip (TEM). Notice the vesicles forming at the edges of the stack and the free vesicles that have presumably just arisen in this way. (c) A schematic drawing of a Golgi complex, showing vesicle formation by budding.

The space between the two nuclear membranes is therefore a part of the same compartment as the lumen of the ER.

The ER can be either *rough* or *smooth*. **Rough endoplasmic reticulum (rough ER)** appears “rough” in the electron microscope because it is studded with ribosomes on the side of the membrane that faces the cytosol (Figure 4-15b, d). These ribosomes are actively synthesizing polypeptides that either accumulate within the membrane or are transported across the ER membrane to accumulate in the luminal space inside the ER. Many membrane proteins and secreted proteins are synthesized in this way. These proteins then travel to the appropriate membrane or to the cell surface via the Golgi complex and secretory vesicles, as described in the following subsection (and in more detail in Chapter 12).

Not all proteins are synthesized by ribosomes associated with membranes of the rough ER, however. Much protein synthesis occurs on free ribosomes that are not attached to the ER but are instead found in the cytosol and are not associated with a membrane (Figure 4-15d). In general, secretory proteins and membrane proteins are made by ribosomes on the rough ER, whereas proteins intended for use within the cytosol or for import into organelles are made on free ribosomes.

The **smooth endoplasmic reticulum (smooth ER)** has no role in protein synthesis and hence no ribosomes. It therefore has a characteristically smooth appearance when viewed by electron microscopy (Figure 4-15c). Smooth ER is involved in the synthesis of lipids and steroids, such as cholesterol and the steroid hormones derived from it. In addition, smooth ER is responsible for inactivating and detoxifying drugs such as barbiturates and other compounds that might otherwise be toxic or harmful to the

cell. When we discuss muscle contraction in detail in Chapter 16, we will see how a specialized type of smooth ER known as the *sarcoplasmic reticulum* is critical for storage and release of the calcium ions that trigger contraction.

The Golgi Complex. Closely related to the ER in both proximity and function is the **Golgi complex** (or *Golgi apparatus*), named after its Italian discoverer, Camillo Golgi. The Golgi complex, shown in Figure 4-16, consists of a stack of flattened vesicles (also known as *cisternae*). The Golgi complex plays an important role in processing and packaging secretory proteins and in synthesizing complex polysaccharides. Vesicles that arise by budding off the ER are accepted by the Golgi complex. Here, the contents of the vesicles (proteins, for the most part) and sometimes the vesicle membranes are further modified and processed. The processed contents are then passed on to other components of the cell in vesicles that arise by budding off the Golgi complex (Figure 4-16c).

Most membrane proteins and secretory proteins are glycoproteins. The initial steps in *glycosylation* (addition of short-chain carbohydrates) take place within the lumen of the rough ER, but the process is usually completed within the Golgi complex. The Golgi complex should therefore be understood as a processing station, with vesicles both fusing with it and arising from it. Almost everything that goes into it comes back out—but in a modified, packaged form, often ready for export from the cell.

Secretory Vesicles. Once processed by the Golgi complex, secretory proteins and other substances intended for export from the cell are packaged into **secretory vesicles**. The cells of your pancreas, for example, contain many

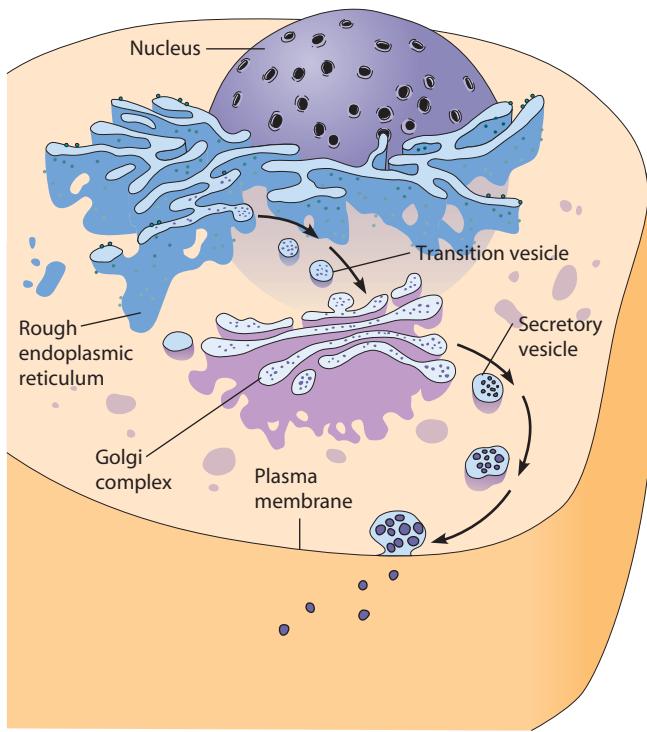

FIGURE 4-17 The Process of Secretion in Eukaryotic Cells. Proteins to be packaged for export are synthesized on the rough ER, passed to the Golgi complex for processing, and eventually compartmentalized into secretory vesicles. These vesicles then make their way to the plasma membrane and fuse with it, releasing their contents to the exterior of the cell.

such vesicles because the pancreas is responsible for the synthesis of several important digestive enzymes. These enzymes are synthesized on the rough ER, packaged by the Golgi complex, and then released from the cell via secretory vesicles, as shown in **Figure 4-17**. These vesicles from the Golgi region move to and fuse with the plasma membrane and discharge their contents to the exterior of the cell by the process of exocytosis. Together, the ER, Golgi, secretory vesicles, and the lysosomes we will discuss shortly constitute the cell's *endomembrane system*. The endomembrane system is responsible for *trafficking* of molecules through the cell, and this process of protein and lipid synthesis, processing, trafficking, and export via the ER, the Golgi complex, and secretory vesicles will be considered in more detail in Chapter 12.

The Lysosome. The next picture at our cellular exhibition is of the **lysosome**, an organelle about $0.5\text{--}1.0\ \mu\text{m}$ in diameter and surrounded by a single membrane (**Figure 4-18**). Lysosomes were discovered in the early 1950s by Christian de Duve and his colleagues. The story of that discovery is recounted in **Box 4B** to underscore the significance of chance observations when they are made by astute investigators and to illustrate the importance of new techniques to the progress of science.

Lysosomes are used by the cell as a means of storing **hydrolases**, enzymes capable of digesting specific biological molecules such as proteins, carbohydrates, or fats. While

cells need such enzymes, both to digest food molecules and to break down damaged cellular constituents, these enzymes must be carefully sequestered until actually needed, lest they digest the normal components that were not scheduled for destruction in the cell.

Like secretory proteins, lysosomal enzymes are synthesized on the rough ER, transported to the Golgi complex, and then packaged into vesicles that can become lysosomes. A special carbohydrate covering on the inner surface of the lysosomal membrane protects this membrane (and the cell) from the hydrolytic activities of these enzymes until they are needed. Equipped with its repertoire of hydrolases, the lysosome is able to break down virtually any kind of biological molecule. Eventually, the digestion products are small enough to pass through the membrane into the cytosol of the cell, where they can be used to synthesize more macromolecules—recycling at the cellular level.

The Peroxisome. The next organelle at our exhibition is the **peroxisome**. Peroxisomes resemble lysosomes in size and general lack of obvious internal structure. Like lysosomes, they are surrounded by a single rather than a double membrane. Peroxisomes are found in plant and animal

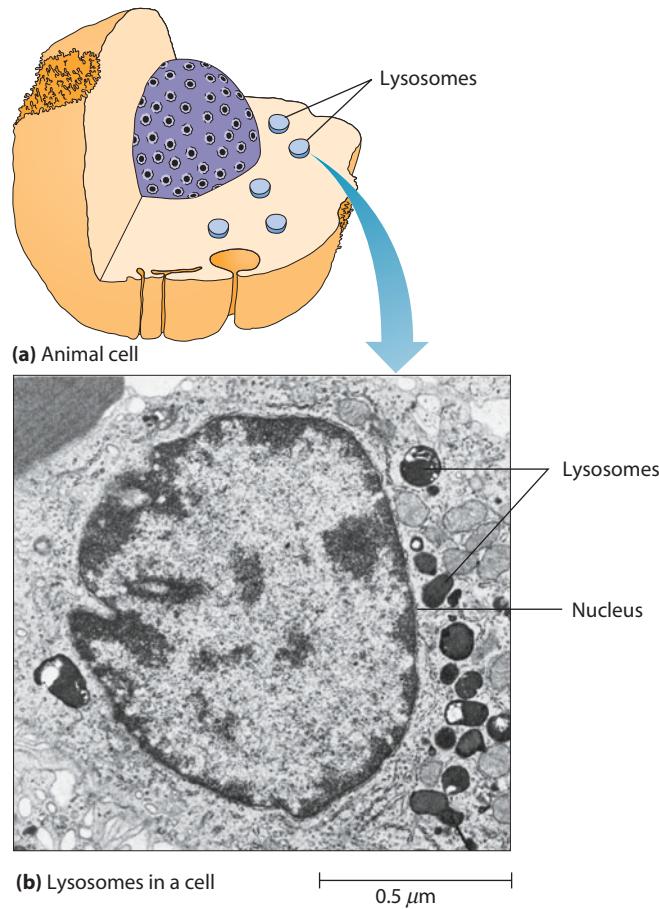

FIGURE 4-18 Lysosomes. (a) A cutaway view showing lysosomes within an animal cell. (b) Lysosomes in an animal cell stained cytochemically for acid phosphatase, a lysosomal enzyme. The cytochemical staining technique results in dense deposits of lead phosphate at the site of acid phosphatase activity (TEM).

Discovering Organelles: The Importance of Centrifuges and Chance Observations

Have you ever wondered how the various organelles within eukaryotic cells were discovered? There are almost as many answers to that question as there are kinds of organelles. In general, they were described by microscopists before their role in the cell was understood. As a result, the names of organelles usually reflect structural features rather than physiological roles. Thus, *chloroplast* simply means “green particle” and *endoplasmic reticulum* just means “network within the plasm (of the cell).”

Such is not the case for the *lysosome*, however. This organelle was the first to have its biochemical properties described before it had ever been reported by microscopists. Only after fractionation data had predicted the existence and properties of just such an organelle were lysosomes actually observed in cells. A suggestion of its function is even inherent in the name given to the organelle because the Greek root *lys-* means “to digest.” (The literal translation is “to loosen,” but that’s essentially what digestion does to chemical bonds!)

The lysosome is something of a newcomer on the cellular biology scene; it was not discovered until the early 1950s. The story of that discovery is fascinating because it illustrates how important chance observations can be, especially when made by the right people at the right time. The account also illustrates how significant new techniques can be, since the discovery depended on subcellular fractionation, a technique that was then still in its infancy.

The story begins in 1949 in the laboratory of Christian de Duve, who later received a Nobel Prize for this work. Like so many scientific advances, the discovery of lysosomes depended on

a chance observation made by an astute investigator. Because of an interest in the effect of insulin on carbohydrate metabolism, de Duve was attempting at the time to pinpoint the cellular location of *glucose-6-phosphatase*, the enzyme responsible for the release of free glucose in liver cells. For the control enzyme (that is, one not involved in carbohydrate metabolism), de Duve happened to choose *acid phosphatase*.

De Duve first homogenized liver tissue and resolved it into several fractions by the new technique of *differential centrifugation*, which separates cellular components based on differences in size and density. In this way, he was able to show that the glucose-6-phosphatase activity could be recovered with the microsomal fraction. (*Microsomes* are small vesicles that form from ER fragments when tissue is homogenized.) This in itself was an important observation because it helped establish the identity of microsomes, which at the time tended to be dismissed as fragments of mitochondria.

But the acid phosphatase results turned out to be still more interesting, even though they were at first quite puzzling. When de Duve and his colleagues assayed the liver homogenates for this enzyme, they found only a fraction of the expected activity. When assayed again for the same enzyme a few days later, however, the same homogenates had about ten times as much activity.

Speculating that he was dealing with some sort of activation phenomenon, de Duve subjected the homogenates to differential centrifugation to see which subcellular fraction the phenomenon was associated with. He and his colleagues were able to demonstrate

cells, as well as in fungi, protozoa, and algae. They perform several distinctive functions that differ with cell type, but they have the common property of both generating and degrading hydrogen peroxide (H_2O_2). Hydrogen peroxide is highly toxic to cells but can be decomposed into water and oxygen by the enzyme *catalase*. Eukaryotic cells protect themselves from the detrimental effects of hydrogen peroxide by packaging peroxide-generating reactions together with catalase in a single compartment, the peroxisome.

In animals, peroxisomes are found in most cell types but are especially prominent in liver and kidney cells (Figure 4-19). Beyond their role in detoxifying hydrogen peroxide, animal peroxisomes have several other functions, among them detoxifying other harmful compounds (such as methanol, ethanol, formate, and formaldehyde) and catabolizing unusual substances (such as D-amino acids). Some researchers speculate that peroxisomes may also be involved in regulating oxygen levels within the cell and may play a role in aging.

Animal peroxisomes also play a role in the oxidative breakdown of fatty acids, which are components of triacylglycerols, phospholipids, and glycolipids (see Figure 3-27). As we will see in Chapter 10, fatty acid breakdown occurs primarily in the mitochondrion. However, fatty acids with

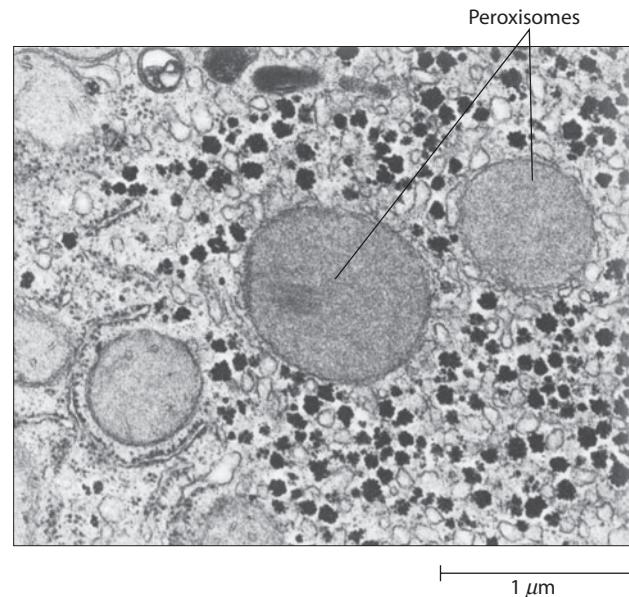

FIGURE 4-19 Animal Peroxisomes. Several peroxisomes can be seen in this cross section of a liver cell (TEM). Peroxisomes are found in most animal cells but are especially prominent features of liver and kidney cells.

that much of the acid phosphatase activity could be recovered in the mitochondrial fraction and that this fraction showed an even greater increase in activity after standing a few days than did the original homogenates.

To their surprise, they then discovered that, upon re-centrifugation, this elevated activity no longer sedimented with the mitochondria but stayed in the supernatant. They went on to show that the activity could be increased and the enzyme solubilized by a variety of treatments, including harsh grinding, freezing and thawing, and exposure to detergents or hypotonic conditions. From these results, de Duve concluded that the enzyme must be present in some sort of membrane-bound particle that could easily be ruptured to release the enzyme. Apparently, the enzyme could not be detected within the particle, probably because the membrane was not permeable to the substrates used in the enzyme assay.

Assuming that particle to be the mitochondrion, they continued to isolate and study this fraction of the liver homogenates. At that point, another chance observation occurred, this time because of a broken centrifuge. The unexpected breakdown forced one of de Duve's students to use an older, slower centrifuge, and the result was a mitochondrial fraction containing little or no acid phosphatase. Based on this unexpected finding, de Duve speculated that the mitochondrial fraction as they usually prepared it might in fact contain two kinds of organelles: the actual mitochondria, which could be sedimented with either centrifuge, and some sort of more slowly sedimenting particle that came down only in the faster centrifuge.

This led them to devise a fractionation scheme that allowed the original mitochondrial fraction to be subdivided into a rapidly sedimenting component and a slowly sedimenting component. As you might guess, the rapidly sedimenting component contained the mitochondria, as evidenced by the presence of enzymes known to be mitochondrial markers. The acid phosphatase, on the other hand, was in the slowly sedimenting component, along with several other hydrolytic enzymes, such as ribonuclease, deoxyribonuclease, β -glucuronidase, and a protease. Each of these enzymes showed the same characteristic of increased activity upon membrane rupture, a property that de Duve termed *latency*.

By 1955, de Duve was convinced that these hydrolytic enzymes were packaged together in a previously undescribed organelle. In keeping with his speculation that this organelle was involved in intracellular lysis (digestion), he called it a *lysosome*.

Thus, the lysosome became the first organelle to be identified entirely on biochemical criteria. At the time, no such particles had been described by microscopy. But when de Duve's lysosome-containing fractions were examined with the electron microscope, they were found to contain membrane-bound vesicles that were clearly not mitochondria and were in fact absent from the mitochondrial fraction. Knowing what the isolated particles looked like, microscopists were then able to search for them in fixed tissue. As a result, lysosomes were soon identified and reported in a variety of animal tissues. Within six years, then, the organelle that began as a puzzling observation in an insulin experiment became established as a bona fide feature of most animal cells.

more than 12 carbon atoms are oxidized relatively slowly by mitochondria. In the peroxisomes, on the other hand, fatty acids up to 22 carbon atoms long are oxidized rapidly. The long chains are degraded by the removal of two carbon units at a time until they get to a length (10–12 carbon atoms) that the mitochondria can efficiently handle.

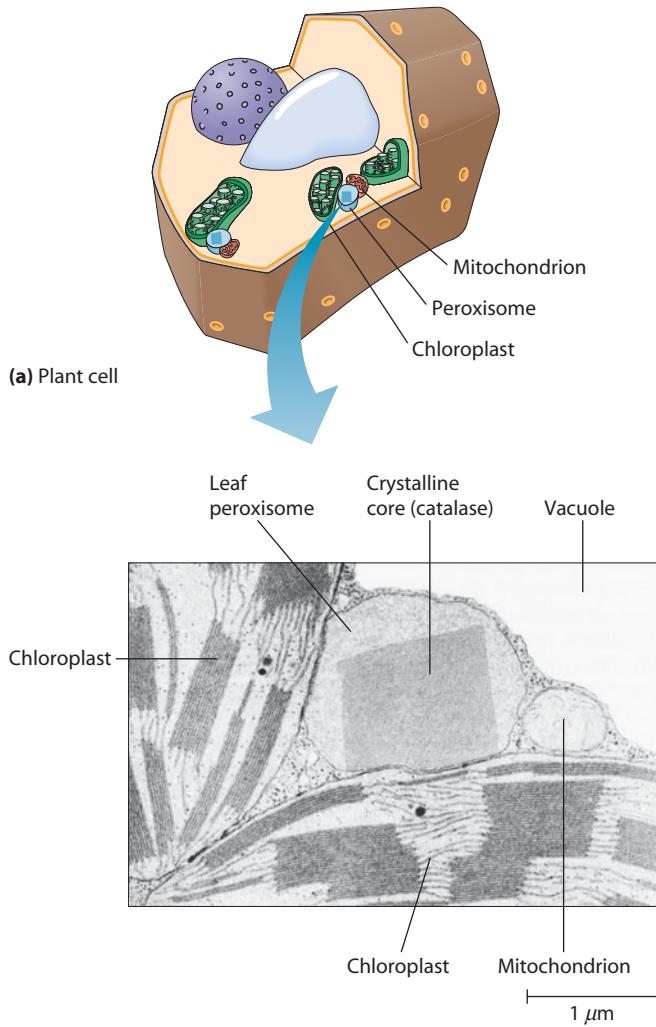

The vital role of peroxisomes in breaking down long-chain fatty acids is underscored by the serious human diseases that result when one or more peroxisomal enzymes involved in degrading long-chain fatty acids are defective or absent. One such disease is neonatal adrenoleukodystrophy (NALD), a sex-linked (male-only) disorder that leads to profound neurological debilitation and eventually to death. (See Box 4A, pages 86–87, for a discussion of NALD and other human diseases associated with deficiencies in peroxisome function.)

The best-understood metabolic roles of peroxisomes occur in plant cells. During the germination of fat-storing seeds, specialized peroxisomes called **glyoxysomes** play a key role in converting stored fat into carbohydrates. In photosynthetic tissue, **leaf peroxisomes** are prominent due to their role in *photorespiration*, the light-dependent uptake of oxygen and release of carbon dioxide (to be discussed further in Chapter 11). The photorespiratory

pathway is an example of a cellular process that involves several organelles. While some of the enzymes that catalyze the reactions in this sequence occur in the peroxisome, others are located in the chloroplast or the mitochondrion. This mutual involvement in a common cellular process is suggested by the intimate association of peroxisomes with mitochondria and chloroplasts in many leaf cells, as shown in **Figure 4-20**.

Vacuoles. Some cells contain another type of membrane-bound organelle called a **vacuole**. In animal and yeast cells, vacuoles are used for temporary storage or transport. Some protozoa take up food particles or other materials from their environment by phagocytosis. Phagocytosis is a form of endocytosis that involves an infolding of the plasma membrane around the desired substance. This infolding is followed by a pinching-off process that internalizes the membrane-bound particle as a type of vacuole, known as a phagosome. Following fusion with a lysosome, the contents of a phagosome are hydrolyzed to provide nutrients for the cell.

Plant cells also contain vacuoles. In fact, a single large vacuole is found in most mature plant cells (**Figure 4-21**). This vacuole, sometimes called the **central vacuole**, may

(b) Organelles in a plant leaf cell

FIGURE 4-20 A Leaf Peroxisome and Its Relationship to Other Organelles in a Plant Cell. (a) A cutaway view showing a peroxisome, a mitochondrion, and a chloroplast within a plant cell. (b) A peroxisome in close proximity to chloroplasts and to a mitochondrion within a tobacco leaf cell (TEM). This is probably a functional relationship because all three organelles participate in the process of photorespiration. The crystalline core frequently observed in leaf peroxisomes is the enzyme catalase, which catalyzes the decomposition of hydrogen peroxide into water and oxygen.

play a limited role in storage and in intracellular digestion. However, its main importance is its role in maintaining the *turgor pressure* that keeps tissue from wilting. The vacuole has a high concentration of solutes; thus, water tends to move into the vacuole, causing it to swell. As a result, the vacuole presses the rest of the cell constituents against the cell wall, thereby maintaining the turgor pressure. The limp appearance of wilted tissue results when the central vacuole does not provide adequate pressure. We can easily demonstrate this by placing a piece of crisp celery in salt water. The high concentration of salt on the outside of the cells will cause water to move out of the cells. As the turgor pressure decreases, the tissue will quickly become limp and lose its crispness.

Ribosomes. The last portrait in our gallery is the **ribosome**. Strictly speaking, the ribosome is not really an organelle because it is not surrounded by a membrane. We will consider it here, however, because ribosomes, like organelles, are the focal point for a specific cellular activity—in this case, protein synthesis. Ribosomes are found in all cells, but bacteria, archaea, and eukaryotes differ from each other in ribosome size and in the number and kinds of ribosomal protein and RNA molecules (see Table 4-1). Bacteria and archaea contain smaller ribosomes than those found in eukaryotes, and all three have different numbers of ribosomal proteins, although there is some similarity between the ribosomal proteins of archaeal and eukaryotic cells. A defining feature is that each of these three cell types has its own unique type of ribosomal RNA, the very molecule whose characteristics were used to define the archaea as a domain distinct from bacteria.

Compared with even the smallest organelles, ribosomes are tiny structures. The ribosomes of eukaryotic and prokaryotic cells have diameters of about 30 and

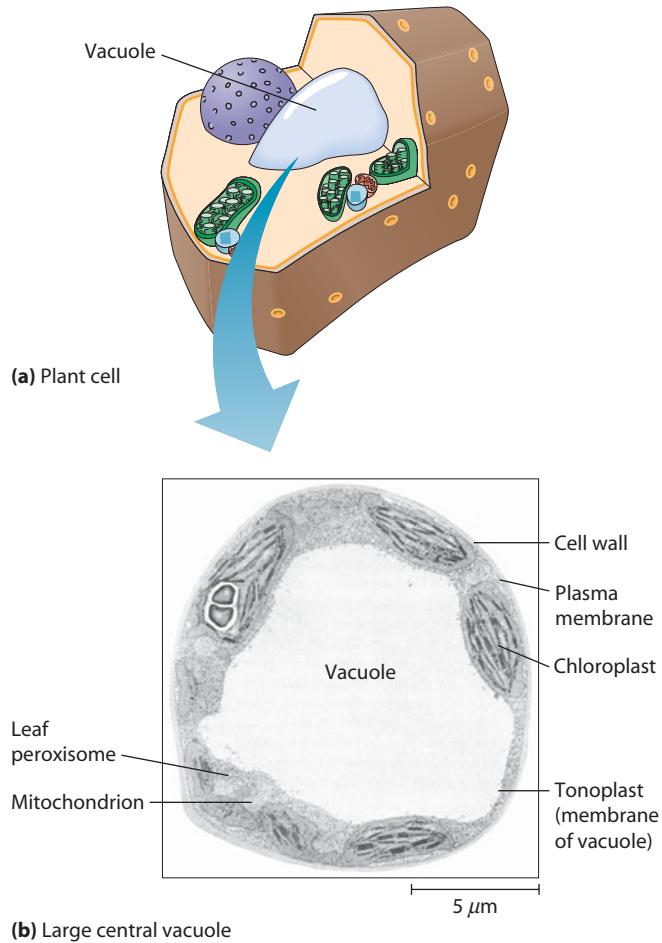

FIGURE 4-21 The Vacuole in a Plant Cell. (a) A cutaway view showing the vacuole in a plant cell. (b) An electron micrograph of a bean leaf cell with a large central vacuole (TEM). The vacuole occupies much of the internal volume of the cell, with the cytoplasm sandwiched into a thin region between the vacuole and the plasma membrane. The membrane of the vacuole is called the tonoplast.

25 nm, respectively. An electron microscope is therefore required to visualize ribosomes (see Figure 4-15d). To appreciate how small ribosomes are, consider that more than 350,000 ribosomes could fit inside a typical bacterial cell, with room to spare!

Another way to express the size of such a small particle is to refer to its **sedimentation coefficient**. The sedimentation coefficient of a particle or macromolecule is a measure of how rapidly the particle sediments in an ultracentrifuge. The rate of sedimentation is expressed in *Svedberg units (S)*, as described in Box 12A, pages 327–329. Sedimentation coefficients are widely used to indicate relative size, especially for large macromolecules such as proteins and nucleic acids and for small particles such as ribosomes. Ribosomes from eukaryotic cells have sedimentation coefficients of about 80S, while those from bacteria and archaea are about 70S (see Table 4-1).

A ribosome consists of two subunits differing in size, shape, and composition (Figure 4-22). In eukaryotic cells, the **large** and **small ribosomal subunits** have sedimentation coefficients of about 60S and 40S, respectively. For bacterial and archaeal ribosomes, the corresponding values are about 50S and 30S. (Note that the sedimentation coefficients of the subunits do not add up to that of the intact ribosome. This is because sedimentation coefficients depend on both size and shape and are therefore not linearly related to molecular weight.) In early 2009, scientists successfully extracted all 55 ribosomal proteins (plus the three rRNAs) from an *E. coli* cell and then were able to reconstruct a functional “artificial” ribosome capable of synthesizing protein. This is a significant step toward the creation of artificial cells *in vitro* that have custom-made ribosomes tailored for industrial uses to produce particular desired proteins.

Ribosomes are far more numerous than most other intracellular structures. Prokaryotic cells usually contain thousands of ribosomes, and eukaryotic cells may have hundreds of thousands or even millions of them. Ribosomes are also found in both mitochondria and chloroplasts, where

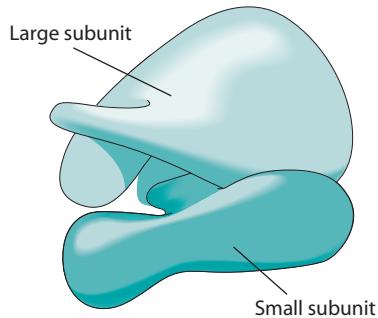

FIGURE 4-22 Structure of a Ribosome. Each ribosome is made up of a large subunit and a small subunit that join together when they attach to a messenger RNA and begin to make a protein. The fully assembled ribosome of a eukaryotic cell has a diameter of about 30 nm. The ribosomes and ribosomal subunits of bacterial and archaeal cells are somewhat smaller than those of eukaryotic cells and consist of their own distinctive protein and RNA molecules.

they function in organelle-specific protein synthesis. The ribosomes of these eukaryotic organelles differ in size and composition from the ribosomes found in the cytoplasm of the same cell, but they are strikingly similar to those found in bacteria and cyanobacteria. This similarity is particularly striking when the nucleotide sequences of ribosomal RNA (rRNA) from mitochondria and chloroplasts are compared with those of bacterial and cyanobacterial rRNAs. These similarities provide further support for the endosymbiotic origins of mitochondria and chloroplasts.

The Cytoplasm of Eukaryotic Cells Contains the Cytosol and Cytoskeleton

The **cytoplasm** of a eukaryotic cell consists of that portion of the interior of the cell not occupied by the nucleus. Thus, the cytoplasm includes organelles such as the mitochondria; it also includes the **cytosol**, the semifluid substance in which the organelles are suspended. In a typical animal cell, the cytosol occupies more than half of the cell's total internal volume. Many cellular activities take place in the cytosol, including the synthesis of proteins, the synthesis of fats, and the initial steps in releasing energy from sugars.

In the early days of cell biology, the cytosol was regarded as a rather amorphous, gel-like substance. Its proteins were thought to be soluble and freely diffusible. However, several new techniques have greatly changed this view. We now know that the cytosol of eukaryotic cells, far from being a structureless fluid, is permeated by an intricate three-dimensional array of interconnected microfilaments, microtubules, and intermediate filaments called the **cytoskeleton** (Figures 4-23 and 4-24). While the cytoskeleton was initially thought to exist only in

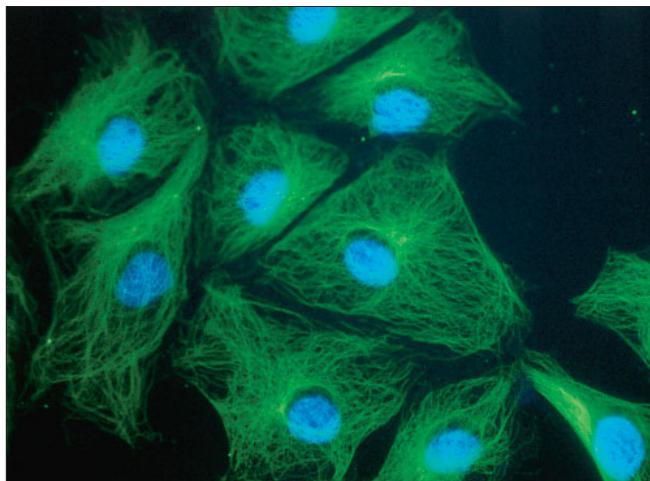

FIGURE 4-23 The Cytoskeleton. This micrograph uses immunofluorescence microscopy to reveal the microtubules in the cytoskeleton of fibroblast cells, which give rise to components of connective tissue and the extracellular matrix (Chapter 17). In this image, one fluorescent antibody is directed against the microtubules (green), and a second highlights the nuclei of the cells (blue).

VIDEOS www.thecellplace.com *The cytoskeleton in a neuron growth cone*

(a) A microtubule. A diagram of a microtubule, showing 13 protofilaments forming a hollow cylinder. Each protofilament is a polymer of tubulin dimers. All the tubulin dimers are oriented in the same direction, giving polarity to the protofilament and hence to the entire microtubule.

(b) A microfilament. A diagram of a microfilament, showing a strand of F-actin twisted into a helical structure. The F-actin polymer consists of monomers of G-actin, all oriented in the same direction to give the microfilament its inherent polarity.

(c) An intermediate filament. A diagram of an intermediate filament. The structural unit is the tetrameric protofilament, consisting of two pairs of coiled polypeptides. Protofilaments assemble by end-to-end and side-to-side alignment, forming an intermediate filament that is thought to be eight protofilaments thick at any point.

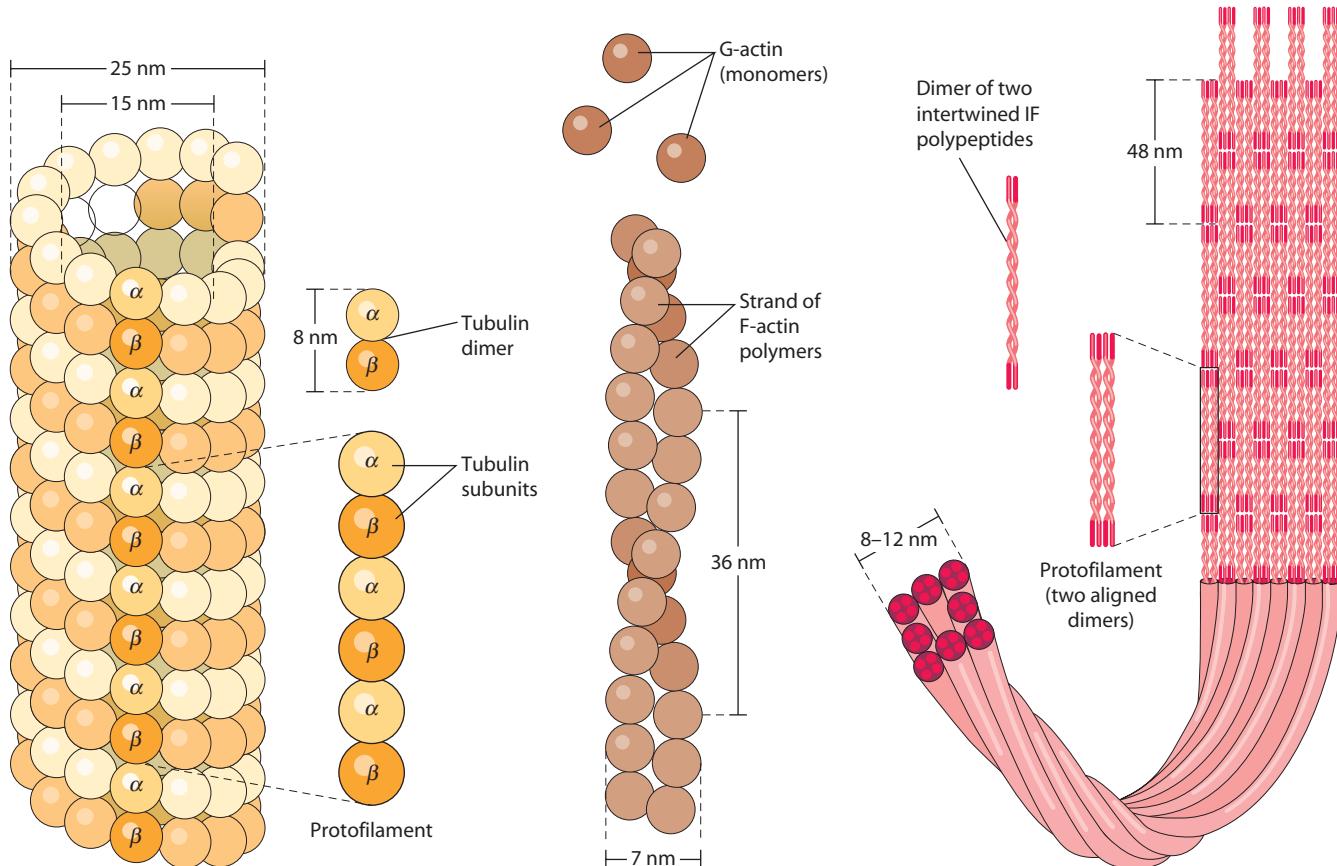

FIGURE 4-24 Structures of Microtubules, Microfilaments, and Intermediate Filaments. This figure illustrates the composition and structural details of the three primary elements making up the cytoskeleton of a eukaryotic cell: (a) microtubules, (b) microfilaments, and (c) intermediate filaments. For more information, see Chapter 15.

eukaryotes, proteins related to the eukaryotic cytoskeletal proteins have recently been discovered in bacteria.

As the name suggests, the cytoskeleton is an internal framework that gives a cell its distinctive shape and high level of internal organization. This elaborate array of microfilaments and microtubules forms a highly structured yet dynamic matrix that helps establish and maintain cell shape. In addition, the cytoskeleton plays an important role in cell movement and cell division. As we will see in later chapters, the microfilaments and microtubules that make up the cytoskeleton function in the contraction of muscle cells, the beating of cilia and flagella, the movement of chromosomes during cell division, and, in some cases, the locomotion of the cell itself. We will also see how, rather than being a static framework inside the cell, the

cytoskeleton is a dynamic system that is constantly being remodeled.

In eukaryotic cells, the cytoskeleton serves as a framework for positioning and actively moving organelles and macromolecules within the cytosol. It may also function similarly in regard to ribosomes and enzymes. Some researchers estimate that up to 80% of the proteins and enzymes of the cytosol are not freely diffusible but are instead associated with the cytoskeleton. Even water, which accounts for about 70% of the cell volume, may be influenced by the cytoskeleton. It has been estimated that as much as 20–40% of the water in the cytosol may be bound to the microfilaments and microtubules of the cytoskeleton.

The three major structural elements of the cytoskeleton—*microtubules*, *microfilaments*, and *intermediate*

filaments—are shown in Figure 4-24. They can be visualized by phase-contrast, immunofluorescence, and electron microscopy. Some of the structures they are found in (such as cilia, flagella, or muscle fibrils) can even be seen by ordinary light microscopy. Microfilaments and microtubules are best known for their roles in contraction and motility. In fact, these roles were appreciated well before it became clear that the same structural elements are also integral parts of the pervasive network of microfilaments and microtubules that gives cells their characteristic shape and structure.

Chapter 15 provides a detailed description of the cytoskeleton, followed in Chapter 16 by a discussion of microtubule- and microfilament-mediated contraction and motility. We will also encounter microtubules and microfilaments in Chapter 19 because of their roles in chromosome separation and cell division, respectively. Here, we will focus on the structural features of the three major components of the cytoskeleton: microtubules, microfilaments, and intermediate filaments.

Microtubules. Of the structural elements found in the cytoskeleton, **microtubules** are the largest. A well-known microtubule-based cellular structure is the *axoneme* of cilia and flagella, the appendages responsible for motility of eukaryotic cells. We have already encountered an example of such a structure—the axoneme of the sperm tail shown in Figure 4-12 consists of microtubules. Microtubules also form the *mitotic spindle fibers* that separate chromosomes prior to cell division, as we will see in Chapter 19.

Besides their involvement in motility and chromosome movement, microtubules also play an important role in the organization of the cytoplasm and the intracellular movement of macromolecules and other materials in the cell. They contribute to the overall shape of the cell, the spatial disposition of its organelles, and the distribution of microfilaments and intermediate filaments. Examples of the diverse phenomena governed by microtubules include the asymmetric shapes of animal cells, the plane of cell division in plant cells, the ordering of filaments during muscle development, and the positioning of mitochondria around the axoneme of motile appendages.

As shown in Figure 4-24a, microtubules are hollow cylinders with an outer diameter of about 25 nm and an inner diameter of about 15 nm. Although microtubules are usually drawn as if they are straight and rigid, video microscopy reveals them to be quite flexible in living cells. The wall of the microtubule consists of longitudinal arrays of *protofilaments*, usually 13 of them arranged side by side around the hollow center, called the *lumen*. Each protofilament is a linear polymer of *tubulin*. Tubulin is a dimeric protein consisting of two similar but distinct polypeptide subunits, α -*tubulin* and β -*tubulin*. All of the tubulin dimers in each of the protofilaments are oriented in the same direction, such that all of the subunits face the same end of the microtubule. This uniform orientation gives the

microtubule an inherent *polarity*. As we will see in Chapter 15, the polarity of microtubules has important implications for their assembly and for the directional movement of membrane-bounded organelles that microtubules are associated with.

Microfilaments. **Microfilaments** are much thinner than microtubules. They have a diameter of about 7 nm, which makes them the smallest of the major cytoskeletal components. Microfilaments are best known for their role in the contractile fibrils of muscle cells, as we will see in more detail in Chapter 16. However, microfilaments are involved in a variety of other cellular phenomena as well. They can form connections with the plasma membrane and thereby influence locomotion, amoeboid movement, and cytoplasmic streaming. Microfilaments also produce the *cleavage furrow* that divides the cytoplasm of an animal cell after the two sets of chromosomes have been separated by the mitotic spindle fibers. In addition, microfilaments contribute importantly to the development and maintenance of cell shape.

Microfilaments are polymers of the protein *actin* (Figure 4-24b). Actin is synthesized as a monomer called *G-actin* (G for globular). G-actin monomers polymerize into long strands of *F-actin* (F for filamentous), with each strand about 4 nm wide. Each microfilament consists of a chain of actin monomers that are assembled into a filament with a helical appearance and a diameter of about 7 nm. Like microtubules, microfilaments show polarity; all of the subunits are oriented in the same direction. This polarity influences the direction of microfilament elongation; assembly usually proceeds more readily at one end of the growing microfilament, whereas disassembly is favored at the other end.

Intermediate Filaments. **Intermediate filaments** (Figure 4-24c) make up the third structural element of the cytoskeleton. Intermediate filaments have a diameter of about 8–12 nm, larger than the diameter of microfilaments but smaller than that of microtubules. Intermediate filaments are the most stable and the least soluble constituents of the cytoskeleton. Because of this stability, some researchers regard intermediate filaments as a scaffold that supports the entire cytoskeletal framework. Intermediate filaments are also thought to have a tension-bearing role in some cells because they often occur in areas that are subject to mechanical stress.

In contrast to microtubules and microfilaments, intermediate filaments differ in their protein composition from tissue to tissue. Based on biochemical criteria, intermediate filaments from animal cells can be grouped into six classes. A specific cell type usually contains only one or sometimes two classes of intermediate filament proteins. Because of this tissue specificity, animal cells from different tissues can be distinguished on the basis of the intermediate filament proteins present. This *intermediate filament typing* serves as a diagnostic tool in medicine.

Despite their heterogeneity of size and chemical properties, all intermediate filament proteins share common structural features. They all have a central rodlike segment that is remarkably similar from one intermediate filament protein to the other. Flanking the central region of the protein are N-terminal and C-terminal segments that differ greatly in size and sequence, presumably accounting for the functional diversity of these proteins.

Several models have been proposed for intermediate filament structure. One possibility is shown in Figure 4-24c. The basic structural unit is a dimer of two intertwined, intermediate filament polypeptides. Two such dimers align laterally to form a tetrameric *protofilament*. Protofilaments then interact with each other to form an intermediate filament that is thought to be eight protofilaments thick at any point, with protofilaments probably joined end to end in an overlapping manner. We have already seen a similar structure in Figure 3-10 when we looked at the proposed structure of the keratin fibers of hair.

The Extracellular Matrix and the Cell Wall Are “Outside” the Cell

So far, we have considered the plasma membrane that surrounds every cell, the nucleus and cytoplasm within, and the variety of organelles, membrane systems, ribosomes, microtubules, and microfilaments found in the cytoplasm of most eukaryotic cells. While it may seem that our tour of the cell is complete, most cells are also characterized by extracellular structures formed from materials that the cells transport outward across the plasma membrane. These structures often give physical support to the cells making up a particular tissue. For many animal cells, these structures are called the **extracellular matrix (ECM)** and consist primarily of *collagen fibers* and *proteoglycans*. For plant and fungal cells, the extracellular structure is the rigid **cell wall**, which consists mainly of *cellulose microfibrils* embedded in a matrix of other polysaccharides and small amounts of protein.

Most bacteria and archaea are also surrounded by an extracellular structure called a cell wall. However, bacterial cell walls consist not of cellulose but mainly of *peptidoglycans*. Peptidoglycans contain long chains of repeating units of *N*-acetylglucosamine (GlcNAc) and *N*-acetylmuramic acid (MurNAc), amino sugars that we encountered in Chapter 3 (see Figure 3-26). These chains are held together to form a netlike structure by crosslinks composed of about a dozen amino acids linked by peptide bonds—thus the name peptidoglycan. In addition, bacterial cell walls contain a variety of other constituents, some of which are unique to each of the major structural groups of bacteria. Archaeal cell walls vary considerably from species to species—some are mainly proteinaceous, while others have peptidoglycan-like components.

These differences among cells are in keeping with the lifestyles of these groups of organisms. Plants are generally *nonmotile*, a lifestyle that is compatible with the rigidity that

cell walls confer on an organism. Animals, on the other hand, are usually *motile*, an essential feature for an organism that needs not only to find food but also to escape becoming food for other organisms! Accordingly, animal cells are not encased in rigid walls; instead, they are surrounded by a strong but elastic network of collagen fibers. Bacteria and archaea may be motile or nonmotile, but they usually live in hypotonic environments (lower concentrations of external solutes than found in the cells), and their cell walls provide rigid support and protection from bursting due to osmotic pressure as water enters the cell.

The ECM of animal cells can vary in structure depending on the cell type. Micrographs of the ECM from bone, cartilage, and connective tissue can be seen in Figure 17-13. The primary function of the ECM is support, but the kinds of extracellular materials and the patterns they are deposited in may regulate such diverse processes as cell motility and migration, cell division, cell recognition and adhesion, and cell differentiation during embryonic development. The main constituents of animal extracellular structures are the collagen fibers and the network of proteoglycans that surround them. In vertebrates, collagen is such a prominent part of tendons, cartilage, and bone that it is the single most abundant protein of the animal body.

Figure 4-25 illustrates the prominence of the cell wall as a structural feature of a typical plant cell. Although the distinction is not made in the figure, plant cell walls are actually of two types. The wall that is laid down during cell division, called the *primary cell wall*, consists mainly of cellulose fibrils embedded in a gel-like polysaccharide matrix. Primary walls are quite flexible and extensible, which allows them to expand somewhat in response to cell enlargement and elongation. As a cell reaches its final size and shape, a much thicker and more rigid *secondary cell wall* may form by deposition of additional cell wall material on the inner surface of the primary wall. The secondary wall usually contains more cellulose than the primary wall and may have a high content of *lignin*, a major component of wood. Deposition of a secondary cell wall renders the cell inextensible and therefore defines the final size and shape of the cell.

Neighboring plant cells, though separated by the wall between them, are actually connected by numerous cytoplasmic bridges, called **plasmodesmata** (singular: **plasmodesma**), which pass through the cell wall. The plasma membranes of adjacent cells are continuous through each plasmodesma, such that the channel is membrane lined. The diameter of a typical plasmodesma is large enough to allow water and small solutes to pass freely from cell to cell. Most of the cells of the plant are interconnected in this way. Primary and secondary cell walls and plasmodesmata will be discussed in more detail in Chapter 17.

Animal cells can also communicate with each other. But instead of plasmodesmata, they have intercellular connections called *gap junctions*, which are specialized for

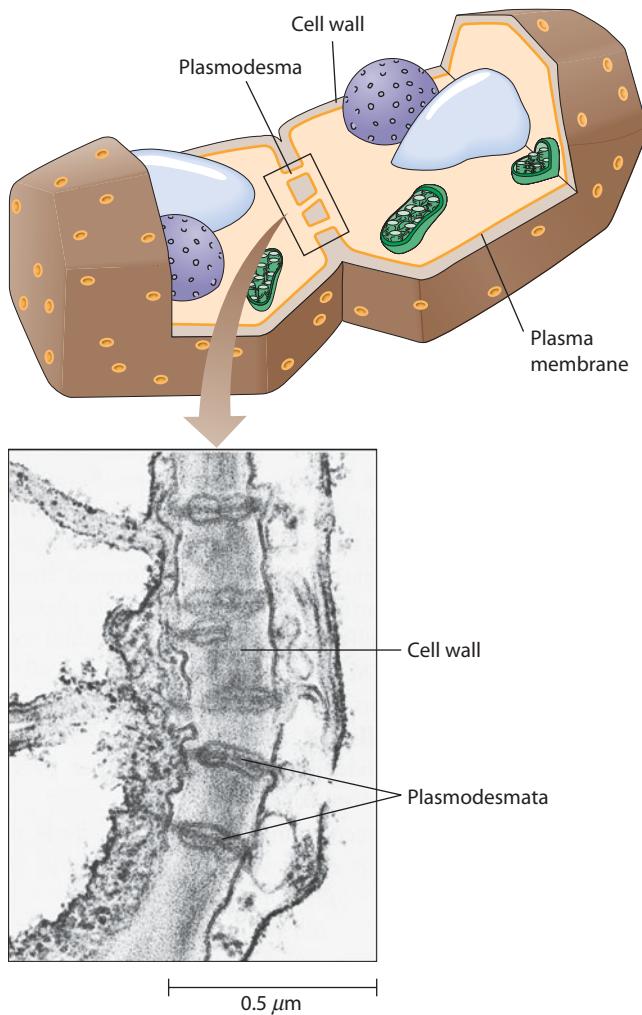

FIGURE 4-25 The Plant Cell Wall. The wall surrounding a plant cell consists of rigid microfibrils of cellulose embedded in a noncellulosic matrix of proteins and sugar polymers. Notice how the neighboring cells are connected by plasmodesmata (TEM).

the transfer of material between the cytoplasms of adjacent cells. Two other types of intercellular junctions are also characteristic of animal cells. *Tight junctions* hold cells together so tightly that the transport of substances through the spaces between the cells is effectively blocked. *Adhesive junctions* also link adjacent cells but for the purpose of connecting them tightly into sturdy yet flexible sheets. Each of these types of junctions is discussed in detail in Chapter 17.

Viruses, Viroids, and Prions: Agents That Invade Cells

Before concluding this preview of cellular biology, we will look at several kinds of agents that invade cells, subverting normal cellular functions and often killing their unwilling hosts. These include the *viruses*, which have been studied for over 100 years, and two other agents we know much less about—the *viroids* and *prions*.

A Virus Consists of a DNA or RNA Core Surrounded by a Protein Coat

Viruses are noncellular, parasitic particles that are incapable of a free-living existence. However, they can invade and infect cells and redirect the synthetic machinery of the infected host cell toward the production of more virus particles. Viruses cannot perform all of the functions required for independent existence and must therefore depend on the cells they invade for most of their needs. They are not considered to be living organisms, nor are they made of cells. A virus particle has no cytoplasm, no ribosomes, no organelles, few or no enzymes, and typically consists of only a few different molecules of nucleic acid and protein.

Viruses are, however, responsible for many diseases in humans, animals, and plants and are thus important in their own right. They are also significant research tools for cell and molecular biologists because they are much less complicated than cells. The tobacco mosaic virus (TMV) that we encountered in Chapter 2 (see Figures 2-20 and 2-21) is a good example of a virus that is important both economically and scientifically—economically because of the threat it poses to tobacco and other crop plants that it can infect and scientifically because it is so amenable to laboratory study. Fraenkel-Conrat's studies on TMV self-assembly described in Chapter 2 are good examples of the usefulness of viruses to cell biologists.

Viruses are typically named for the diseases they cause. Poliovirus, influenza virus, herpes simplex virus, and TMV are several common examples. Other viruses have more cryptic laboratory names (such as T4, Q β , λ , or Epstein-Barr virus). Viruses that infect bacterial cells are called *bacteriophages*, or often just *phages* for short. Bacteriophages and other viruses will figure prominently in our discussion of molecular genetics in Chapters 18–23.

Viruses are smaller than all but the tiniest cells, with most ranging in size from about 25 to 300 nm. They are small enough to pass through a filter that traps bacteria, and the collected filtrate will still be infectious. Because of this, their existence was postulated by Louis Pasteur 50 years before they were able to be seen in the electron microscope! The smallest viruses are about the size of a ribosome, whereas the largest ones are about one-quarter the diameter of a typical bacterial cell. Each virus has a characteristic shape, as defined by its protein capsid. Some of these varied shapes are shown in **Figure 4-26**.

Despite their morphological diversity, viruses are chemically quite simple. Most viruses consist of little more than a *coat* (or *capsid*) of protein surrounding a *core* that contains one or more molecules of either RNA or DNA, depending on the type of virus. This is another feature distinguishing viruses from cells, which always have both DNA and RNA. The simplest viruses, such as TMV, have a single nucleic acid molecule surrounded by a capsid consisting of proteins of a single type (see Figure 2-20). More complex viruses have cores that contain several nucleic

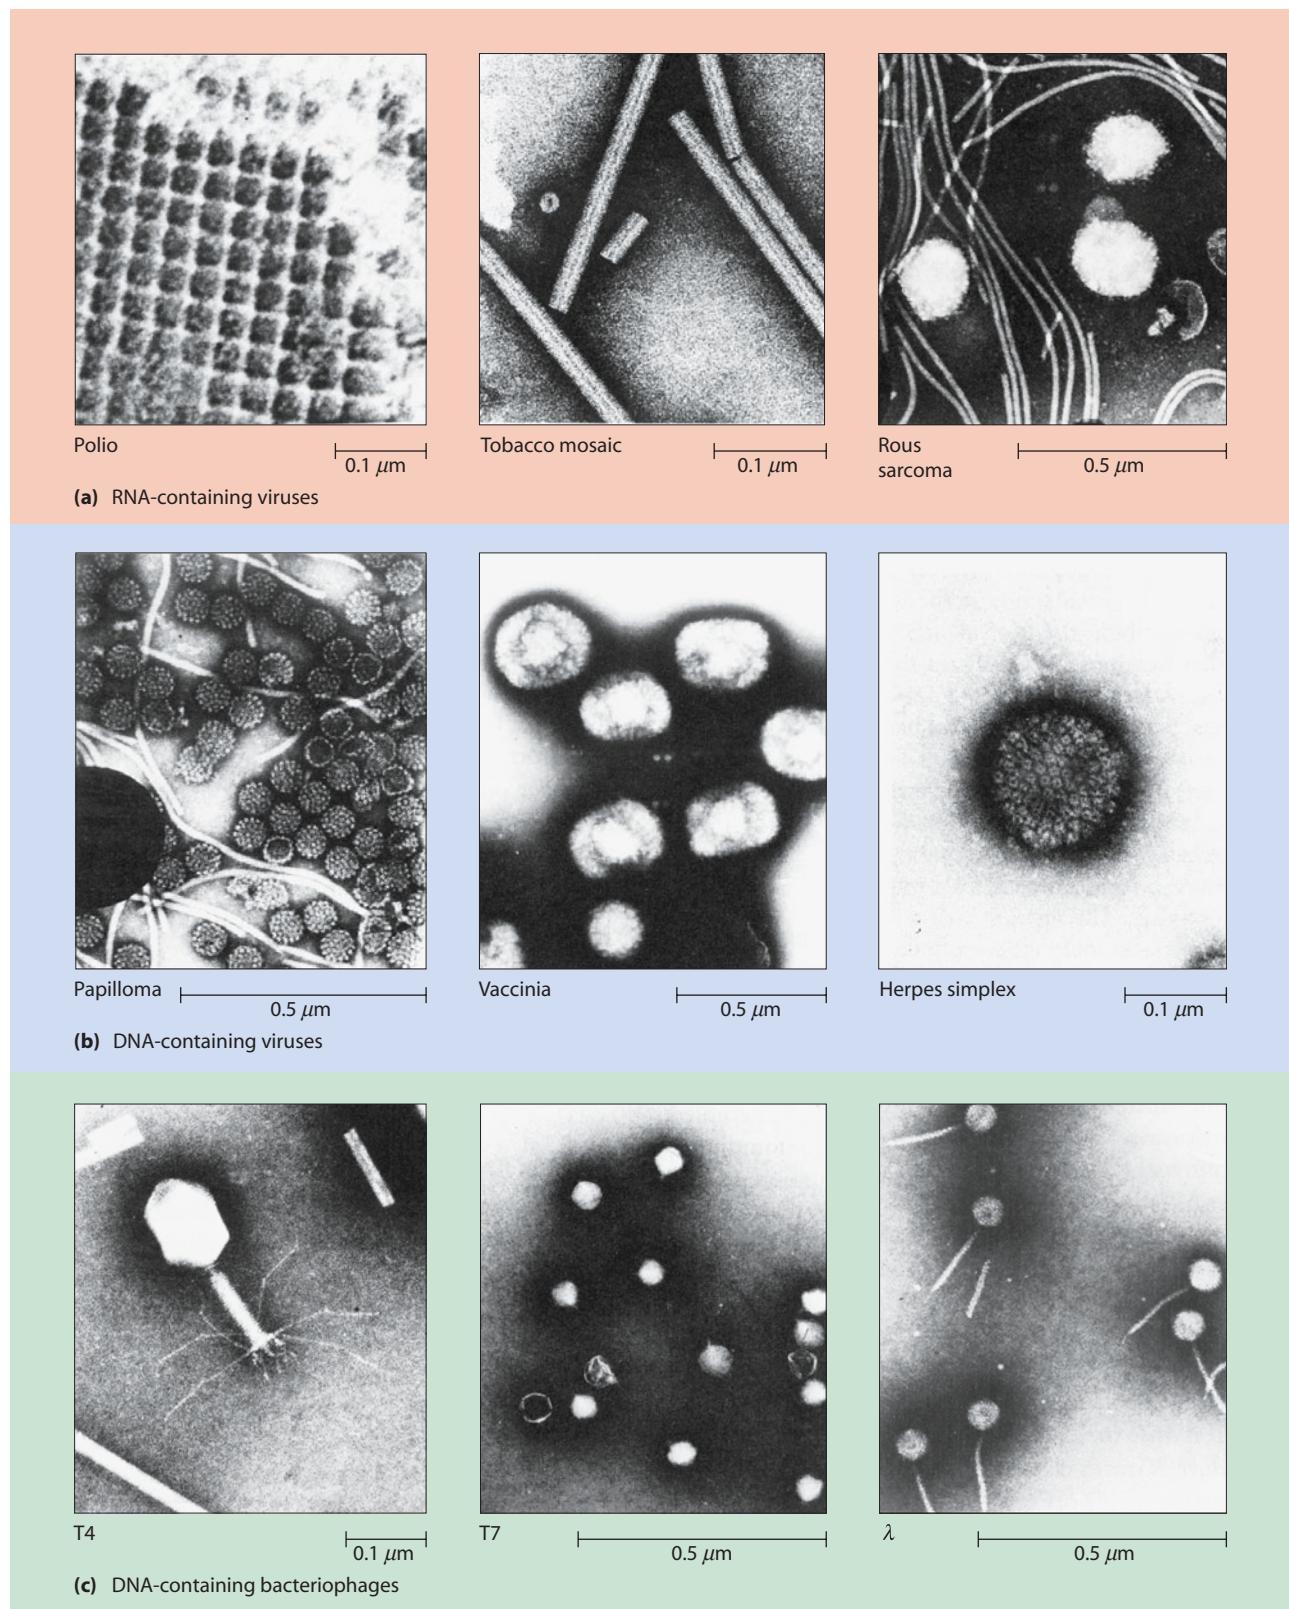

FIGURE 4-26 Sizes and Shapes of Viruses. These electron micrographs illustrate the morphological diversity of viruses. (a) RNA-containing viruses (left to right): polio, tobacco mosaic, and Rous sarcoma viruses. (b) DNA-containing viruses: papilloma, vaccinia, and herpes simplex viruses. (c) DNA-containing bacteriophages: T4, T7, and λ (all TEMs).

acid molecules and capsids consisting of several (or even many) different kinds of proteins. Some viruses are surrounded by a membrane that is derived from the plasma membrane of the host cell in which the viral particles were previously made and assembled. Such viruses are called *enveloped viruses*. Human immunodeficiency virus (HIV), the virus that causes AIDS (acquired immune deficiency syndrome), is an enveloped virus; it is covered by a membrane that it received from the previously infected white blood cell.

Students sometimes ask whether viruses are living. The answer depends crucially on what we mean by “living,” and it is probably worth pondering only to the extent that it helps us more fully understand what viruses are—and what they are not. The most fundamental properties of living things are *metabolism* (cellular reactions organized into coherent pathways), *irritability* (perception of, and response to, environmental stimuli), and the *ability to reproduce*. Viruses clearly do not satisfy the first two criteria. Outside their host cells, viruses are inert and inactive. They can, in fact, be isolated and crystallized almost like a chemical compound. It is only in an appropriate host cell that a virus becomes functional, undergoing a cycle of synthesis and assembly that gives rise to more viruses.

Even the ability of viruses to reproduce has to be qualified carefully. A basic tenet of the cell theory is that cells arise only from preexisting cells, but this is not true of viruses. No virus can give rise to another virus by any sort of self-duplication process. Rather, the virus must take over the metabolic and genetic machinery of a host cell, reprogramming it for synthesis of the proteins necessary to package the DNA or RNA molecules that arise by copying the genetic information of the parent virus.

Viroids Are Small, Circular RNA Molecules

As simple as viruses are, there are even simpler noncellular agents that can infect eukaryotic cells (though apparently not prokaryotic cells, as far as we currently know). The **viroids** found in some plant cells represent one class of such agents. Viroids are small, circular RNA molecules, and they are the smallest known infectious agents. These RNA molecules are only about 250–400 nucleotides long and are replicated in the host cell even though they do not code for any protein. Some have been shown to have enzymatic properties that aid in their replication.

Viroids are responsible for diseases of several crop plants, including potatoes and tobacco. A viroid disease that has severe economic consequences is *cadang-cadang*

disease of the coconut palm. It is not yet clear how viroids cause disease. They may enter the nucleus and interfere with the transcription of DNA into RNA in a process known as *gene silencing*. Alternatively, they may interfere with the subsequent processing required of most eukaryotic mRNAs, disrupting subsequent protein synthesis.

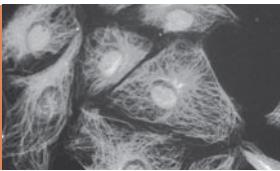

Viroids do not occur in free form but can be transmitted from one plant cell to another when the surfaces of adjacent cells are damaged and there is no membrane barrier for the RNA molecules to cross. There are also reports that they can be transmitted by seed, pollen, or agricultural implements used in cultivation and harvesting. Recent studies have shown that many plant species harbor latent viroids that cause no obvious symptoms.

Prions Are “Proteinaceous Infective Particles”

Prions represent another class of noncellular infectious agents. The term was coined to describe *proteinaceous infective particles* that are responsible for neurological diseases such as scrapie in sheep and goats, kuru in humans, and mad cow disease in cattle. *Scrapie* is so named because infected animals rub incessantly against trees or other objects, scraping off most of their wool in the process. *Kuru* is a degenerative disease of the central nervous system originally reported among native peoples in New Guinea who consumed infected brain tissue. Patients with this or other prion-based diseases suffer initially from mild physical weakness and dementia; but the effects slowly become more severe, and the diseases are eventually fatal. For a discussion of *mad cow disease*, see Box 22A, page 692.

Prion proteins are abnormally folded versions of normal cellular proteins. Both the normal and variant forms of the prion protein are found on the surfaces of neurons, suggesting that the protein may somehow affect the receptors that detect nerve signals. Some biologists speculate that a similar mechanism is responsible for the plaques of misfolded proteins that are found in the brains of deceased Alzheimer syndrome patients.

Prions are not destroyed by cooking or boiling, so special precautions are recommended in areas where prion-caused diseases are known to occur. For example, a prion disease known as *chronic wasting disease* is found in some deer and elk, especially in the Rocky Mountain region of the western United States. Hunters in areas where this prion is known to occur are cautioned to have meat tested for this prion and to avoid eating meat from any animal that tests positive or appears sick.

SUMMARY OF KEY POINTS

Properties and Strategies of Cells

- Based on gross morphology, cells have traditionally been described as either eukaryotic (animals, plants, fungi, protozoa, and algae) or prokaryotic (bacteria and archaea) based on the presence or absence of a membrane-bound nucleus. More recently, analysis of ribosomal RNA sequences and other molecular data suggests a tripartite view of organisms, with eukaryotes, bacteria, and archaea as the three main domains.
- A plasma membrane and ribosomes are the only two structural features common to cells of all three groups. Organelles are found only in eukaryotic cells, where they play indispensable roles in the compartmentalization of function. Bacterial and archaeal cells are relatively small and structurally less complex than eukaryotic cells, lacking the internal membrane systems and organelles of eukaryotes.
- Cell size is limited by the need for an adequate amount of surface area for exchange of materials with the environment and the need for high enough concentrations of the compounds necessary to sustain life. Eukaryotic cells are much larger than prokaryotic cells and compensate for their lower surface area/volume ratio by the compartmentalization of materials within membrane-bound organelles.

The Eukaryotic Cell in Overview

- Besides the plasma membrane and ribosomes common to all cells, eukaryotic cells have a nucleus that houses most of the cell's DNA, a variety of organelles, and the cytosol with its cytoskeleton of microtubules, microfilaments, and intermediate filaments. Also, plant cells have a rigid cell wall, and animal cells are usually surrounded by a strong but flexible extracellular matrix of collagen and proteoglycans.
- The nucleus contains the cell's DNA complexed with protein in the form of chromatin, which condenses during cell division to form the visible structures we call chromosomes. The nucleus is surrounded by a double membrane called the nuclear envelope, which has pores that allow the regulated exchange of macromolecules with the cytoplasm.
- Mitochondria, which are surrounded by a double membrane, oxidize food molecules to provide the energy used to make ATP. Mitochondria also contain ribosomes and their own circular DNA molecules.
- Chloroplasts trap solar energy and use it to “fix” carbon dioxide into organic form and convert it to sugar. Chloroplasts are surrounded by a double membrane and have an extensive

system of internal membranes called the thylakoids, in which most of the components involved in ATP generation are found. Chloroplasts also contain ribosomes and circular DNA molecules.

- The endoplasmic reticulum is an extensive network of membranes that are known as either rough ER or smooth ER. Rough ER is studded with ribosomes and is responsible for the synthesis of secretory and membrane proteins, whereas smooth ER is involved in lipid synthesis and drug detoxification. Proteins synthesized on the rough ER are further processed and packaged in the Golgi complex and are then transported either to membranes or to the surface of the cell via secretory vesicles.
- Lysosomes contain hydrolytic enzymes and are involved in cellular digestion. They were the first organelles to be discovered on the basis of their function rather than their morphology. Because of their close functional relationships, the ER, Golgi complex, secretory vesicles, and lysosomes are collectively called the endomembrane system.
- Peroxisomes are about the same size as lysosomes, and both generate and degrade hydrogen peroxide. Animal peroxisomes play an important role in catabolizing long-chain fatty acids. In plants, specialized peroxisomes known as glyoxysomes are involved in the process of photorespiration and in converting stored fat into carbohydrate during seed germination.
- Ribosomes are sites of protein synthesis in all cells. The striking similarities between mitochondrial and chloroplast ribosomes and those of bacteria and cyanobacteria, respectively, lend strong support to the endosymbiont theory that these organelles are of bacterial origin.
- The cytoskeleton is an extensive network of microtubules, microfilaments, and intermediate filaments that gives eukaryotic cells their distinctive shapes. The cytoskeleton is also important in cellular motility and the intracellular movement of cellular structures and materials.

Agents That Invade Cells

- Viruses satisfy some, though not all, of the basic criteria of living things. Viruses are important both as infectious agents that cause diseases in humans, animals, and plants and as laboratory tools, particularly for geneticists. Viroids and prions are infectious agents that are even smaller (and less well understood) than viruses. Viroids are small self-replicating RNA molecules, whereas prions are misfolded proteins that are thought to be abnormal products of normal cellular genes.

MAKING CONNECTIONS

In the first few chapters, we have had an overview of the history and scope of cell biology, a review of chemistry, and a discussion of the macromolecular components of cells. We have just finished an introduction to overall cell structure and the types of organelles found in eukaryotic cells. Next you will see how these cellular components function and interact to give cells the incredible abilities we associate with life. After a discussion of bioenergetics and enzyme function in the next two chapters, you will see how the plasma membrane functions in transport, metabolism, and cell-to-cell communication. As we study the mitochondrion and chloroplast in more detail in Chapters

10 and 11, you will learn how cells obtain energy to live, grow, and reproduce. We will revisit the roles of the endoplasmic reticulum, Golgi complex, lysosomes, and peroxisomes in studies of protein and membrane trafficking and specialized types of metabolism in Chapter 12. Later, in Chapters 13 through 17, you will learn about the role of the cytoskeleton in cell motility and muscle contraction and how the cytoskeleton interacts with the extracellular matrix. Following that, we will return to the nucleus as we investigate its role as the command center of the cell for genetic information transfer, cell reproduction, and control of nearly all cellular activities.

PROBLEM SET

More challenging problems are marked with a •.

4-1 Wrong Again. For each of the following false statements, change the statement to make it true.

- (a) Archaea are ancient bacteria that are the ancestors of modern bacteria.
- (b) Bacteria differ from eukaryotes in having no nucleus, mitochondria, chloroplasts, or ribosomes.
- (c) Instead of a cell wall, eukaryotic cells have an extracellular matrix for structural support.
- (d) All the ribosomes found in a typical human muscle cell are identical.
- (e) DNA is found only in the nucleus of a cell.
- (f) Because bacterial cells have no organelles, they cannot carry out either ATP synthesis or photosynthesis.
- (g) Even the simplest types of infectious agents must have DNA, RNA, and protein.
- (h) A large amount of the DNA in eukaryotic cells has no function and is called “junk DNA.”

4-2 Cellular Specialization. Each of the cell types listed here is a good example of a cell that is specialized for a specific function. Match each cell type in list A with the appropriate function from list B, and explain why you matched each as you did.

List A	List B
(a) Pancreatic cell	Cell division
(b) Cell from flight muscle	Absorption
(c) Palisade cell from leaf	Motility
(d) Cell of intestinal lining	Photosynthesis
(e) Nerve cell	Secretion
(f) Bacterial cell	Transmission of electrical impulses

4-3 Toward an Artificial Cell. Scientists have recently constructed an artificial ribosome *in vitro* from purified ribosomal proteins and rRNAs.

- (a) What types of intermolecular forces do you think are holding the individual proteins and rRNAs together in this supramolecular complex?

(b) Describe specifically how high temperature, high salt, or low pH would disrupt its structure, causing the ribosome to fall apart.

(c) If you were asked to determine which organism the ribosomal components were from, how could you do this?

(d) What other molecules would you have to add to the test tube in order for the ribosomes to make polypeptides? (This may require some sleuthing in later chapters.)

4-4 Sentence Completion. Complete each of the following statements about cellular structure in ten words or less.

- (a) If you were shown an electron micrograph of a section of a cell and were asked to identify the cell as plant or animal, one thing you might do is . . .
- (b) A slice of raw apple placed in a concentrated sugar solution will . . .
- (c) A cellular structure that is visible with an electron microscope but not with a light microscope is . . .
- (d) Several environments in which you are more likely to find archaea than bacteria are . . .
- (e) One reason that it might be difficult to separate lysosomes from peroxisomes by centrifugation techniques is that . . .
- (f) The nucleic acid of a virus is composed of . . .

4-5 Telling Them Apart. Suggest a way to distinguish between the two elements in each of the following pairs:

- (a) Bacterial cells; archaeal cells
- (b) Rough ER; smooth ER
- (c) Animal peroxisomes; leaf peroxisomes
- (d) Peroxisomes; lysosomes
- (e) Viruses; viroids
- (f) Microfilaments; intermediate filaments
- (g) Polio virus; herpes simplex virus
- (h) Eukaryotic ribosomes; bacterial ribosomes
- (i) mRNA; miRNA

4-6 Structural Relationships. For each pair of structural elements, indicate with an A if the first element is a constituent part of the second, with a B if the second element is a constituent part of the first, and with an N if they are separate structures with no particular relationship to each other.

- (a) Mitochondrion; crista
- (b) Golgi complex; nucleus
- (c) Cytoplasm; cytoskeleton
- (d) Cell wall; extracellular matrix
- (e) Nucleolus; nucleus
- (f) Smooth ER; ribosome
- (g) Lipid bilayer; plasma membrane
- (h) Peroxisome; thylakoid
- (i) Chloroplast; granum

• 4-7 Protein Synthesis and Secretion. Although we will not encounter protein synthesis and secretion in detail until later chapters, you already have enough information about these processes to order the seven events that are now listed randomly. Order events 1–7 so that they represent the correct sequence corresponding to steps a–g, tracing a typical secretory protein from the initial transcription (readout) of the relevant genetic information in the nucleus to the eventual secretion of the protein from the cell by exocytosis.

Transcription → (a) → (b) → (c) →
(d) → (e) → (f) → (g) → Secretion

1. The protein is partially glycosylated within the lumen of the ER.
2. The secretory vesicle arrives at and fuses with the plasma membrane.
3. The RNA transcript is transported from the nucleus to the cytoplasm.
4. The final sugar groups are added to the protein in the Golgi complex.
5. As the protein is synthesized, it passes across the ER membrane into the lumen of a Golgi cisterna.
6. The protein is packaged into a secretory vesicle and released from the Golgi complex.

Bioenergetics: The Flow of Energy in the Cell

Broadly speaking, every cell has four essential needs: molecular building blocks, chemical catalysts called enzymes, information to guide all its activities, and energy to drive the various reactions and processes that are essential to life and biological function. In Chapters 3 and 4, we saw that cells need amino acids, nucleotides, sugars, and lipids in order to synthesize the macromolecules used to build cellular structures and organelles. Cells also need catalysts known as enzymes (Chapter 6) to speed up chemical reactions that would otherwise occur much too slowly to maintain life as we know it. The third general requirement of cells is for information to guide and direct their activities. This information is encoded within the nucleotide sequences of DNA and RNA and expressed in the ordered synthesis of specific proteins.

All cells also require energy in addition to molecules, enzymes, and information. Energy is needed to drive the chemical reactions involved in the formation of cellular components and to power the many activities that cells carry out. The capacity to obtain, store, and use energy is, in fact, one of the obvious features of most living organisms and helps to define life itself (Figure 5-1). Like the flow of information, the flow of energy is a major theme of this text and will be considered in more detail in Chapters 9–11. In this chapter, we will learn the basics of bioenergetics and see how the thermodynamic concept of free energy can allow us to predict whether specific chemical reactions can occur spontaneously in the cell.

The Importance of Energy

All living systems require an ongoing supply of **energy**. Usually, energy is defined as the capacity to do work. But that turns out to be a somewhat circular definition because work is frequently defined in terms of energy changes. A more useful definition is that *energy is the capacity to cause specific physical or chemical changes*. Since life is characterized first and foremost by change,

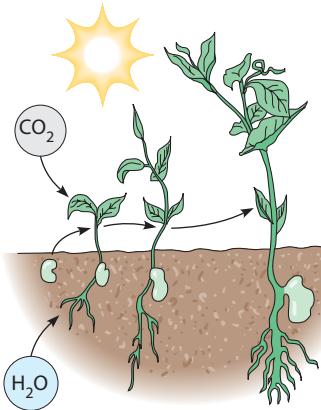

FIGURE 5-1 Energy and Life. The capacity to expend energy is one of the most obvious features of life at both the cellular and organismal levels.

this definition underscores the total dependence of all forms of life on the continuous availability of energy.

Cells Need Energy to Drive Six Different Kinds of Changes

Now that we have defined energy in this way, you may ask: What kinds of cellular activities give rise to specific physical and chemical changes? Six categories of change come to mind, which in turn define six kinds of work that require an input of energy: synthetic work, mechanical work, concentration work, and electrical work, as well as the generation of heat and light (Figure 5-2).

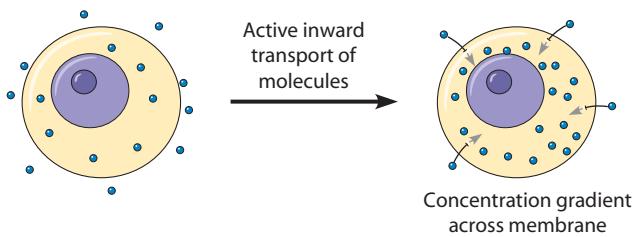

(a) Synthetic work: the process of photosynthesis

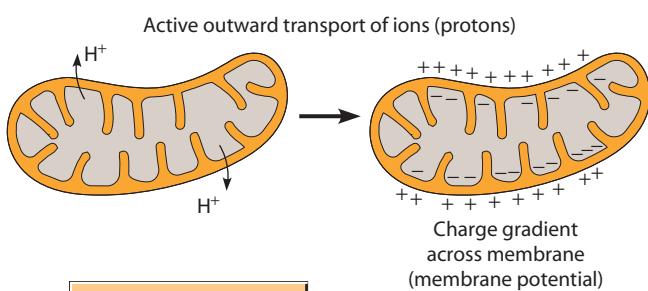

(b) Mechanical work: the contraction of a weight lifter's muscles

(c) Concentration work: the accumulation of molecules in a cell

(d) Electrical work: the membrane potential of a mitochondrion

(e) Heat production: shivering in the cold

(f) Bioluminescence: the courtship of fireflies

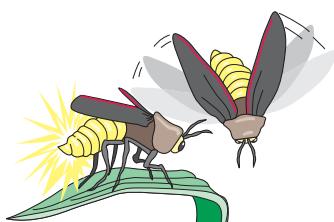

FIGURE 5-2 Several Kinds of Biological Work. The six major categories of biological work are shown here (a-f). All require an input of energy to cause a physical or chemical change.

1. Synthetic Work: Changes in Chemical Bonds. An important activity of virtually every cell at all times is the work of **biosynthesis**, which results in the formation of new chemical bonds and the synthesis of new molecules. This activity is especially obvious in a population of growing cells, where additional molecules must be synthesized for cells to increase in size or number or both. Also, synthetic work is required to maintain existing cellular structures. Because most structural components of the cell are in a state of constant turnover, the molecules that make up these structures are continuously being degraded and replaced. Almost all of the energy that cells require for biosynthetic work is used to make energy-rich organic molecules from simpler starting materials and to incorporate them into macromolecules.

2. Mechanical Work: Changes in the Location or Orientation of a Cell or a Subcellular Structure. Cells often need energy for **mechanical work**, which involves a physical change in the position or orientation of a cell or some part of the cell. An especially good example is the movement of a cell with respect to its environment. This movement often requires one or more appendages such as cilia or flagella (Figure 5-3), which require energy in order to propel the cell forward. In other cases, the environment is moved past the cell, as when the ciliated cells that line your trachea beat upward to sweep inhaled particles upward and away from the lungs. This motion also requires energy. Muscle contraction is another good example of mechanical work, involving not just a single cell but a large number of muscle cells working together (see Figure 16-10). Other examples of mechanical work that we will see happening inside cells include the movement of chromosomes along the spindle fibers during mitosis, the streaming of cytoplasm, the movement of organelles and vesicles along microtubules, and the translocation of a ribosome along a strand of messenger RNA.

3. Concentration Work: Moving Molecules Across a Membrane Against a Concentration Gradient. Less conspicuous than either of the previous two categories but every bit as important to the cell is the work of moving molecules or ions against a concentration gradient. The purpose of **concentration work** is either to accumulate substances within a cell or organelle or to remove potentially toxic by-products of cellular activity. As we saw in Chapter 4, diffusion of materials (from areas of high concentration to areas of low concentration) is a spontaneous process and requires no added energy. Therefore, the opposite process, concentration, requires an input of energy. Examples of concentration work include the import of certain sugar and amino acid molecules from low to high concentration across the plasma membrane, the concentration of specific molecules and enzymes within organelles, and the accumulation of digestive enzymes into secretory vesicles to be released as you digest your food.

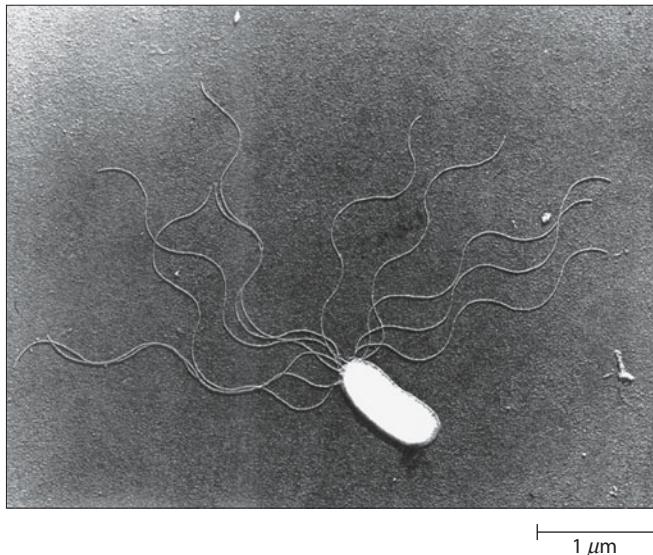

FIGURE 5-3 A Flagellated Bacterium. The spinning motion of bacterial flagella is an example of mechanical work, providing motility for some bacterial species (TEM).

4. Electrical Work: Moving Ions Across a Membrane

Against an Electrochemical Gradient. Often, **electrical work** is considered a specialized case of concentration work because it also involves movement across membranes. In this case, however, ions are transported, and the result is not just a change in concentration. A charge difference, known as an *electrical potential* or a *membrane potential*, is also established across the membrane. Every cellular membrane has some characteristic electrical potential that is generated in this way. A difference in the concentration of protons on either side of the mitochondrial or chloroplast membrane forms an electrical potential that is essential for the production of ATP in both cellular respiration (Chapter 10) and photosynthesis (Chapter 11). Electrical work is also important in the transmission of impulses in nerve cells. This involves the establishment of a membrane potential, resulting from pumping Na^+ and K^+ ions into and out of the cell (Chapter 13). An especially dramatic example of electrical work is found in *Electrophorus electricus*, the electric eel. Individual cells in its electric organ use energy to generate a membrane potential of about 150 millivolts (mV) in one cell, and thousands of such cells arranged in series allow the electric eel to develop electric potentials of several hundred volts (ouch!).

5. Heat: An Increase in Temperature That Is Useful to Warm-Blooded Animals

Although living organisms do not use **heat** as a form of energy in the same way that a steam engine does, heat production is a major use of energy in all *homeotherms* (animals that regulate their body temperature independent of the environment). Heat is released as a by-product of many chemical reactions, and we, as homeotherms, take advantage of this “waste product” every

day. In fact, as you read these lines, about two-thirds of your metabolic energy is being used just to maintain your body at 37°C, the temperature at which it functions most effectively. When you are cold, your muscles use energy to shiver, generating heat to keep you warm.

6. Bioluminescence: The Production of Light. To complete this list, we will include the production of light, or **bioluminescence**, as yet another way that cells use energy. Light is produced by a number of bioluminescent organisms, such as fireflies, certain jellyfish, and luminous toadstools, and is generated by the reaction of ATP with specific luminescent compounds. This bioluminescence is usually pale blue, yellow, or green. For cell biologists, bioluminescence has become a very powerful tool to study specific proteins inside cells. Scientists have isolated and characterized several proteins that are responsible for bioluminescence: the enzyme luciferase from the firefly, green fluorescent protein (GFP) from the jellyfish *Aequorea victoria*, and a variant of GFP known as yellow fluorescent protein (YFP). When one of these proteins is fused to a particular protein of interest, the fusion protein produces bioluminescence, and its distribution and movement can be followed in live cells using fluorescence microscopy (**Figure 5-4**).

Organisms Obtain Energy Either from Sunlight or from the Oxidation of Chemical Compounds

Nearly all life on Earth is sustained, directly or indirectly, by the sunlight that continuously floods our planet with energy. Not all organisms can obtain energy from sunlight directly, of course. In fact, based on their energy sources, organisms (and cells) can be classified as either *phototrophs* (literally, “light-feeders”) or *chemotrophs* (“chemical-feeders”). Organisms can also be classified as

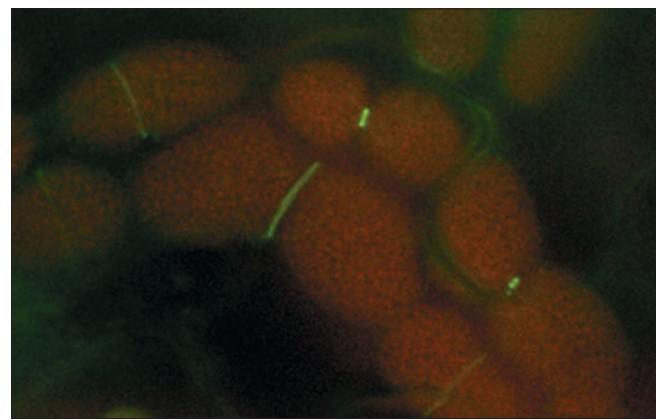

FIGURE 5-4 Bioluminescent Protein Localization. In this experiment, a protein known as PVD2 was fused to the bioluminescent protein YFP in order to study its distribution in *Arabidopsis* leaf cells. This fluorescence microscopy image shows that the PVD2-YFP fusion protein is found in an equatorial ring around dividing chloroplasts (red), demonstrating the involvement of PVD2 in chloroplast division.

autotrophs (“self-feeders”) or *heterotrophs* (“other-feeders”), depending on whether their source of carbon is CO₂ or organic molecules, respectively. Most organisms are either photoautotrophs or chemoheterotrophs.

Phototrophs capture light energy from the sun using light-absorbing pigments and then transform this light energy into chemical energy, storing the energy in the form of ATP. *Photoautotrophs* use solar energy to produce all their necessary carbon compounds from CO₂ during photosynthesis. Examples of photoautotrophs include plants, algae, cyanobacteria, and photosynthetic bacteria. *Photoheterotrophs* (some bacteria) harvest solar energy to power cellular activities, but they must rely on the intake of organic molecules for their carbon needs.

In contrast, **chemotrophs** get energy by oxidizing chemical bonds in organic or inorganic molecules. *Chemoautotrophs* (a few bacteria) oxidize inorganic compounds such as H₂S, H₂ gas, or inorganic ions for energy and synthesize all their organic compounds from CO₂. *Chemoheterotrophs*, on the other hand, ingest and use chemical compounds such as carbohydrates, fats, and proteins to provide both energy and carbon for cellular needs. All animals, protozoa, fungi, and many bacteria are chemoheterotrophs.

Keep in mind that, although phototrophs can utilize solar energy when it is available, they must function as chemotrophs whenever they are not illuminated. Most plants are really a mixture of phototrophic and chemotrophic cells. A plant root cell, for example, though part of an obviously phototrophic organism, usually cannot carry out photosynthesis and is every bit as chemotrophic as an animal cell (or a plant leaf cell in the dark).

Energy Flows Through the Biosphere Continuously

Before we continue our discussion of energy flow, first let’s review the chemical concepts of oxidation and reduction because they are critical to understanding energy flow in cells and organisms. *Oxidation* is the removal of electrons from a substance and, in biology, it usually involves the removal of hydrogen atoms (a hydrogen ion plus an electron) and the addition of oxygen atoms. Oxidation reactions release energy, as shown below when either glucose or methane is oxidized to carbon dioxide. Note that each carbon atom in glucose or methane has lost hydrogen atoms and has gained oxygen atoms as carbon dioxide is formed and energy is released. *Reduction* is the reverse reaction—the addition of electrons to a substance and usually the addition of hydrogen atoms (and a loss of oxygen atoms). Reduction reactions require an input of energy, as shown below when carbon dioxide is reduced to glucose during photosynthesis. The carbon atoms in six molecules of carbon dioxide have gained hydrogen atoms and lost oxygen atoms during this energy-requiring reduction to glucose.

Glucose oxidation:

Methane oxidation:

Carbon dioxide reduction:

The flow of energy and matter through the biosphere is depicted in **Figure 5-5**. Phototrophs are producers that use solar energy to convert carbon dioxide and water into more reduced cellular compounds such as glucose during photosynthesis. These reduced compounds are converted into other carbohydrates, proteins, lipids, nucleic acids, and all the materials a cell needs to survive. In a sense, we can consider the entire phototrophic organism to be the product of photosynthesis because every carbon atom in every molecule of that organism is derived from carbon dioxide that is fixed into organic form by the photosynthetic process.

Chemotrophs, on the other hand, are consumers that are unable to use solar energy directly and therefore must depend completely on energy that has been packaged into oxidizable food molecules by phototrophs. A world composed solely of chemoheterotrophs would last only so long as food supplies lasted, for even though we live on a planet that is flooded with solar energy each day, this energy is in a form that we humans cannot use to meet our energy needs.

Both phototrophs and chemotrophs use energy to carry out the six kinds of work we have already discussed (see Figure 5-2). An important principle of energy conversion is that no chemical or physical process occurs with 100% efficiency—some energy is released as heat. Although biological processes are remarkably efficient in energy conversion, loss of energy as heat is inevitable in biological processes. Sometimes the heat that is liberated during cellular processes is utilized, as when warm-blooded animals use heat to maintain a constant body temperature. Some plants use metabolically generated heat to attract pollinators or to melt overlying snow (**Figure 5-6**). In general, however, the heat is simply dissipated into the environment, representing a loss of energy from the organism.

Viewed on a cosmic scale, there is a continuous, massive, and unidirectional flow of energy on Earth from its source in the nuclear fusion reactions of the sun to its eventual sink, the environment. We here in the biosphere are the transient custodians of an infinitesimally small portion of that energy. It is precisely that small but critical fraction of energy and its flow through the living systems of the biosphere that is of concern to us. The flow of energy in the biosphere begins with phototrophs, which use light energy to drive electrons energetically “uphill” to create high-energy, reduced compounds. This energy is then released by both phototrophs and chemotrophs in “downhill” oxidation reactions. This flux of energy

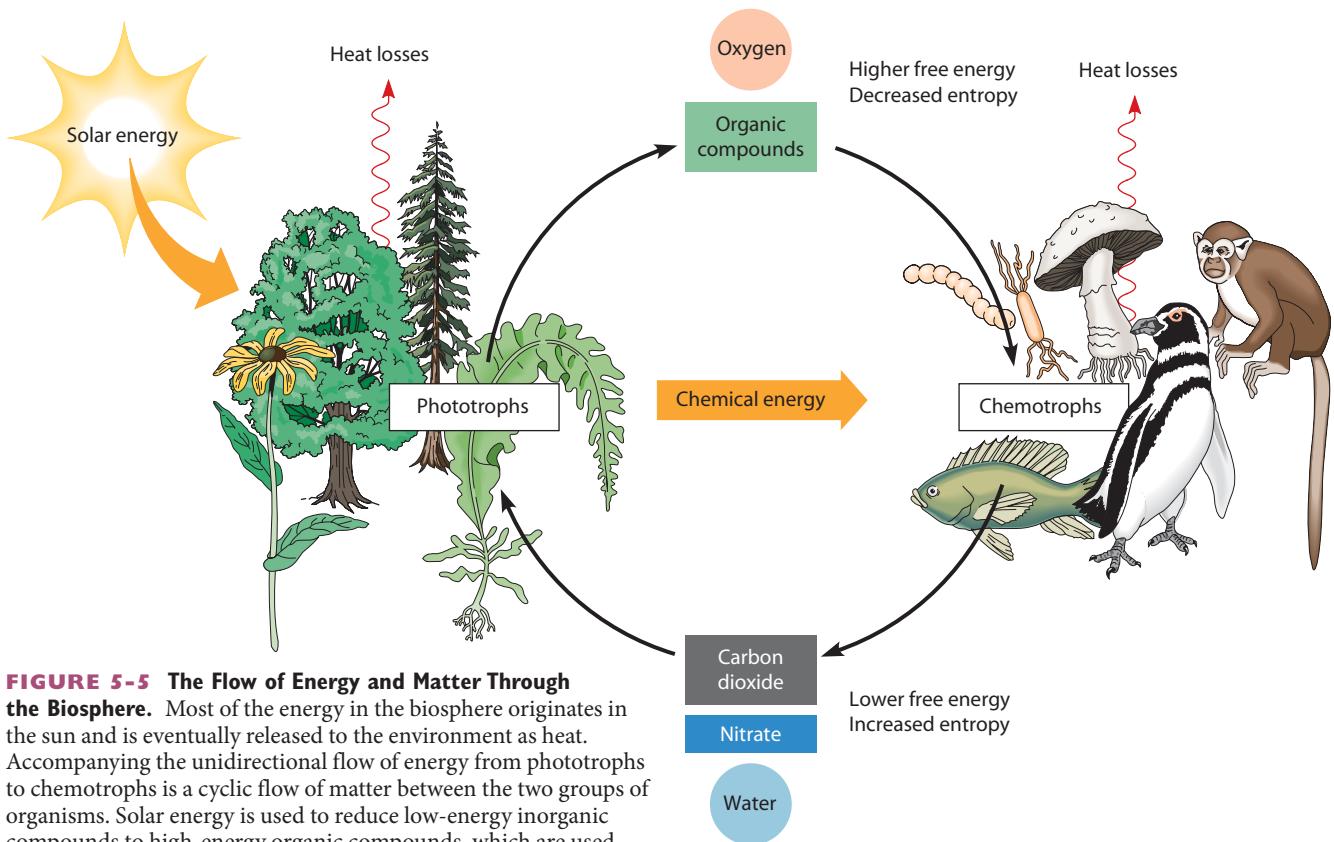

FIGURE 5-5 **The Flow of Energy and Matter Through the Biosphere.** Most of the energy in the biosphere originates in the sun and is eventually released to the environment as heat. Accompanying the unidirectional flow of energy from phototrophs to chemotrophs is a cyclic flow of matter between the two groups of organisms. Solar energy is used to reduce low-energy inorganic compounds to high-energy organic compounds, which are used by both phototrophs and chemotrophs.

Bio Flix® www.thecellplace.com The carbon cycle

through living matter—from the sun to phototrophs to chemotrophs to heat—drives all life processes.

The Flow of Energy Through the Biosphere Is Accompanied by a Flow of Matter

Energy enters the biosphere as photons of light unaccompanied by matter and leaves the biosphere as heat similarly unaccompanied by matter. While it is passing through the biosphere, however, energy exists primarily in the form of chemical bond energies of oxidizable organic molecules in cells and organisms. As a result, the flow of energy in the biosphere is coupled to a correspondingly immense flow of matter.

Whereas energy flows unidirectionally from the sun through phototrophs to chemotrophs and to the environment, matter flows in a cyclic fashion between phototrophs and chemotrophs (Figure 5-5). Phototrophs use solar energy to create organic nutrients from inorganic starting materials such as carbon dioxide and water, releasing oxygen in the process. Phototrophs use some of these high-energy, reduced nutrients themselves, and some of them become available to chemotrophs that consume these phototrophs. Chemotrophs typically take in organic nutrients from their surroundings and use oxygen to oxidize them back to carbon dioxide and water, providing energy. Low-energy, oxidized molecules are returned to the environment and then become the raw materials that

FIGURE 5-6 **Skunk Cabbage, a Plant That Depends on Metabolically Generated Heat.** The skunk cabbage plant (*Symplocarpus foetidus*) is one of the earliest-flowering plants in the eastern United States. The heat that it generates enables it to melt through overlying snow in late winter and begin growing when most other plants are still dormant.

phototrophic organisms use to make new organic molecules, returning oxygen to the environment in the process and completing the cycle.

In addition, there is an accompanying cycle of nitrogen. Phototrophs obtain nitrogen from the environment in an oxidized, inorganic form (as nitrate from the soil or, in some cases, as N₂ from the atmosphere). They reduce it to ammonia (NH₃), a high-energy form of nitrogen used in the synthesis of amino acids, proteins, nucleotides, and nucleic acids. Eventually, these cellular molecules, like other components of phototrophic cells, are consumed by chemotrophs. The nitrogen in these molecules is then converted back into ammonia and eventually oxidized to nitrate, mostly by soil microorganisms.

Carbon, oxygen, nitrogen, and water thus cycle continuously between the phototrophic and chemotrophic worlds. They enter the chemotrophic sphere as reduced, energy-rich compounds and leave in an oxidized, energy-poor form. The two great groups of organisms can therefore be thought of as living in a symbiotic relationship with each other, with a cyclic flow of matter and a unidirectional flow of energy as components of that symbiosis.

When we deal with the overall macroscopic flux of energy and matter through living organisms, we find cellular biology interfacing with ecology. Ecologists study cycles of energy and nutrients, the roles of various species in these cycles, and environmental factors affecting the flow. In contrast, our ultimate concern in cell biology is how the flux of energy and matter functions on a microscopic and molecular scale. We will be able to understand these energy transactions and the chemical processes that occur within cells as soon as we acquaint ourselves with the physical principles underlying energy transfer in cells. For that we turn to the topic of bioenergetics.

Bioenergetics

The principles governing energy flow are the subject of an area of science known as **thermodynamics**. Although the prefix *thermo-* suggests that the term is limited to heat (and that is indeed its historical origin), thermodynamics also takes into account other forms of energy and processes that convert energy from one form to another. Specifically, thermodynamics concerns the laws governing the energy transactions that inevitably accompany most physical processes and all chemical reactions. **Bioenergetics**, in turn, can be thought of as *applied thermodynamics*—the application of thermodynamic principles to reactions and processes in the biological world.

To Understand Energy Flow, We Need to Understand Systems, Heat, and Work

It is useful to define energy not simply as the capacity to do work, but specifically as the ability to cause change. Without energy, all processes would be at a standstill, including those that we associate with living cells.

Energy exists in various forms, many of them of interest to biologists. Think, for example, of the energy represented by a ray of sunlight, a teaspoon of sugar, a moving flagellum, an excited electron, or the concentration of ions or small molecules within a cell or an organelle. These phenomena are diverse, but they are all governed by certain basic principles of energetics.

Energy is distributed throughout the universe—and for some purposes it is necessary to consider the total energy of the universe, at least in a theoretical way. Whereas the total energy of the universe remains constant, we are usually interested in the energy content of only a small portion of it. We might, for example, be concerned with a reaction or process occurring in a beaker of chemicals, in a cell, or in a particular organism. By convention, the restricted portion of the universe that is being considered at any given moment is called the **system**, and all the rest of the universe is referred to as the **surroundings**. Sometimes the system has a natural boundary, such as a glass beaker or a cell membrane. In other cases, the boundary between the system and its surroundings is just a hypothetical one used only for convenience of discussion, such as the imaginary boundary around one mole of glucose molecules in a solution.

Systems can be either open or closed, depending on whether they can exchange energy with their surroundings (**Figure 5-7**). A *closed system* is sealed from its environment and can neither take in nor release energy in any form. An *open system*, on the other hand, can have energy added to it or removed from it. The levels of organization and complexity that biological systems routinely display are possible only because cells and organisms are open systems, capable of both the uptake and the release of energy. Specifically, biological systems require a constant, large-scale influx of energy from their surroundings both to attain and to maintain the levels of complexity that are characteristic of them. That is essentially why plants need sunlight and you need food.

Whenever we talk about a system, we have to be careful to specify the state of the system. A system is said to be in a specific **state** if each of its variable properties (such as temperature, pressure, and volume) is held constant at a specified value. In such a situation, the total energy content of the system, while not directly measurable, has some unique value. If such a system then changes from one state to another as a result of some interaction between the system and its surroundings, the change in its total energy is determined uniquely by the initial and final states of the system. The magnitude of the energy change is not affected by the mechanism causing the change nor by the intermediate states through which the system may pass. This is a useful property because it allows energy changes to be determined from a knowledge of the initial and final states only, independent of the path taken.

The problem of keeping track of system variables and their effect on energy changes can be simplified if one or more of the variables are held constant. Fortunately, this

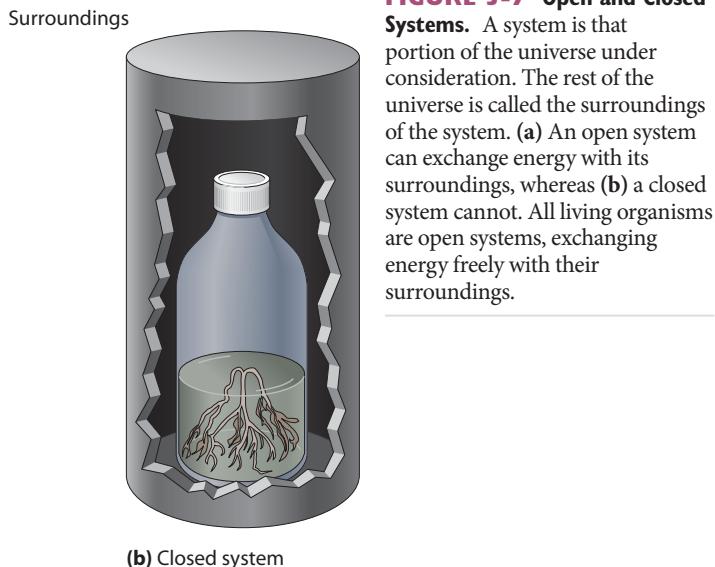

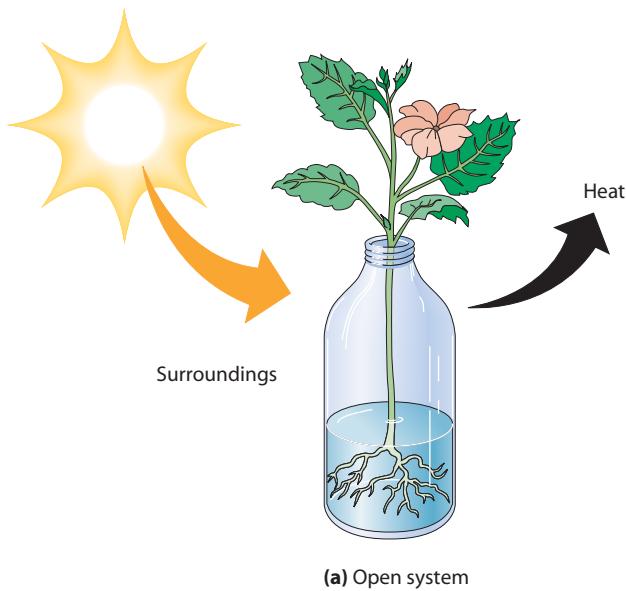

FIGURE 5-7 Open and Closed Systems. A system is that portion of the universe under consideration. The rest of the universe is called the surroundings of the system. (a) An open system can exchange energy with its surroundings, whereas (b) a closed system cannot. All living organisms are open systems, exchanging energy freely with their surroundings.

is the case with most biological reactions because they usually occur in dilute solutions within cells that are at approximately the same temperature, pressure, and volume during the entire course of the reaction. These environmental conditions are generally slow to change compared with the speed of biological reactions. This means that three of the most important system variables that physical chemists need to consider—temperature, pressure, and volume—are essentially constant for most biological reactions.

The exchange of energy between a system and its surroundings occurs either as heat or as work. Heat is energy transfer from one place to another as a result of a temperature difference and occurs spontaneously from the hotter place to the colder place. Heat is an extremely useful form of energy for machines designed either to accomplish mechanical work or to transform heat into other forms of energy. However, heat has only limited biological utility because many biological systems operate under *isothermal* conditions of fixed temperature. Such systems lack the temperature gradients required to convert heat into other forms of energy. As a result, heat is generally not a useful source of energy for cells—although it can be used for such purposes as maintaining body temperature or attracting pollinators, as we noted earlier.

In biological systems, **work** is the use of energy to drive any process other than heat flow. For example, work is performed when the muscles in your arm expend chemical energy to lift this book, when a corn leaf uses light energy to synthesize sugar, or when an electric eel creates the ion concentration gradients to deliver a shock. We will be primarily interested in the amount of useful energy available to do cellular work when we begin calculating energy changes associated with specific reactions in cells.

To quantify energy changes during chemical reactions or physical processes, we need units in which energy can be expressed. In biological chemistry, energy changes are

usually expressed in terms of the **calorie (cal)**, which is defined as the amount of energy required to warm 1 gram of water 1 degree centigrade at a pressure of 1 atmosphere. One **kilocalorie (kcal)** equals 1000 calories. An alternative energy unit, the **joule (J)**, is preferred by physicists and is used in some biochemistry texts. Conversion is easy: 1 cal = 4.184 J, or 1 J = 0.239 cal.

Energy changes are often measured on a per-mole basis, and the most common forms of energy units in biological chemistry are calories or kilocalories per mole (cal/mol or kcal/mol). (Be careful to distinguish between the *calorie* as defined here and the *nutritional Calorie* that is often used to express the energy content of foods. The nutritional Calorie is represented with a capital C and is really a *kilocalorie* as defined here.)

The First Law of Thermodynamics Tells Us That Energy Is Conserved

Much of what we understand about the principles governing energy flow can be summarized by the three laws of thermodynamics. For cell biologists, only the first and second laws are of particular relevance. The **first law of thermodynamics** is called the *law of conservation of energy*. The first law of thermodynamics states that *in every physical or chemical change, the total amount of energy in the universe remains constant, although the form of the energy may change*. Or, in other words, energy can be converted from one form to another but can never be created or destroyed.

Applied to the universe as a whole or to a closed system, the first law means that the total amount of energy present in all forms must be the same before and after any process or reaction occurs. Applied to an open system such as a cell, the first law says that, during the course of any reaction or process, the total amount of energy that leaves the system must be exactly equal to the energy that

enters the system minus any energy that remains behind and is therefore stored within the system.

The total energy stored within a system is called the **internal energy** of the system, represented by the symbol *E*. We are not usually concerned with the actual value of *E* for a system because that value cannot be measured directly. However, it is possible to measure the *change in internal energy*, ΔE , that occurs during a given process. ΔE is the difference in internal energy of the system before the process (E_1) and after the process (E_2):

$$\Delta E = E_2 - E_1 \quad (5-4)$$

Equation 5-4 is valid for all physical and chemical processes under any conditions. For a chemical reaction, we can write

$$\Delta E = E_{\text{products}} - E_{\text{reactants}} \quad (5-5)$$

In the case of biological reactions and processes, we are usually more interested in the change in **enthalpy**, or *heat content*. Enthalpy is represented by the symbol *H* (for heat) and is related to the internal energy *E* by a term that combines both pressure (*P*) and volume (*V*):

$$H = E + PV \quad (5-6)$$

H is dependent on both *E* and *PV* because changes in heat content following a process or reaction can affect the total energy as well as the pressure and volume. Unlike many chemical reactions, biological reactions generally proceed with little or no change in either pressure or volume. So, for biological reactions, both ΔP and ΔV are usually zero (or at least negligible), and we can write

$$\Delta H = \Delta E + \Delta(PV) \cong \Delta E \quad (5-7)$$

Thus, biologists routinely determine changes in heat content for reactions of interest, confident that the values are valid estimates of ΔE .

The enthalpy change that accompanies a specific reaction is simply the difference in the heat content between the reactants and the products of the reaction:

$$\Delta H = H_{\text{products}} - H_{\text{reactants}} \quad (5-8)$$

The ΔH value for a specific reaction or process will be either negative or positive. If the heat content of the products is less than that of the reactants, heat is released, ΔH will be negative, and the reaction is said to be **exothermic**. For example, the burning (oxidation) of gasoline in your car is exothermic because the heat content of the products (CO_2 and H_2O) is less than the heat content of the reactants (gasoline and O_2).

If the heat content of the products is greater than that of the reactants, ΔH will be positive, and the reaction is **endothermic**. In an endothermic reaction or process, heat energy is absorbed, as in the melting of an ice cube—the heat content of the resulting liquid water is greater than

the heat content of the ice before melting. Thus, the ΔH value for any reaction is simply a measure of the heat that is either liberated from or taken up by that reaction as it occurs under conditions of constant temperature and pressure.

The Second Law of Thermodynamics Tells Us That Reactions Have Directionality

So far, all that thermodynamics has been able to tell us is that energy is conserved whenever a process or reaction occurs—that all of the energy going into a system must either be stored within the system or released again to the surroundings. We have seen the usefulness of ΔH as a measure of how much the total enthalpy of a system would change if a given process were to occur, but we have no way as yet of predicting whether and to what extent the process will in fact occur under the prevailing conditions.

We have, at least in some cases, an intuitive feeling that some reactions or processes are possible, whereas others are not. We are sure that if we set a match to a sheet of paper made of cellulose, it will burn. The oxidation of the glucose monomers of the cellulose to carbon dioxide and water is, in other words, a favorable reaction. Or, to use more precise terminology, it is a *thermodynamically spontaneous* reaction. In the context of thermodynamics, the term *spontaneous* has a specific, restricted meaning that is different from its commonplace usage. **Thermodynamic spontaneity** is a measure of whether a reaction or process *can go*, but it says nothing about whether it *will go*. Our sheet of paper illustrates this point well. The oxidation of cellulose is clearly a *possible* reaction, but we know that it does not “just happen.” It needs some impetus—a match, in this particular case.

Not only are we convinced that a sheet of paper will burn if ignited, but we also know—if only intuitively—that there is *directionality* to the process. We are, in other words, equally convinced that the reverse reaction will not occur. If we were to stand around clutching the charred remains, the paper would not spontaneously reassemble in our hands. We have, in other words, a feeling for both the *possibility* and the *directionality* of cellulose oxidation.

You can probably think of other processes that you can make such thermodynamic predictions about with equal confidence. We know, for example, that drops of dye diffuse in water, that ice cubes melt at room temperature, and that sugar dissolves in water. We can therefore label these as thermodynamically spontaneous events. But if we ask why we recognize them as such, the answer has to do with repeated experience. We have seen paper burn, ice cubes melt, and sugar dissolve often enough to know intuitively that these processes really occur—and with such predictability that we can label them as spontaneous, provided only that we know the conditions.

However, when we move from the world of familiar physical processes to the realm of chemical reactions in cells, we quickly find that we cannot depend on experience to

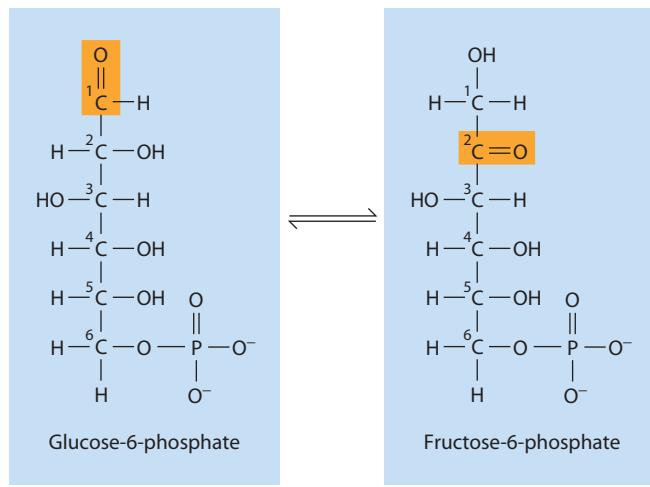

FIGURE 5-8 The Interconversion of Glucose-6-Phosphate and Fructose-6-Phosphate. This reaction involves the interconversion of the phosphorylated forms of an aldose sugar (glucose) and a ketose sugar (fructose). The reaction is catalyzed by an enzyme called phosphoglucoisomerase and is readily reversible. This reaction is part of the glycolytic pathway, as we will see in Chapter 9.

guide us in our predictions. Consider, for example, the conversion of glucose-6-phosphate into fructose-6-phosphate:

This particular interconversion is a significant reaction in all cells, and it is shown in detail in **Figure 5-8**. It is, in fact, the second step in an important and universal energy-yielding pathway called *glycolysis*, which we will return to in Chapter 9. For now, ask yourself what predictions you can make about the likelihood of glucose-6-phosphate being converted into fructose-6-phosphate. You will probably be at a loss to make any predictions at all. We know what will happen with burning paper and melting ice, but we lack the familiarity and experience with phosphorylated sugars even to make an intelligent guess. Clearly, what we need is a reliable means of determining whether a given physical or chemical change can occur under specific conditions without having to rely on experience, intuition, or guesswork.

Thermodynamics provides us with exactly such a measure of spontaneity in the **second law of thermodynamics**, or the *law of thermodynamic spontaneity*. This law tells us that *in every physical or chemical change, the universe always tends toward greater disorder or randomness (entropy)*. The second law is useful for our purposes because it allows us to predict in what direction a reaction will proceed under specified conditions, how much energy the reaction will release as it proceeds, and how the energetics of the reaction will be affected by specific changes in the conditions.

An important point to note is that *no process or reaction disobeys the second law of thermodynamics*. Some processes may seem to do so because they result in more, rather than less, order. Think, for example, of the increase

in order when a house is built, your room is cleaned, or a human being develops from a single egg cell. In each of these cases, however, the increase in order is limited to a specific system (the house, the room, or the embryo). The increase in order is possible only because it is an open system so that energy can be added from the outside, whether by means of an electric saw, your arm muscles, or nutrients supplied by the mother.

Entropy and Free Energy Are Two Alternative Means of Assessing Thermodynamic Spontaneity

Thermodynamic spontaneity—whether a reaction *can* go—can be measured by changes in either of two parameters: *entropy* or *free energy*. These concepts are abstract and can be somewhat difficult to understand. We will therefore limit our discussion here to their use in determining what kinds of changes can occur in biological systems. For further help, see **Box 5A** for an essay that uses jumping beans to introduce the concepts of internal energy, entropy, and free energy.

Entropy. Although we cannot quantify **entropy** directly, we can get some feel for it by considering it to be a measure of *randomness* or *disorder*. Entropy is represented by the symbol S. For any system, the *change in entropy*, ΔS , represents a change in the degree of randomness or disorder of the components of the system. For example, the combustion of paper involves an increase in entropy because the carbon, oxygen, and hydrogen atoms of cellulose are much more randomly distributed in space once they are converted to carbon dioxide and water. Entropy also increases as ice melts or as a volatile solvent such as gasoline is allowed to evaporate. Likewise, entropy decreases when a system becomes more ordered, as when the mobile molecules in liquid water become locked in place in ice or when large molecules such as glucose are synthesized from several smaller (randomly moving) carbon dioxide molecules.

Entropy Change as a Measure of Thermodynamic Spontaneity. How can the second law of thermodynamics help predict what changes will occur in a cell? There is an important link between spontaneous events and entropy changes because *all processes or reactions that occur spontaneously result in an increase in the total entropy of the universe*. Or, in other words, the value of $\Delta S_{\text{universe}}$ is positive for every spontaneous process or reaction.

We have to keep in mind, however, that this formulation of the second law pertains to the universe as a whole and may not apply to the specific system under consideration. Every real process, without exception, must be accompanied by an increase in the entropy of the universe. But for a given system, the entropy may increase, decrease, or stay the same as the result of a specific process. For example, the combustion of paper is clearly

spontaneous and is accompanied by an *increase* in the system entropy. On the other hand, the freezing of water at -1°C is also a spontaneous event, yet it involves a *decrease* in the system entropy as the water molecules become less randomly arranged in the resulting ice crystals. Thus, while the change in entropy of the universe is a valid measure of the spontaneity of a process, the change in entropy of the system is not.

To express the second law in terms of entropy change is therefore of limited value in predicting the spontaneity of biological processes because it would require keeping track of changes occurring not only within the system but also in its surroundings. Far more convenient would be a parameter that would enable prediction of the spontaneity of reactions by considering the system alone.

Free Energy. As you might guess, a measure of spontaneity for the system alone does in fact exist. It is called **free energy** and is represented by the symbol **G** (after Josiah Willard Gibbs, who first developed the concept). Because of its predictive value and its ease of calculation, *the free energy function is one of the most useful thermodynamic concepts in biology*. In fact, our entire discussion of thermodynamics so far has really been a way of getting us to this concept of free energy because it is here that the usefulness of thermodynamics for cell biologists becomes apparent.

Like most other thermodynamic functions, free energy is defined in terms of mathematical relationships. For biological reactions at constant pressure, volume, and temperature, the **free energy change**, ΔG , is dependent on the free energies of the products and the reactants:

$$\Delta G = G_{\text{products}} - G_{\text{reactants}} \quad (5-10)$$

This free energy change is related to the changes in enthalpy and entropy by the formula

$$\Delta G = \Delta H - T\Delta S \quad (5-11)$$

where ΔG is the change in free energy, ΔH is the change in enthalpy, T is the temperature of the system in degrees Kelvin ($K = ^{\circ}\text{C} + 273$, and ΔS is the change in entropy.

Notice that ΔG is the algebraic sum of two terms, ΔH and $-T\Delta S$, and is therefore influenced by changes in both enthalpy and entropy. As we saw earlier, ΔH will be positive for endothermic reactions and negative for exothermic reactions. Similarly, ΔS for a specific reaction or process can be either positive (increase in entropy) or negative (decrease in entropy). Because of the minus sign, the term $-T\Delta S$ will be negative if entropy increases or positive if entropy decreases. Therefore, you can see that the change in free energy of a reaction, ΔG , will increase when the change in heat content, ΔH , increases or when the change in entropy (randomness), ΔS , decreases.

Free Energy Change as a Measure of Thermodynamic Spontaneity. Free energy is an exceptionally useful concept as a readily measurable indicator of spontaneity, and we will soon see how ΔG can be calculated in real-life situations. ΔG provides exactly what we have been looking for: a measure of the spontaneity of a reaction based solely on the properties of the system in which the reaction is occurring. This will tell us whether a given reaction will proceed spontaneously from left to right as written.

Specifically, every spontaneous reaction is characterized by a *decrease* in the free energy of the system ($\Delta G_{\text{system}} < 0$) just as surely as it is characterized by an *increase* in the entropy of the universe ($\Delta S_{\text{universe}} > 0$). This is true because with the temperature and pressure held constant, ΔG for the system is related to ΔS for the universe in a simple but inverse way. This gives us a second, equally valid way of expressing the second law of thermodynamics: *All processes or reactions that occur spontaneously result in a decrease in the free energy content of the system.* In other words, *the value of ΔG_{system} is negative for every spontaneous process or reaction.* This occurs when the free energy of the products is less than the free energy of the reactants, as shown in Equation 5-10.

Such processes or reactions are called **exergonic**, which means *energy-yielding*. In contrast, any process or reaction that would result in an increase in the free energy of the system is called **endergonic** (*energy-requiring*) and cannot proceed under the conditions for which ΔG was calculated. Note carefully that we are considering only the overall change in free energy and not the specific changes either in the enthalpy or in the entropy of the system. Enthalpy and entropy changes may be negative, positive, or zero for a given reaction and, considered individually, are *not* valid measures of thermodynamic spontaneity.

Because the values for ΔH and $-T\Delta S$ can each be either positive or negative, the value of ΔG for a given reaction will depend on both the signs and numerical values of the ΔH and $-T\Delta S$ terms (Figure 5-9, see p. 118). If both the ΔH and $-T\Delta S$ terms for a given reaction are positive (endothermic and a decrease in entropy), ΔG will be positive, and the reaction will be endergonic and not spontaneous (Figure 5-9a). In contrast, a reaction that is exothermic (i.e., ΔH is negative) and results in an increase in entropy (i.e., ΔS is positive and $-T\Delta S$ is negative) has a ΔG value that is the *sum* of these two negative terms and is therefore exergonic and spontaneous (Figure 5-9b).

However, if the ΔH and $-T\Delta S$ terms differ in sign, the ΔG value can be either positive or negative, depending on the magnitudes of the ΔH and $-T\Delta S$ terms. For example, a reaction that is endothermic (i.e., ΔH is positive) and results in an increase in entropy (i.e., ΔS is positive and $-T\Delta S$ is negative) will have a ΔG value that is either positive (Figure 5-9c) or negative (Figure 5-9d), depending on the relative numerical values of ΔH and $-T\Delta S$.

Jumping Beans and Free Energy

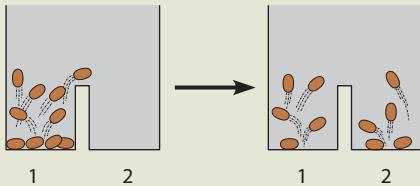

If you are finding the concepts of free energy, entropy, and enthalpy difficult to grasp, perhaps a simple analogy might help.* For this we will need an imaginary supply of jumping beans, which are really seeds of certain Mexican shrubs, with larvae of the moth *Laspeyresia saltitans* inside. Whenever the larvae inside the seed wiggle about, the seeds wiggle, too. The “jumping” action probably serves to get the larvae out of direct sunlight, which could heat them to lethal temperatures.

The Jumping Reaction

For purposes of illustration, imagine that we have some high-powered jumping beans in two chambers separated by a low partition, as shown below. Notice that the chambers have the same floor area and are at the same level, although we will want to vary both of these properties shortly. As soon as we place a handful of jumping beans in chamber 1, they begin jumping about randomly. Although most of the beans jump only to a modest height most of the time, occasionally one of them, in a burst of ambition, gives a more energetic leap, surmounting the barrier and falling into chamber 2. We can write this as the *jumping reaction*:

We will imagine this to be a completely random event, happening at irregular, infrequent intervals. Occasionally, one of the beans that has reached chamber 2 will happen to jump back into chamber 1, which is the *back reaction*. At first, of course, there will be more beans jumping from chamber 1 to chamber 2 because there are more beans in chamber 1, but things will eventually even out so that, on average, there will be the same number of beans in both compartments. The system will then be at *equilibrium*. Beans will still continue to jump between the two chambers, but the numbers jumping in both directions will be equal.

The Equilibrium Constant

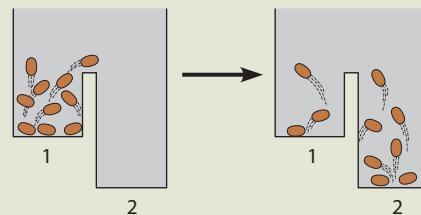

Once our system is at equilibrium, we can count up the number of beans in each chamber and express the results as the ratio of the number of beans in chamber 2 to the number in chamber 1. This is simply the *equilibrium constant* (K_{eq}) for the jumping reaction:

$$K_{\text{eq}} = \frac{\text{number of beans in chamber 2 at equilibrium}}{\text{number of beans in chamber 1 at equilibrium}}$$

For the specific case shown above, the numbers of beans in the two chambers are equal at equilibrium, so the equilibrium constant for the jumping reaction under these conditions is 1.0.

Enthalpy Change (ΔH)

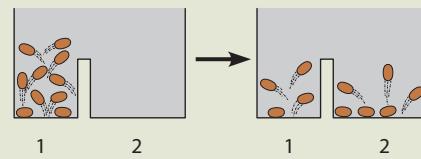

Now suppose that the level of chamber 1 is somewhat higher than that of chamber 2, as shown in the next diagram. Jumping beans placed in chamber 1 will again tend to distribute themselves between chambers 1 and 2, but this time a higher jump is required to get from 2 to 1 than from 1 to 2, so the latter will occur more frequently. As a result, there will be more beans in chamber 2 than in chamber 1 at equilibrium, and the equilibrium constant will therefore be greater than 1.

The relative heights of the two chambers can be thought of as measures of the *enthalpy*, or *heat content* (H), of the chambers, such that chamber 1 has a higher H value than chamber 2, and the difference between them is represented by ΔH . Since it is a “downhill” jump from chamber 1 to chamber 2, it makes sense that ΔH has a negative value for the jumping reaction from chamber 1 to chamber 2. Similarly, it seems reasonable that ΔH for the reverse reaction should have a positive value because that jump is “uphill.”

Entropy Change (ΔS)

So far, it might seem as if the only thing that can affect the equilibrium distribution of beans between the two chambers is the difference in enthalpy, ΔH . But that is only because we have kept the floor area of the two chambers constant. Imagine instead the situation shown below, where the two chambers are again at the same height, but chamber 2 now has a greater floor area than chamber 1. The probability of a bean finding itself in chamber 2 is therefore correspondingly greater, so there will be more beans in chamber 2 than in chamber 1 at equilibrium, and the equilibrium constant will be greater than 1 in this case also. This means that the equilibrium position of the jumping reaction has been shifted to the right, even though there is no change in enthalpy.

The floor area of the chambers can be thought of as a measure of the *entropy*, or *randomness*, of the system, S , and the difference between the two chambers can be represented by ΔS . Since chamber 2 has a greater floor area than chamber 1, the entropy change is positive for the jumping reaction as it proceeds from left to right under these conditions. Note that for ΔH , negative values

are associated with favorable reactions, while for ΔS , favorable reactions are indicated by positive values.

Free Energy Change (ΔG)

So far, we have encountered two different factors that affect the distribution of beans: the difference in levels of the two chambers (ΔH) and the difference in floor area (ΔS). Moreover, it should be clear that neither of these factors by itself is an adequate indicator of how the beans will be distributed at equilibrium because a favorable (negative) ΔH could be more than offset by an unfavorable (negative) ΔS , and a favorable (positive) ΔS could be more than offset by an unfavorable (positive) ΔH . You should, in fact, be able to design chamber conditions that illustrate both of these situations, as well as situations in which ΔH and ΔS tend to reinforce rather than counteract each other.

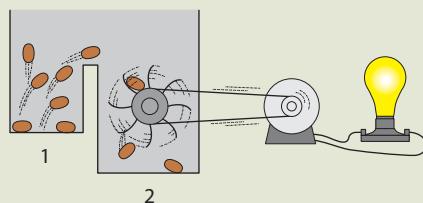

Clearly, what we need is a way of summing these two effects algebraically to see what the net tendency will be. The new measure we come up with is called the *free energy change*, ΔG , which turns out to be the most important thermodynamic parameter for our purposes. ΔG is defined so that negative values correspond to favorable (i.e., thermodynamically spontaneous) reactions and positive values represent unfavorable reactions. Thus, ΔG should have the same sign as ΔH (since a negative ΔH is also favorable) but the opposite sign from ΔS (since for ΔS , a positive value is favorable). Based on real-life thermodynamics, the expression for ΔG in terms of ΔH and ΔS is

$$\Delta G = \Delta H - T\Delta S$$

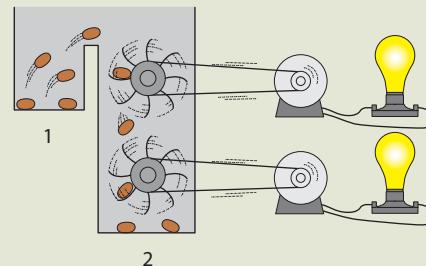

(Notice that the temperature dependence of ΔS is the only feature of this relationship that cannot be readily explained by our model, unless we assume that the effect of changes in room size is somehow greater at higher temperatures.)

ΔG and the Capacity to Do Work

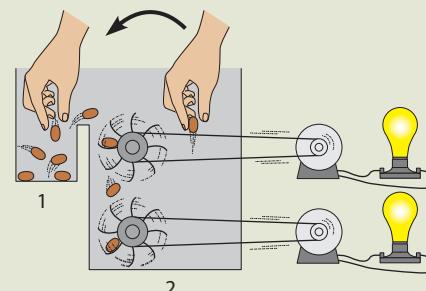

You should be able to appreciate the difficulty of suggesting a physical equivalent for ΔG because it represents an algebraic sum of entropy and energy changes, which may either reinforce or partially offset each other. But as long as ΔG is negative, beans will continue to jump from chamber 1 to chamber 2, whether driven primarily by changes in entropy, enthalpy, or both. This means that if some sort of bean-powered “bean wheel” is placed between the two chambers as shown below, the movement of beans from one chamber to the other can be harnessed to do work until equilibrium is reached, at which point no further work is possible. Furthermore, the greater the difference in free energy between the

two chambers (that is, the more highly negative ΔG is), the more work the system can do.

Thus, ΔG is first and foremost a measure of the capacity of a system to do work under specified conditions. You might, in fact, want to think of ΔG as free energy in the sense of energy that is free or available to do useful work. Moreover, if we contrive to keep ΔG negative by continuously adding beans to chamber 1 and removing them from chamber 2, we have a dynamic steady state, a condition that effectively harnesses the inexorable drive to achieve equilibrium. Work can then be performed continuously by beans that are forever jumping toward equilibrium but that never actually reach it.

Looking Ahead

To anticipate the transition from the thermodynamics of this chapter to the kinetics of the next, begin thinking about the rate at which beans actually proceed from chamber 1 to chamber 2. Clearly, ΔG measures how much energy will be released if beans do jump, but it says nothing at all about the rate. That would appear to depend critically on how high the barrier between the two chambers is. Label this the *activation energy barrier*, and then contemplate how you might get the beans to move over the barrier more rapidly. One approach might be to heat the chambers; this would be effective because the larvae inside the seeds wiggle more vigorously if they are warmed. Cells, on the other hand, have a far more effective and specific means of speeding up reactions: They lower the activation barrier by using catalysts called enzymes, which we will meet in the next chapter.

*We are indebted to Princeton University Press for permission to use this analogy, which was first developed by Harold F. Blum in the book *Time's Arrow and Evolution* (3rd ed., 1968), pp. 17–26.

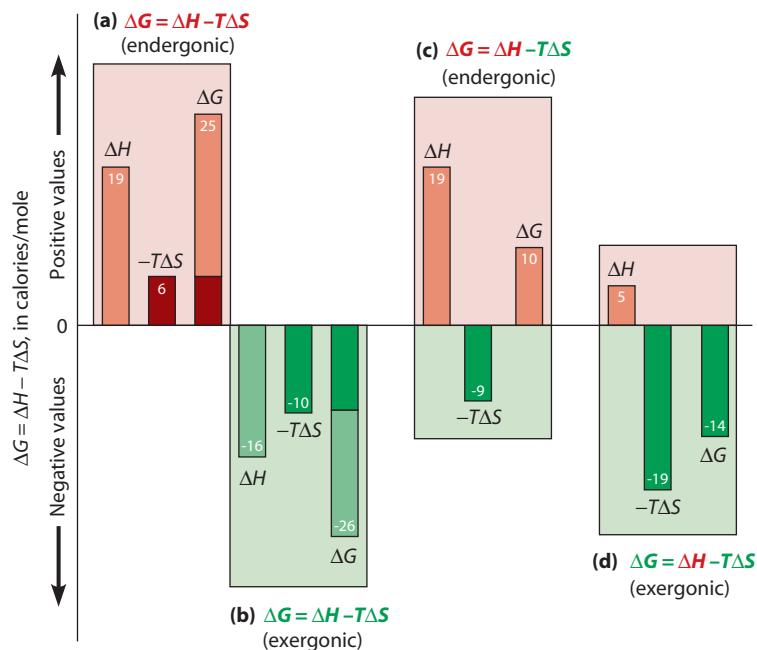

FIGURE 5-9 Dependence of ΔG on the Signs and Numerical Values of ΔH and the Term $-T\Delta S$. The ΔG value for a specific process or reaction is the algebraic sum of the change in enthalpy (ΔH) and the temperature-dependent entropy term ($-T\Delta S$). Green letters and bars identify terms that have negative values (that will increase spontaneity), whereas red letters identify terms that have positive values (that will decrease spontaneity). The numbers shown on the bars in white have been added so you can make the calculations yourself.

Free Energy Change and Thermodynamic Spontaneity:

A Biological Example. For a biological example of an exergonic reaction, consider again the oxidation of glucose to carbon dioxide and water:

You may recognize this as the summary equation for the process of aerobic respiration, whereby chemotrophs obtain energy from glucose. (Most of the cells in your body are carrying out this process right now.) As **Figure 5-10a** illustrates (and as you already know if you've ever held a marshmallow over the campfire too long), the oxidation of glucose is a highly exergonic process, with a highly negative ΔG value. By combusting glucose under *standard conditions* of temperature, pressure, and concentration (25°C, 1 atmosphere of pressure, and 1 M each of reactant and product), we can show that 673 kcal of heat (673,000 cal) are liberated for every mole of glucose that is oxidized, meaning that ΔH for Reaction 5-12 is -673 kcal/mol. The $-T\Delta S$ term can also be determined experimentally and is known to be -13 kcal/mol at 25°C, so this is an example of a reaction in which the ΔH and $-T\Delta S$ terms are additive, with a ΔG of -686 kcal/mol.

Now consider the reverse reaction, by which phototrophs synthesize sugars such as glucose from carbon dioxide and water, with the release of oxygen:

As you might guess, the values of ΔH , ΔS , and ΔG for this reaction are identical in magnitude, but opposite in sign, when determined under standard conditions and compared with the corresponding values for Reaction 5-12. Specifically, this reaction has a ΔG value of +686 kcal/mol,

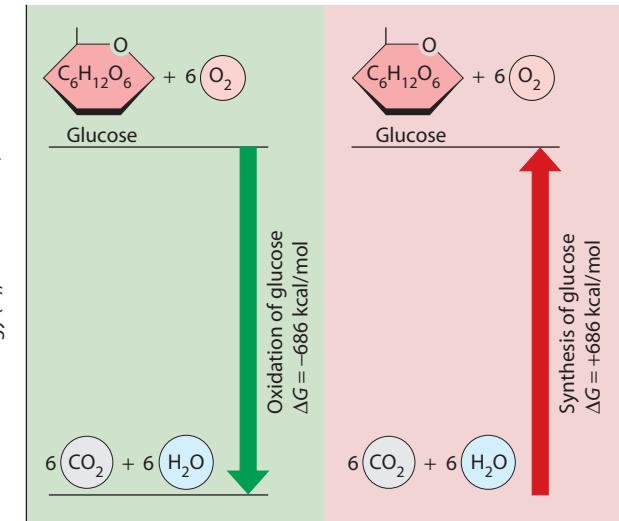

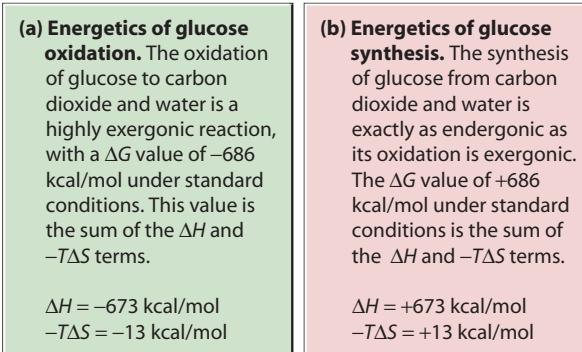

FIGURE 5-10 Changes in Free Energy for the Oxidation and Synthesis of Glucose The exergonic oxidation of glucose shown in (a) has a large negative ΔG that is exactly equal in magnitude but opposite in sign to the large positive ΔG for the endergonic synthesis of glucose shown in (b).

which makes it a highly endergonic reaction (Figure 5-10b). Phototrophs must therefore use large amounts of energy to drive this reaction in the direction of glucose synthesis—and that, of course, is where the energy of the sun comes in, as we'll see when we get to photosynthesis in Chapter 11.

The Meaning of Spontaneity. Before considering how we can actually calculate ΔG and use it as a measure of thermodynamic spontaneity, we need to look more closely at what is—and what is not—meant by the term *spontaneous*. As we noted earlier, spontaneity tells us only that a reaction *can* go; it says nothing at all about whether it *will* go. A reaction can have a negative ΔG value and yet not actually proceed to any measurable extent. The cellulose of paper obviously burns spontaneously once ignited, consistent with a highly negative ΔG value of -686 kcal/mol of glucose units. Yet in the absence of a match, paper is reasonably stable and might require hundreds of years to oxidize.

Thus, ΔG can really tell us only whether a reaction or process is thermodynamically feasible—whether it has the *potential* for occurring. Whether an exergonic reaction will in fact proceed depends not only on its favorable (negative) ΔG but also on the availability of a mechanism or pathway to get from the initial state to the final state. Usually, an initial input of activation energy is required as well, such as the heat energy from the match that was used to ignite the piece of paper.

Thermodynamic spontaneity is therefore a necessary but insufficient criterion for determining whether a reaction will actually occur. In Chapter 6, we will explore the subject of reaction rates in the context of enzyme-catalyzed reactions. For the moment, we need only note that when we designate a reaction as thermodynamically spontaneous, we simply mean it is an energetically feasible event that will liberate free energy if and when it actually takes place.

Understanding ΔG

Our final task in this chapter will be to understand how ΔG is calculated and how it can then be used to assess the thermodynamic feasibility of reactions under specified conditions. For that, we come back to the reaction that converts glucose-6-phosphate into fructose-6-phosphate (Reaction 5-9) and ask what we can learn about the spontaneity of the conversion in the direction written (from left to right). Experience and familiarity provide no clues here, nor is it obvious how the entropy of the universe would be affected if the reaction were to proceed. Clearly, we need to be able to calculate ΔG and to determine whether it is positive or negative under the particular conditions we specify for the reaction. It will be helpful to refer to **Table 5-1** periodically during the following discussion.

The Equilibrium Constant Is a Measure of Directionality

To assess whether a reaction can proceed in a given direction under specified conditions, we must understand the **equilibrium constant K_{eq}** , which is the ratio of product concentrations to reactant concentrations at *equilibrium*. When a reversible reaction is at equilibrium, this means there is no net change in the concentrations of either products or reactants with time. For the general reaction in which A is converted reversibly into B, the equilibrium constant is simply the ratio of the equilibrium concentrations of A and B:

$$K_{\text{eq}} = \frac{[B]_{\text{eq}}}{[A]_{\text{eq}}} \quad (5-15)$$

where $[A]_{\text{eq}}$ and $[B]_{\text{eq}}$ are the concentrations of A and B, in moles per liter, when Reaction 5-14 is at equilibrium at

Table 5-1 The Meaning of ΔG° and $\Delta G'$

The Meaning of ΔG°

ΔG° Negative ($K'_{\text{eq}} > 1.0$)

Products predominate over reactants at equilibrium at standard temperature, pressure, and pH.
Reaction goes spontaneously to the right under standard conditions.

ΔG° Positive ($K'_{\text{eq}} < 1.0$)

Reactants predominate over products at equilibrium at standard temperature, pressure, and pH.
Reaction goes spontaneously to the left under standard conditions.

$\Delta G^\circ = 0$ ($K'_{\text{eq}} = 1.0$)

Products and reactants are present equally at equilibrium at standard temperature, pressure, and pH.
Reaction is at equilibrium under standard conditions.

The Meaning of $\Delta G'$

$\Delta G'$ Negative

Reaction is thermodynamically feasible as written under the conditions for which $\Delta G'$ was calculated.

Work can be done by the reaction under the conditions for which $\Delta G'$ was calculated.

$\Delta G'$ Positive

Reaction is not feasible as written under the conditions for which $\Delta G'$ was calculated.

Energy must be supplied to drive the reaction under the conditions for which $\Delta G'$ was calculated.

$\Delta G' = 0$

Reaction is at equilibrium under the conditions for which $\Delta G'$ was calculated.

No work can be done nor is energy required by the reaction under the conditions for which $\Delta G'$ was calculated.

25°C. Given the equilibrium constant for a reaction, you can easily tell whether a specific mixture of products and reactants is at equilibrium. If it is not, it is easy to tell how far away the reaction is from equilibrium and the direction it must proceed to reach equilibrium.

For example, the equilibrium constant for Reaction 5-9 at 25°C is known to be 0.5. This means that, at equilibrium, there will be one-half as much fructose-6-phosphate as glucose-6-phosphate, regardless of the actual magnitudes of the concentrations:

$$K_{\text{eq}} = \frac{[\text{fructose-6-phosphate}]_{\text{eq}}}{[\text{glucose-6-phosphate}]_{\text{eq}}} = 0.5 \quad (5-16)$$

If the two compounds are present in any other concentration ratio, the reaction will not be at equilibrium and will move toward equilibrium. Thus, a concentration ratio *less* than K_{eq} means that there is too little fructose-6-phosphate present, and the reaction will tend to proceed to the right to generate more fructose-6-phosphate at the expense of glucose-6-phosphate. Conversely, a concentration ratio *greater* than K_{eq} indicates that the relative concentration of fructose-6-phosphate is too high, and the reaction will tend to proceed to the left.

Figure 5-11 illustrates this concept for the interconversion of A and B (Reaction 5-14), showing the relationship between the free energy of the reaction and how far the concentrations of A and B are from equilibrium. (Notice that K_{eq} is assumed to be 1.0 in this illustration; for other values of K_{eq} , the curve would be the same shape but still centered over K_{eq} .) The point of Figure 5-11 is clear: The free energy is lowest at equilibrium and increases as the system is displaced from equilibrium in either direction. Moreover, if we know how the ratio of prevailing

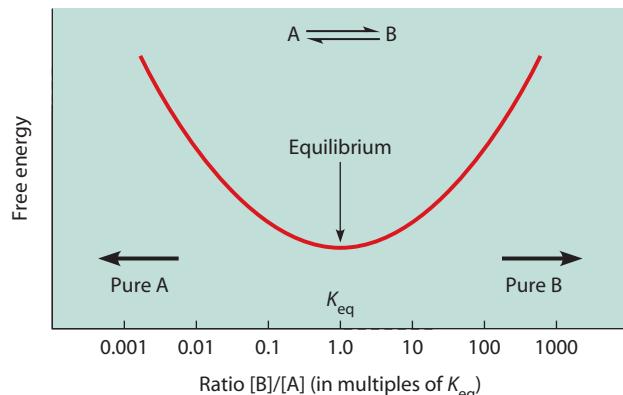

FIGURE 5-11 **Free Energy and Chemical Equilibrium.** The amount of free energy available from a chemical reaction depends on how far the components are from equilibrium. This principle is illustrated here for a reaction that interconverts A and B and has an equilibrium constant, K_{eq} , of 1.0. The free energy of the system increases as the $[B]/[A]$ ratio changes on either side of the equilibrium point. For a reaction with a K_{eq} value other than 1.0, the graph would have the same shape but would be centered over the K_{eq} value for that reaction.

concentrations compares with the equilibrium concentration ratio, we can predict in which direction a reaction will tend to proceed *and* how much free energy will be released as it does so. Thus, *the tendency toward equilibrium provides the driving force for every chemical reaction*, and a comparison of prevailing and equilibrium concentration ratios provides one measure of that tendency.

ΔG Can Be Calculated Readily

It should come as no surprise that ΔG is really just a means of calculating how far from equilibrium a reaction lies under specified conditions and how much energy will be released as the reaction proceeds toward equilibrium. Nor should it be surprising that both the equilibrium constant and the prevailing concentrations of reactants (A) and products (B) are needed to calculate ΔG . For Reaction 5-14, the equation relating these variables is

$$\begin{aligned} \Delta G &= RT \ln \frac{[B]_{\text{pr}}}{[A]_{\text{pr}}} - RT \ln \frac{[B]_{\text{eq}}}{[A]_{\text{eq}}} \\ &= RT \ln \frac{[B]_{\text{pr}}}{[A]_{\text{pr}}} - RT \ln K_{\text{eq}} \\ &= -RT \ln K_{\text{eq}} + RT \ln \frac{[B]_{\text{pr}}}{[A]_{\text{pr}}} \end{aligned} \quad (5-17)$$

where ΔG is the free energy change, in cal/mol, under the specified conditions; R is the gas constant (1.987 cal/mol-K); T is the temperature in kelvins (use 25°C = 298 K unless otherwise specified); $[A]_{\text{pr}}$ and $[B]_{\text{pr}}$ are the prevailing concentrations of A and B in moles per liter; $[A]_{\text{eq}}$ and $[B]_{\text{eq}}$ are the equilibrium concentrations of A and B in moles per liter; K_{eq} is the equilibrium constant at the standard temperature of 298 K (25°C); and \ln stands for the natural logarithm of (i.e., the logarithm of a quantity to the base of the natural logarithm system, e , which equals approximately 2.718). Natural logarithms are used because they describe processes in which the rate of change of the process is directly related to the quantity of material undergoing the change (e.g., as in describing radioactive decay).

More generally, for a reaction in which a molecules of reactant A combine with b molecules of reactant B to form c molecules of product C plus d molecules of product D,

ΔG is calculated as

$$\Delta G = -RT \ln K_{\text{eq}} + RT \ln \frac{[C]_{\text{pr}}^c [D]_{\text{pr}}^d}{[A]_{\text{pr}}^a [B]_{\text{pr}}^b} \quad (5-19)$$

where all the constants and variables are as previously defined, and K_{eq} is the equilibrium constant for Reaction 5-18.

Returning to Reaction 5-9, assume that the prevailing concentrations of glucose-6-phosphate and fructose-6-phosphate in a cell are $10 \mu M$ ($10 \times 10^{-6} M$) and $1 \mu M$ ($1 \times 10^{-6} M$), respectively, at $25^\circ C$. Since the ratio of prevailing product concentrations to reactant concentrations is 0.1 and the equilibrium constant is 0.5, there is clearly too little fructose-6-phosphate present relative to glucose-6-phosphate for the reaction to be at equilibrium. The reaction should therefore tend toward the right in the direction of fructose-6-phosphate generation. In other words, the reaction is thermodynamically favorable in the direction written. This, in turn, means that ΔG must be negative under these conditions.

The actual value for ΔG is calculated as follows:

$$\begin{aligned}\Delta G &= -(1.987 \text{ cal/mol-K})(298 \text{ K}) \ln(0.5) \\ &\quad + (1.987 \text{ cal/mol-K})(298 \text{ K}) \ln \frac{1 \times 10^{-6} M}{10 \times 10^{-6} M} \\ &= -(592 \text{ cal/mol}) \ln(0.5) + (592 \text{ cal/mol}) \ln(0.1) \\ &= -(592 \text{ cal/mol})(-0.693) + (592 \text{ cal/mol})(-2.303) \\ &= +410 \text{ cal/mol} - 1364 \text{ cal/mol} \\ &= -954 \text{ cal/mol}\end{aligned}\quad (5-20)$$

Notice that our expectation of a negative ΔG is confirmed, and we now know exactly how much free energy is liberated upon the spontaneous conversion of 1 mole of glucose-6-phosphate into 1 mole of fructose-6-phosphate under the specified conditions. The free energy liberated in this or some other exergonic reaction can be either “harnessed” to do work, stored in the chemical bonds of ATP, or released as heat.

It is important to understand exactly what this calculated value for ΔG means and under what conditions it is valid. Because it is a thermodynamic parameter, ΔG can tell us whether a reaction is thermodynamically possible as written, but it says nothing about the rate or the mechanism of the reaction. It simply says that if the reaction does occur, it will proceed to the right and will liberate 954 calories (0.954 kcal) of free energy for every mole of glucose-6-phosphate that is converted to fructose-6-phosphate, *provided* that the concentrations of both the reactant and the product are *maintained at the initial values* (10 and $1 \mu M$, respectively) throughout the course of the reaction.

In upcoming chapters, we will see examples of how some of the energy provided by exergonic reactions can be harnessed by the use of *coupled reactions*. In coupled reactions, an endergonic reaction happens simultaneously with an exergonic reaction, and the free energy of the exergonic reaction is used to permit the endergonic reaction to occur. For example, although the synthesis of ATP is endergonic, often this reaction is coupled to an exergonic oxidative reaction such that the overall sum of the two reactions has a negative ΔG and both reactions can proceed spontaneously. Rather than being released as heat, some of the energy of the oxidation has been conserved in the chemical bonds of the high-energy ATP molecule.

More generally, ΔG is a measure of thermodynamic spontaneity for a reaction in the direction in which it is written (from left to right), at the specified concentrations of reactants and products. In a beaker or test tube, this requirement for constant reactant and product concentrations means that reactants must be added continuously and products must be removed continuously. In the cell, each reaction is part of a metabolic pathway, and its reactants and products are maintained at fairly constant, nonequilibrium concentrations by the reactions that precede and follow it in the sequence.

The Standard Free Energy Change Is ΔG Measured Under Standard Conditions

Because it is a thermodynamic parameter, ΔG is independent of the actual mechanism or pathway of a reaction, but it depends crucially on the conditions under which the reaction occurs. A reaction characterized by a large decrease in free energy under one set of conditions may have a much smaller (but still negative) ΔG or may even have a positive ΔG under a different set of conditions. The melting of ice, for example, depends on temperature; it proceeds spontaneously above $0^\circ C$ but goes in the opposite direction (freezing) below that temperature. It is therefore important to identify the conditions under which a given measurement of ΔG is made.

By convention, biochemists have agreed on certain arbitrary conditions to define the **standard state** of a system for convenience in reporting, comparing, and tabulating free energy changes in chemical reactions. For systems consisting of dilute aqueous solutions, these are usually a standard temperature of $25^\circ C$ (298 K), a pressure of 1 atmosphere, and all products and reactants present at a concentration of 1 M.

The only common exception to this standard concentration rule is water. The concentration of water in a dilute aqueous solution is approximately 55.5 M and does not change significantly during the course of reactions, even when water is itself a reactant or product. By convention, biochemists do not include the concentration of water in calculations of free energy changes, even though the reaction may indicate a net consumption or production of water.

In addition to standard conditions of temperature, pressure, and concentration, biochemists also frequently specify a standard pH of 7.0 because most biological reactions occur at or near neutrality. The concentration of hydrogen ions (and of hydroxyl ions) is therefore $10^{-7} M$, so the standard concentration of 1.0 M does not apply to H^+ or OH^- ions when a pH of 7.0 is specified. Values of K_{eq} , ΔG , or other thermodynamic parameters determined or calculated at pH 7.0 are always written with a prime (as K'_{eq} , $\Delta G'$, and so on) to indicate this exception to standard conditions.

Energy changes for reactions are usually reported in standardized form as the change that would occur if the

reactions were run under the standard conditions. More precisely, the standard change in any thermodynamic parameter refers to the conversion of a mole of a specified reactant to products or the formation of a mole of a specified product from the reactants under conditions where the temperature, pressure, pH, and concentrations of all relevant species are maintained at their standard values.

The free energy change calculated under these conditions is called the **standard free energy change**, designated $\Delta G^\circ'$, where the superscript ($^\circ$) refers to standard conditions of temperature, pressure, and concentration, and the prime ('') emphasizes that the standard hydrogen ion concentration for biochemists is $10^{-7} M$, not $1.0 M$.

It turns out that $\Delta G^\circ'$ bears a simple linear relationship to the natural logarithm of the equilibrium constant K'_{eq} (**Figure 5-12**). This relationship can readily be seen by rewriting Equation 5-19 with primes and then assuming standard concentrations for all reactants and products. All concentration terms are now 1.0 and the natural logarithm of 1.0 is zero, so the second term in the general expression for $\Delta G'$ is eliminated, and what remains is an equation for $\Delta G^\circ'$, the free energy change under standard conditions:

$$\begin{aligned}\Delta G^\circ' &= -RT \ln K'_{\text{eq}} + RT \ln 1 \\ &= -RT \ln K'_{\text{eq}}\end{aligned}\quad (5-21)$$

In other words, $\Delta G^\circ'$ can be calculated directly from the equilibrium constant, provided that the latter has also

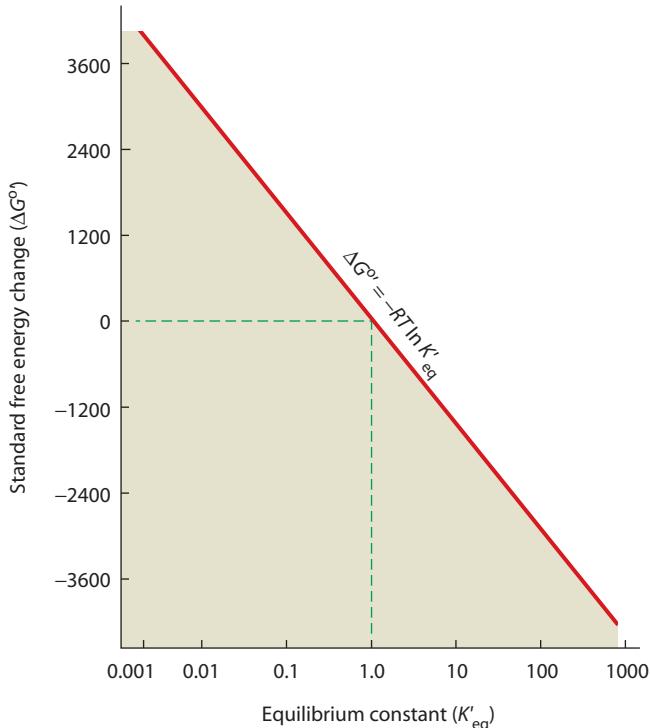

FIGURE 5-12 The Relationship Between $\Delta G^\circ'$ and K'_{eq} .

The standard free energy change and the equilibrium constant are related by the equation $\Delta G^\circ' = -RT \ln K'_{\text{eq}}$. Note that if the equilibrium constant is 1.0, the standard free energy change is zero.

been determined under the same standard conditions of temperature, pressure, and pH. This, in turn, allows Equation 5-19 to be simplified as

$$\Delta G' = \Delta G^\circ' + RT \ln \frac{[C]_{\text{pr}}^c [D]_{\text{pr}}^d}{[A]_{\text{pr}}^a [B]_{\text{pr}}^b} \quad (5-22)$$

At the standard temperature of 25°C (298 K), the term RT becomes $(1.987)(298) = 592 \text{ cal/mol}$, so Equations 5-21 and 5-22 can be rewritten as follows, in what are the most useful formulas for our purposes:

$$\Delta G^\circ' = -592 \ln K'_{\text{eq}} \quad (5-23)$$

$$\Delta G' = \Delta G^\circ' + 592 \ln \frac{[C]_{\text{pr}}^c [D]_{\text{pr}}^d}{[A]_{\text{pr}}^a [B]_{\text{pr}}^b} \quad (5-24)$$

Summing Up: The Meaning of $\Delta G'$ and $\Delta G^\circ'$

Equations 5-23 and 5-24 represent the most important contribution of thermodynamics to biochemistry and cell biology—a means of assessing the feasibility of a chemical reaction based on the prevailing concentrations of products and reactants and a knowledge of the equilibrium constant. Equation 5-23 expresses the relationship between the standard free energy change $\Delta G^\circ'$ and the equilibrium constant K'_{eq} and enables us to calculate the free energy change that would be associated with any reaction of interest if all reactants and products were maintained at a standard concentration of $1.0 M$.

If K'_{eq} is greater than 1.0, then $\ln K'_{\text{eq}}$ will be positive and $\Delta G^\circ'$ will be negative, and the reaction can proceed to the right under standard conditions. This makes sense because if K'_{eq} is greater than 1.0, products will predominate over reactants at equilibrium. A predominance of products can be achieved from the standard state only by the conversion of reactants to products, so the reaction will tend to proceed spontaneously to the right. Conversely, if K'_{eq} is less than 1.0, then $\Delta G^\circ'$ will be positive and the reaction cannot proceed to the right. Instead, it will tend toward the left because $\Delta G^\circ'$ for the reverse reaction will have the same absolute value but will be opposite in sign. This is in keeping with the small value for K'_{eq} , which specifies that reactants are favored over products (that is, the equilibrium lies to the left).

The $\Delta G^\circ'$ values are convenient both because they can easily be determined from the equilibrium constant and because they provide a uniform convention for reporting free energy changes. But bear in mind that a $\Delta G^\circ'$ value is an arbitrary standard in that it refers to an arbitrary state specifying conditions of concentration that cannot be achieved with most biologically important compounds. $\Delta G^\circ'$ is therefore useful for standardized reporting, but *it is not a valid measure of the thermodynamic spontaneity of reactions as they occur under real conditions*.

For real-life situations in cell biology, we will use $\Delta G'$, which provides a direct measure of how far from equilibrium a reaction is at the concentrations of reactants and products that actually prevail in the cell (Equation 5-24). Therefore, $\Delta G'$ is the most useful measure of thermodynamic spontaneity. If it is negative, the reaction in question is thermodynamically spontaneous and can proceed as written under the conditions for which the calculations were made. Its magnitude serves as a measure of how much free energy will be liberated as the reaction occurs under the specified conditions. This, in turn, determines the maximum amount of work that can be performed on the surroundings, provided a mechanism is available to conserve and use the energy as it is liberated.

A positive $\Delta G'$, on the other hand, indicates that the reaction cannot occur in the direction written under the conditions for which the calculations were made. Such reactions can sometimes be rendered spontaneous, however, by increasing the concentrations of reactants or by decreasing the concentrations of products. Throughout the text, you will often see reactions that are unfavorable under standard conditions but are able to proceed because the products are rapidly removed by a subsequent reaction.

For the special case where $\Delta G' = 0$, the reaction is clearly at equilibrium, and no net energy change accompanies the conversion of reactant molecules into product molecules or vice versa. As we will see shortly, reactions in living cells are rarely at equilibrium. Table 5-1 summarizes the basic features of K'_{eq} , $\Delta G^\circ'$, and $\Delta G'$.

Free Energy Change: Sample Calculations

To illustrate the calculation and utility of $\Delta G'$ and $\Delta G^\circ'$, we return once more to the interconversion of glucose-6-phosphate and fructose-6-phosphate (Reaction 5-9). We already know that the equilibrium constant for this reaction under standard conditions of temperature, pH, and pressure is 0.5 (Equation 5-16). This means that if the enzyme that catalyzes this reaction in cells is added to a solution of glucose-6-phosphate at 25°C, 1 atmosphere, and pH 7.0, and the solution is incubated until no further reaction occurs, fructose-6-phosphate and glucose-6-phosphate will be present in an equilibrium ratio of 0.5. (Notice that this ratio is independent of the actual starting concentration of glucose-6-phosphate and could have been achieved equally well by starting with any concentration of fructose-6-phosphate or any mixture of both, in any starting concentrations.)

The standard free energy change $\Delta G^\circ'$ can be calculated from K'_{eq} as follows:

$$\begin{aligned}\Delta G^\circ' &= -RT \ln K'_{\text{eq}} = -592 \ln K'_{\text{eq}} \\ &= -592 \ln 0.5 = -592(-0.693) \\ &= +410 \text{ cal/mol}\end{aligned}\quad (5-25)$$

The positive value for $\Delta G^\circ'$ is therefore another way of expressing that the reactant (glucose-6-phosphate) is the predominant species at equilibrium. A positive $\Delta G^\circ'$ value also means that under standard conditions of concentration, the reaction is nonspontaneous (thermodynamically impossible) in the direction written. In other words, if we begin with both glucose-6-phosphate and fructose-6-phosphate present at concentrations of 1.0 M, no net conversion of glucose-6-phosphate to fructose-6-phosphate can occur.

As a matter of fact, the reaction will proceed to the left under standard conditions. Fructose-6-phosphate will be converted into glucose-6-phosphate until the equilibrium ratio of 0.5 is reached. Alternatively, if both species were added or removed continuously as necessary to maintain the concentrations of both at 1.0 M, the reaction would proceed continuously and spontaneously to the left, with the liberation of 410 cal of free energy per mole of fructose-6-phosphate converted to glucose-6-phosphate. In the absence of any provision for conserving this energy, it would be dissipated as heat.

In a real cell, neither of these phosphorylated sugars would ever be present at a concentration even approaching 1.0 M. In fact, experimental values for the actual concentrations of these substances in human red blood cells are as follows:

$$\begin{aligned}[\text{glucose-6-phosphate}] &: 83 \mu\text{M} (83 \times 10^{-6} \text{ M}) \\ [\text{fructose-6-phosphate}] &: 14 \mu\text{M} (14 \times 10^{-6} \text{ M})\end{aligned}$$

Using these values, we can calculate the actual $\Delta G'$ for the interconversion of these sugars in red blood cells as follows:

$$\begin{aligned}\Delta G' &= \Delta G^\circ' + 592 \ln \frac{[\text{fructose-6-phosphate}]_{\text{pr}}}{[\text{glucose-6-phosphate}]_{\text{pr}}} \\ &= +410 + 592 \ln \frac{14 \times 10^{-6}}{83 \times 10^{-6}} \\ &= +410 + 592 \ln 0.169 \\ &= +410 + 592(-1.78) = +410 - 1054 \\ &= -644 \text{ cal/mol}\end{aligned}\quad (5-26)$$

The negative value for $\Delta G'$ means that the conversion of glucose-6-phosphate into fructose-6-phosphate is thermodynamically possible under the actual conditions of concentration prevailing in red blood cells and that the reaction will yield 644 cal of free energy per mole of reactant converted to product. Thus, the conversion of reactant to product is thermodynamically impossible under standard conditions, but the red blood cell maintains these two phosphorylated sugars at concentrations adequate to offset the positive $\Delta G'$, thereby rendering the reaction possible. This adaptation, of course, is essential if the red blood cell is to be successful in carrying out the glucose-degrading process of glycolysis of which this reaction is a part.

Life and the Steady State: Reactions That Move Toward Equilibrium Without Ever Getting There

As this chapter has emphasized, the driving force in all reactions is their tendency to move toward equilibrium. Indeed, ΔG° and $\Delta G'$ are really just convenient means of quantifying how far and in what direction from equilibrium a reaction lies under the specific conditions dictated by standard or prevailing concentrations of products and reactants. But to understand how cells really function, we must appreciate the importance of reactions that move toward equilibrium without ever achieving it. At equilibrium, the forward and backward rates are the same for a reaction, and there is therefore no net flow of matter in either direction. Most importantly, no further energy can be extracted from the reaction because $\Delta G'$ is zero for a reaction at equilibrium. Perhaps you can use Equations 5-21 and 5-22 to prove mathematically that every reaction at equilibrium has a $\Delta G' = 0$.

For all practical purposes, then, a reaction that is at equilibrium is a reaction that has stopped. But a living cell is characterized by reactions that are continuous, not stopped. A cell at equilibrium would be a dead cell. We might, in fact, define life as a continual struggle to maintain many cellular reactions in positions far from equilibrium—because at equilibrium, no net reactions are possible, no energy can be released, no work can be done, and the order of the living state cannot be maintained.

Thus, life is possible only because living cells maintain themselves in a **steady state**, with most of their reactions far from thermodynamic equilibrium. The levels of glucose-6-phosphate and fructose-6-phosphate found in red blood cells illustrate this point. As we have seen, these compounds are maintained in the cell at steady-state concentrations far from the equilibrium condition predicted

by the K'_{eq} value of 0.5. In fact, the levels are so far from equilibrium concentrations that the conversion of glucose-6-phosphate to fructose-6-phosphate can occur continuously in the cell, even though the equilibrium state has a positive $\Delta G^\circ'$ and actually favors glucose-6-phosphate. The same is true of most reactions and pathways in the cell. They can proceed and can be harnessed to perform various kinds of cellular work because reactants, products, and intermediates are maintained at steady-state concentrations far from the thermodynamic equilibrium.

This state, in turn, is possible only because a cell is an open system and receives large amounts of energy from its environment. If the cell were a closed system, all its reactions would gradually run to equilibrium. The cell would come inevitably to a state of minimum free energy, after which no further changes could occur, no work could be accomplished, and life would cease. The steady state so vital to life is possible only because the cell is able to take up energy continuously from its environment, whether in the form of light or preformed organic food molecules. This continuous uptake of energy and the accompanying flow of matter make possible the maintenance of a steady state in which all the reactants and products of cellular chemistry are kept far enough from equilibrium to ensure that the thermodynamic drive toward equilibrium can be harnessed by the cell to perform useful work, thereby maintaining and extending its activities and structural complexity.

We will focus on how this is accomplished in later chapters. In the next chapter, we will look at principles of enzyme catalysis that determine the rates of cellular reactions—that is, we will translate the *can go* of thermodynamics into the *will go* of kinetics. Then we will be ready to move on to subsequent chapters, where we will encounter functional metabolic pathways that result from a series of such reactions acting in concert.

SUMMARY OF KEY POINTS

The Importance of Energy

- The complexity of cells is possible only due to the availability of energy from the environment. All cells require energy, the capacity to cause physical or chemical changes in the cells. These energy-requiring changes include biosynthesis, movement, concentration or electrical work and the generation of heat or bioluminescence.
- Phototrophs obtain energy directly from the sun and use it to reduce low-energy inorganic molecules such as carbon dioxide and nitrate to high-energy molecules such as carbohydrates, proteins, and lipids. These molecules are used

both to build cellular structures and to provide energy in the absence of sunlight.

- Chemotrophs cannot harvest solar energy directly but must obtain their energy by oxidizing the high-energy molecules synthesized by phototrophs.
- There is a unidirectional flow of energy in the biosphere as energy moves from the sun to phototrophs to chemotrophs and is ultimately released into the environment as heat. Matter flows in a cyclic manner between phototrophs and chemotrophs as carbon and nitrogen atoms are alternately reduced and oxidized.

Bioenergetics

- All living cells and organisms are open systems that exchange energy with their environment. The flow of energy through these living systems is governed by the laws of thermodynamics.
- The first law specifies that energy can change form but must always be conserved. The second law provides a measure of thermodynamic spontaneity, although this means only that a reaction can occur and says nothing about whether it will actually occur or at what rate.
- Spontaneous processes are always accompanied by an *increase* in the entropy of the universe and a *decrease* in the free energy of the system. Free energy is a far more practical indicator of spontaneity because it can be calculated readily from the equilibrium constant, the prevailing concentrations of reactants and products, and the temperature.

Understanding ΔG

- The equilibrium constant K_{eq} is a measure of the directionality of a particular chemical reaction. It can be used to calculate ΔG° , the free energy change under standard conditions.
- $\Delta G'$, which describes the free energy change under specified conditions, is a measure of how far from equilibrium a reaction

is. It represents how much energy will be released as the reaction moves toward equilibrium.

- An exergonic reaction has a negative $\Delta G'$ and proceeds spontaneously in the direction written, while an endergonic reaction has a positive $\Delta G'$ and requires the input of energy to proceed as written.
- A negative $\Delta G'$ is a necessary prerequisite for a reaction to proceed spontaneously, but it does not guarantee that the reaction will actually occur at a reasonable rate. Even a reaction with a positive standard free energy change, ΔG° , can proceed if the actual concentration of product is kept low enough to provide a negative $\Delta G'$.

Life and the Steady State: Reactions That Move Toward Equilibrium Without Ever Getting There

- Cells obtain the energy they need to carry out their activities by maintaining the many reactants and products of the various reactions at steady-state concentrations far from equilibrium. This allows the reactions to move exergonically toward equilibrium without ever actually reaching it.
- A reaction at equilibrium has a $\Delta G' = 0$, and no useful work can be done by this reaction. Therefore, a cell with all reactions at equilibrium is a dead cell.

MAKING CONNECTIONS

In this chapter, we have learned the basics of bioenergetics—the flow of energy through biological systems and the application of thermodynamic principles to biological processes and reactions. We have also used the concept of free energy changes to predict whether particular cellular reactions can occur in the direction as written. However, whether and at what rate a reaction will actually proceed depends on the presence of specific biological catalysts known as enzymes, which we will discuss in detail in the next chapter. Throughout the text, we will see many examples of how cells use energy to perform work, and we will understand them better thanks to what we have just learned. All cells need energy for the biosynthesis of macromolecules to make the cellular structures and organelles that we encountered in the previous chapters. All cells need energy to move

materials across membranes as they perform concentration and electrical work (Chapters 7 and 8). They need energy to move themselves or to move materials inside the cell—the subject of later chapters. Exactly how do cells obtain and store this energy for when it is needed? This is the subject of Chapters 9 through 11, where we will use our understanding of free energy changes to dissect the details of the pathways by which cells obtain energy from foods or from the sun. Throughout the rest of the text, as we study cell motility and cell signaling in Chapters 13 to 17, or chromosome movement, DNA replication, and the expression of genetic material in Chapters 18 to 24, keep in mind that all these processes require an input of energy. Moreover, they all obey the laws of thermodynamics and use the principles of bioenergetics that we have just learned.

PROBLEM SET

More challenging problems are marked with a •.

5-1 Solar Energy. Although we sometimes hear concerns about a global energy crisis, we actually live on a planet that is flooded continuously with an extravagant amount of energy in the form of solar radiation. Every day, year in and year out, solar energy arrives at the upper surface of the Earth's atmosphere at the rate of 1.94 cal/min/cm² of cross-sectional area (the *solar energy constant*).

(a) Assuming the cross-sectional area of the Earth to be about 1.28×10^{18} cm², what is the total annual amount of incoming energy?

- (b) A substantial portion of that energy, particularly in the wavelength ranges below 300 nm and above 800 nm, never reaches the Earth's surface. Can you suggest what happens to it?
- (c) Of the radiation that reaches the Earth's surface, only a small proportion is actually trapped photosynthetically by phototrophs. (You can calculate the actual value in Problem 5-2.) Why do you think the efficiency of utilization is so low?

5-2 Photosynthetic Energy Transduction. The amount of energy trapped and the volume of carbon converted to organic form by

photosynthetic energy transducers are mind-boggling: about 5×10^{16} g of carbon per year over the entire Earth's surface.

- Assuming that the average organic molecule in a cell has about the same proportion of carbon as glucose does, how many grams of organic matter are produced annually by carbon-fixing phototrophs?
- Assuming that all the organic matter in part a is glucose (or any molecule with an energy content equivalent to that of glucose), how much energy is represented by that quantity of organic matter? Assume that glucose has a free energy content (free energy of combustion) of 3.8 kcal/g.
- Referring to the answer for Problem 5-1a, what is the average efficiency with which the radiant energy incident on the upper atmosphere is trapped photosynthetically on the Earth's surface?
- What proportion of the net annual phototrophic production of organic matter calculated in part a do you think is consumed by chemotrophs each year?

5-3 Energy Conversion. Most cellular activities involve converting energy from one form to another. For each of the following cases, give a biological example and explain the significance of the conversion.

- Chemical energy into mechanical energy
- Chemical energy into light energy
- Solar (light) energy into chemical energy
- Chemical energy into electrical energy
- Chemical energy into the potential energy of a concentration gradient

5-4 Enthalpy, Entropy, and Free Energy. The oxidation of glucose to carbon dioxide and water is represented by the following reaction, whether the oxidation occurs by combustion in the laboratory or by biological oxidation in living cells:

When combustion is carried out under controlled conditions in the laboratory, the reaction is highly exothermic, with an enthalpy change (ΔH) of -673 kcal/mol. As you know from Figure 5-10, ΔG for this reaction at 25°C is -686 kcal/mol, so the reaction is also highly exergonic.

- Explain in your own words what the ΔH and ΔG values mean. What do the negative signs mean in each case?
- What does it mean to say that the difference between the ΔG and ΔH values is due to entropy?
- Without doing any calculations, would you expect ΔS (entropy change) for this reaction to be positive or negative? Explain your answer.
- Now calculate ΔS for this reaction at 25°C . Does the calculated value agree in sign with your prediction in part c?
- What are the values of ΔG , ΔH , and ΔS for the reverse of the above reaction as carried out by a photosynthetic algal cell that is using CO_2 and H_2O to make $\text{C}_6\text{H}_{12}\text{O}_6$?

5-5 The Equilibrium Constant. The following reaction is one of the steps in the glycolytic pathway, which we will encounter

again in Chapter 9. You should recognize it already, however, because we used it as an example earlier (Reaction 5-9):

The equilibrium constant K_{eq} for this reaction at 25°C is 0.5.

- Assume that you incubate a solution containing 0.15 M glucose-6-phosphate (G6P) overnight at 25°C with the enzyme phosphoglucoisomerase that catalyzes Reaction 5-28. How many millimoles of fructose-6-phosphate (F6P) will you recover from 10 mL of the incubation mixture the next morning, assuming you have an appropriate chromatographic procedure to separate F6P from G6P?
- What answer would you get for part a if you had started with a solution containing 0.15 M F6P instead?
- What answer would you expect for part a if you had started with a solution containing 0.15 M G6P but forgot to add phosphoglucoisomerase to the incubation mixture?
- Would you be able to answer the question in part a if you had used 15°C as your incubation temperature instead of 25°C ? Why or why not?

5-6 Calculating ΔG° and $\Delta G'$. Like Reaction 5-28, the conversion of 3-phosphoglycerate (3PG) to 2-phosphoglycerate (2PG) is an important cellular reaction because it is one of the steps in the glycolytic pathway (see Chapter 9):

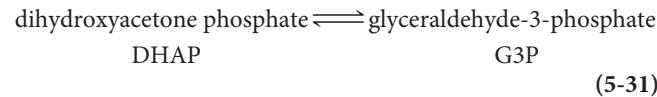

If the enzyme that catalyzes this reaction is added to a solution of 3PG at 25°C and pH 7.0, the equilibrium ratio between the two species will be 0.165:

$$K'_{\text{eq}} = \frac{[\text{2-phosphoglycerate}]_{\text{eq}}}{[\text{3-phosphoglycerate}]_{\text{eq}}} = 0.165 \quad (5-30)$$

Experimental values for the actual steady-state concentrations of these compounds in human red blood cells are $61\text{ }\mu\text{M}$ for 3PG and $4.3\text{ }\mu\text{M}$ for 2PG.

- Calculate ΔG° . Explain in your own words what this value means.
- Calculate $\Delta G'$. Explain in your own words what this value means. Why are $\Delta G'$ and ΔG° different?
- If conditions in the cell change such that the concentration of 3PG remains fixed at $61\text{ }\mu\text{M}$ but the concentration of 2PG begins to rise, how high can the 2PG concentration get before Reaction 5-29 will cease because it is no longer thermodynamically feasible?

5-7 Backward or Forward? The interconversion of dihydroxyacetone phosphate (DHAP) and glyceraldehyde-3-phosphate (G3P) is a part of both the glycolytic pathway (see Chapter 9) and the Calvin cycle for photosynthetic carbon fixation (see Chapter 11):

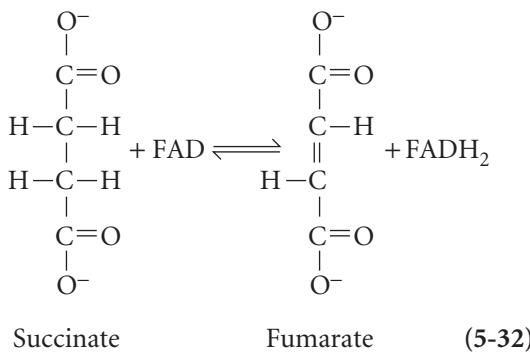

The value of ΔG° for this reaction is $+1.8$ kcal/mol at 25°C . In the glycolytic pathway, this reaction goes to the *right*, converting

DHAP to G3P. In the Calvin cycle, this reaction proceeds to the left, converting G3P to DHAP.

- In which direction does the equilibrium lie? What is the equilibrium constant at 25°C?
- In which direction does this reaction tend to proceed under standard conditions? What is $\Delta G'$ for the reaction *in that direction*?
- In the glycolytic pathway, this reaction is driven to the right because G3P is consumed by the next reaction in the sequence, thereby maintaining a low G3P concentration. What will $\Delta G'$ be (at 25°C) if the concentration of G3P is maintained at 1% of the DHAP concentration (i.e., if $[G3P]/[DHAP] = 0.01$)?
- In the Calvin cycle, this reaction proceeds to the left. How high must the $[G3P]/[DHAP]$ ratio be to ensure that the reaction is exergonic by at least -3.0 kcal/mol (at 25°C)?

5-8 Succinate Oxidation. The oxidation of succinate to fumarate is an important cellular reaction because it is one of the steps in the tricarboxylic acid (TCA) cycle (see Chapter 10). The two hydrogen atoms that are removed from succinate are accepted by a coenzyme molecule called flavin adenine dinucleotide (FAD), which is thereby reduced to FADH₂:

ΔG° for Reaction 5-32 is 0 cal/mol.

- If you start with a solution containing 0.01 M each of succinate and FAD and add an appropriate amount of the enzyme that catalyzes this reaction, will any fumarate be formed? If so, calculate the resulting equilibrium concentrations of all four species. If not, explain why not.
- Answer part a assuming that 0.01 M FADH₂ is also present initially.
- Assuming that the steady-state conditions in a cell are such that the FADH₂/FAD ratio is 5 and the fumarate concentration is 2.5 μM, what steady-state concentration of succinate would be necessary to maintain $\Delta G'$ for succinate oxidation at -1.5 kcal/mol?

5-9 Protein Folding. In Chapter 2, we learned that a polypeptide in solution usually folds spontaneously into its proper three-dimensional shape. The driving force for this folding is the tendency to achieve the most favored thermodynamic conformation. A folded polypeptide can be induced to unfold (i.e., will undergo denaturation) if the solution is heated or made acidic or alkaline. The denatured polypeptide is a random structure, with many possible conformations.

- What is the sign of ΔG for the folding process? What about for the unfolding (denaturation) process? How do you know?
- What is the sign for ΔS for the folding process? What about for the unfolding (denaturation) process? How do you know?
- Will the contribution of ΔS to the free energy change be positive or negative?
- What are the main kinds of bonds and interactions that must be broken or disrupted if a folded polypeptide is to be unfolded? Why do heat and extremes of pH cause unfolding?

5-10 Membrane Transport. As we will learn in Chapter 8, we can treat the transport of molecules across a membrane as a chemical reaction and calculate ΔG as we would for any other reaction. The general “reaction” for the transport of molecule X from the outside of the cell to the inside can be represented as

and the free energy change can be written as

$$\Delta G_{\text{inward}} = \Delta G^\circ + RT \ln [X]_{\text{inside}} / [X]_{\text{outside}} \quad (5-34)$$

However, the K_{eq} for the transport of an uncharged solute across a membrane is always 1, so ΔG° is always 0—and the equation for ΔG is simplified accordingly.

- Why is the K_{eq} for the transport of molecules across a membrane always 1? Why is ΔG° always 0?
- What is the simplified equation for ΔG_{inward} ? What about for $\Delta G_{\text{outward}}$?
- Suppose that the concentration of lactose within a bacterial cell is to be maintained at 10 mM, whereas the external lactose concentration is only 0.2 mM. Do you predict that the ΔG_{inward} for lactose will be positive or negative? Explain your reasoning.
- Calculate the ΔG_{inward} for lactose, assuming a temperature of 25°C. Does the sign agree with your prediction in part c?
- One of the several sources of energy to drive lactose uptake under these conditions is ATP hydrolysis, which has a ΔG° value of -7.3 kcal/mol. Will the hydrolysis of a single ATP molecule be adequate to drive the inward transport of one lactose molecule under these conditions?

• 5-11 Proof of Additivity. A useful property of thermodynamic parameters such as $\Delta G'$ or ΔG° is that they are additive for sequential reactions. Assume that K'_{AB} , K'_{BC} , and K'_{CD} are the respective equilibrium constants for reactions 1, 2, and 3 of the following sequence:

- Prove that the equilibrium constant K'_{AD} for the overall conversion of A to D is the *product* of the three component equilibrium constants:

$$K'_{AD} = K'_{AB} K'_{BC} K'_{CD} \quad (5-36)$$

- Prove that the ΔG° for the overall conversion of A to D is the *sum* of the three component ΔG° values:

$$\Delta G^\circ_{AD} = \Delta G^\circ_{AB} + \Delta G^\circ_{BC} + \Delta G^\circ_{CD} \quad (5-37)$$

- Prove that the $\Delta G''$ values are similarly additive.

• **5-12 Utilizing Additivity.** The additivity of thermodynamic parameters discussed in Problem 5-11 applies not just to sequential reactions in a pathway, but to *any* reactions or processes. Moreover, it applies to subtraction of reactions. Use this information to answer the following questions:

(a) The phosphorylation of glucose using inorganic phosphate (abbreviated P_i) is endergonic ($\Delta G^\circ' = +3.3 \text{ kcal/mol}$), whereas the dephosphorylation (hydrolysis) of ATP is exergonic ($\Delta G^\circ' = -7.3 \text{ kcal/mol}$):

Write a reaction for the phosphorylation of glucose by the transfer of a phosphate group from ATP, and calculate $\Delta G^\circ'$ for the reaction.

(b) Phosphocreatine is used by your muscle cells to store energy. The dephosphorylation of phosphocreatine (Reaction 5-40), like that of ATP, is a highly exergonic reaction with $\Delta G^\circ' = -10.3 \text{ kcal/mol}$:

Write a reaction for the transfer of phosphate from phosphocreatine to ADP to generate creatine and ATP, and calculate $\Delta G^\circ'$ for the reaction.

Enzymes: The Catalysts of Life

In Chapter 5, we encountered $\Delta G'$, the change in free energy, and saw its importance as an indicator of thermodynamic spontaneity. Specifically, the sign of $\Delta G'$ tells us whether a reaction is possible in the indicated direction, and the magnitude of $\Delta G'$ indicates how much energy will be released (or must be provided) as the reaction proceeds in that direction. At the same time, we were careful to note that, because it is a thermodynamic parameter, $\Delta G'$ tells us only whether a reaction can go but not about whether it actually will go. For that distinction, we need to know not just the direction and energetics of the reaction, but something about the reaction mechanism and its rate as well.

This brings us to the topic of **enzyme catalysis** because virtually all cellular reactions or processes are mediated by protein (or, in certain cases, RNA) catalysts called enzymes. The only reactions that occur at any appreciable rate in a cell are those for which the appropriate enzymes are present and active. Thus, enzymes almost always spell the difference between “can go” and “will go” for cellular reactions. It is only as we explore the nature of enzymes and their catalytic properties that we begin to understand how reactions that are energetically feasible actually take place in cells and how the rates of such reactions are controlled.

In this chapter, we will first consider why thermodynamically spontaneous reactions do not usually occur at appreciable rates without a catalyst. Then we will look at the role of enzymes as specific biological catalysts. We will also see how the rate of an enzyme-catalyzed reaction is affected by the concentration of available substrate, by the affinity of the enzyme for substrate, and by covalent modification of the enzyme itself. We will also see some of the ways in which reaction rates are regulated to meet the needs of the cell.

Activation Energy and the Metastable State

If you stop to think about it, you are already familiar with many reactions that are thermodynamically feasible yet do not occur to any appreciable extent. An obvious example from Chapter 5 is the oxidation of glucose (see Reaction 5-1). This reaction (or series of reactions, really) is highly exergonic ($\Delta G^\circ = -686$ kcal/mol) and yet does not take place on its own. In fact, glucose crystals or a glucose solution can be exposed to the oxygen in the air indefinitely, and little or no oxidation will occur. The cellulose in the paper these words are printed on is another example—and so, for that matter, are *you*, consisting as you do of a complex collection of thermodynamically unstable molecules.

Not nearly as familiar, but equally important to cellular chemistry, are the many thermodynamically feasible reactions in cells that could go but do not proceed at an appreciable rate on their own. As an example, consider the high-energy molecule adenosine triphosphate (ATP), which has a highly favorable ΔG° (-7.3 kcal/mol) for the hydrolysis of its terminal phosphate group to form the corresponding diphosphate (ADP) and inorganic phosphate (P_i):

This reaction is very exergonic under standard conditions and is even more so under the conditions that prevail in cells. Yet despite the highly favorable free energy change, this reaction occurs only slowly on its own, so that ATP remains stable for several days when dissolved in pure water. This property turns out to be shared by many biologically important molecules and reactions, and it is important to understand why.

Before a Chemical Reaction Can Occur, the Activation Energy Barrier Must Be Overcome

Molecules that could react with one another often do not because they lack sufficient energy. For every reaction, there is a specific **activation energy** (E_A), which is the minimum amount of energy that reactants must have before collisions between them will be successful in giving rise to products. More specifically, reactants need to reach an intermediate chemical stage called the **transition state**, which has a free energy higher than that of the initial reactants. **Figure 6-1a** shows the activation energy required for molecules of ATP and H₂O to reach their transition state. $\Delta G^\circ'$ measures the difference in free energy between reactants and products (−7.3 kcal/mol for this particular reaction), whereas E_A indicates the minimum energy required for the reactants to reach the transition state and hence to be capable of giving rise to products.

The actual rate of a reaction is always proportional to the fraction of molecules that have an energy content equal to or greater than E_A . When in solution at room temperature, molecules of ATP and water move about readily, each possessing a certain amount of energy at any instant. As Figure 6-1b shows, the energy distribution among molecules will be normally distributed around a mean value (a bell-shaped curve). Some molecules will have very little energy, some will have a lot, and most will be somewhere near the average. The important point is

that the only molecules that are capable of reacting at a given instant are those with enough energy to exceed the **activation energy barrier**, E_A (Figure 6-1b, dashed line).

The Metastable State Is a Result of the Activation Barrier

For most biologically important reactions at normal cellular temperatures, the activation energy is sufficiently high that the proportion of molecules possessing that much energy at any instant is extremely small. Accordingly, the rates of uncatalyzed reactions in cells are very low, and most molecules appear to be stable even though they are potential reactants in thermodynamically favorable reactions. They are, in other words, thermodynamically unstable, but they do not have enough energy to exceed the activation energy barrier.

Such seemingly stable molecules are said to be in a **metastable state**. For cells and cell biologists, high activation energies and the resulting metastable state of cellular constituents are crucial because life by its very nature is a system maintained in a steady state a long way from equilibrium. Were it not for the metastable state, all reactions would proceed quickly to equilibrium, and life as we know it would be impossible. Life, then, depends critically on the high activation energies that prevent most cellular reactions from occurring at appreciable rates in the absence of a suitable catalyst.

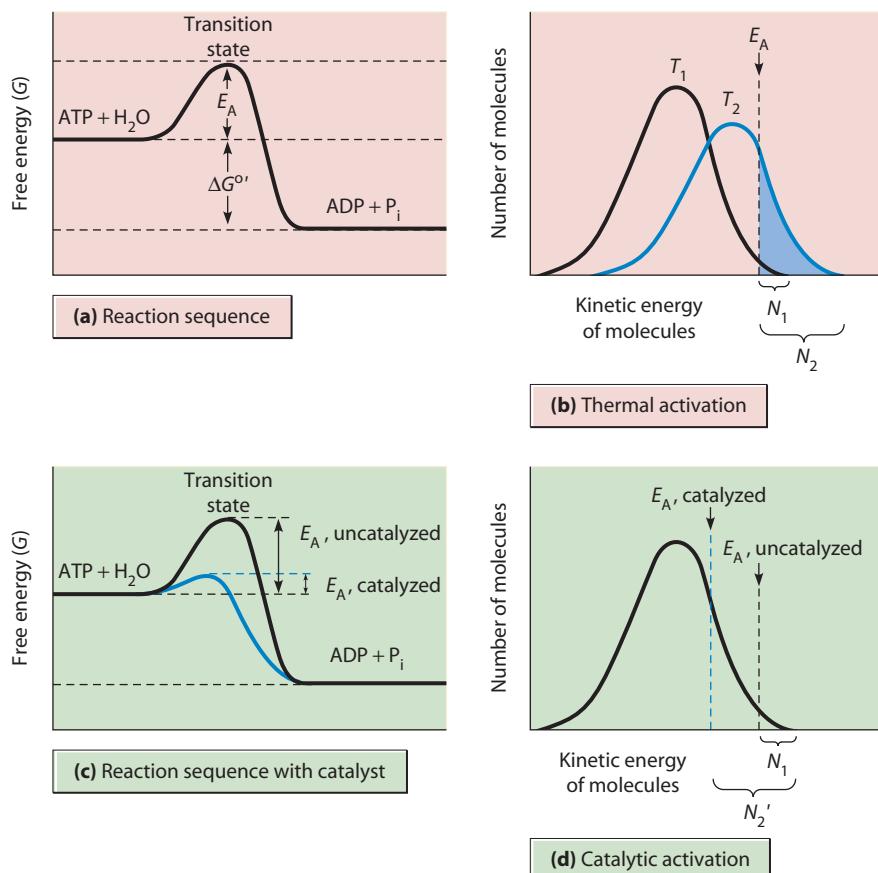

FIGURE 6-1 The Effect of Catalysis on Activation Energy and Number of Molecules Capable of Reaction. (a) The activation energy E_A is the amount of kinetic energy that reactant molecules (here, ATP and H₂O) must possess to reach the transition state leading to product formation. After reactants overcome the activation energy barrier and enter into a reaction, the products have less free energy by the amount $\Delta G^\circ'$. (b) The number of molecules N_1 that have sufficient energy to exceed the activation energy barrier (E_A) can be increased to N_2 by raising the temperature from T_1 to T_2 . (c) Alternatively, the activation energy can be lowered by a catalyst (blue line), thereby (d) increasing the number of molecules from N_1 to N_2' with no change in temperature.

An analogy might help you to understand and appreciate the metastable state. Imagine an egg in a bowl near the edge of a table—its static position represents the metastable state. Although energy would be released if the egg hit the floor, it cannot do so because the edge of the bowl acts as a barrier. A small amount of energy must be applied to lift it up out of the bowl and over the table edge. Then, a much greater amount of energy is released as the egg spontaneously drops to the floor and breaks.

Catalysts Overcome the Activation Energy Barrier

The activation energy requirement is a barrier that must be overcome if desirable reactions are to proceed at reasonable rates. Since the energy content of a given molecule must exceed E_A before that molecule is capable of undergoing reaction, the only way a reaction involving metastable reactants will proceed at an appreciable rate is to increase the proportion of molecules with sufficient energy. This can be achieved either by increasing the average energy content of all molecules or by lowering the activation energy requirement.

One way to increase the energy content of the system is by the input of heat. As Figure 6-1b illustrates, simply increasing the temperature of the system from T_1 to T_2 will increase the kinetic energy of the average molecule, thereby ensuring a greater number of reactive molecules (N_2 instead of N_1). Thus, the hydrolysis of ATP could be facilitated by heating the solution, giving each ATP and water molecule more energy. The problem with using an elevated temperature is that such an approach is not compatible with life because biological systems require a relatively constant temperature. Cells are basically *isothermal* (constant-temperature) systems and require isothermal methods to solve the activation problem.

The alternative to an increase in temperature is to lower the activation energy requirement, thereby ensuring that a greater proportion of molecules will have sufficient energy to collide successfully and undergo reaction. This would be like changing the shape of the bowl holding the egg described earlier into a shallow dish. Now, less energy is needed to lift the egg over the edge of the dish. If the reactants can be bound on some sort of surface in an arrangement that brings potentially reactive portions of adjacent molecules into close juxtaposition, their interaction will be greatly favored and the activation energy effectively reduced.

Providing such a reactive surface is the task of a **catalyst**—an agent that enhances the rate of a reaction by lowering the energy of activation (Figure 6-1c), thereby ensuring that a higher proportion of the molecules possess sufficient energy to undergo reaction without the input of heat (Figure 6-1d). A primary feature of a catalyst is that *it is not permanently changed or consumed as the reaction proceeds*. It simply provides a suitable surface and environment to facilitate the reaction.

Recent work suggests an additional mechanism to overcome the activation energy barrier. This mechanism is known as “quantum tunneling” and sounds like something from a science fiction novel. It is based in part on the realization that matter has both particle-like and wave-like properties. In certain dehydrogenation reactions, the enzyme is believed to allow a hydrogen atom to tunnel *through* the barrier, effectively ending up on the other side without actually going over the top. Unlike most enzyme-catalyzed reactions, these tunneling reactions are temperature independent because an input of thermal energy is not required to ascend the activation energy barrier.

For a specific example of catalysis, let’s consider the decomposition of hydrogen peroxide (H_2O_2) into water and oxygen:

This is a thermodynamically favorable reaction, yet hydrogen peroxide exists in a metastable state because of the high activation energy of the reaction. However, if we add a small number of ferric ions (Fe^{3+}) to a hydrogen peroxide solution, the decomposition reaction proceeds about 30,000 times faster than without the ferric ions. Clearly, Fe^{3+} is a catalyst for this reaction, lowering the activation energy (as shown in Figure 6-1c) and thereby ensuring that a significantly greater proportion (30,000-fold more) of the hydrogen peroxide molecules possess adequate energy to decompose at the existing temperature without the input of added energy.

In cells, the solution to hydrogen peroxide breakdown is not the addition of ferric ions but the enzyme *catalase*, an iron-containing protein. In the presence of catalase, the reaction proceeds about 100,000,000 times faster than the uncatalyzed reaction. Catalase contains iron atoms bound to the enzyme, thus taking advantage of inorganic catalysis within the context of a protein molecule. This combination is obviously a much more effective catalyst for hydrogen peroxide decomposition than ferric ions by themselves. The rate enhancement (catalyzed rate \div uncatalyzed rate) of about 10^8 for catalase is not at all an atypical value. The rate enhancements of enzyme-catalyzed reactions range from 10^7 to as high as 10^{17} compared with the uncatalyzed reaction. These values underscore the extraordinary importance of enzymes as catalysts and bring us to the main theme of this chapter.

Enzymes as Biological Catalysts

Regardless of their chemical nature, all catalysts share the following three basic properties:

1. A catalyst increases the rate of a reaction by lowering the activation energy requirement, thereby allowing a thermodynamically feasible reaction to occur at a reasonable rate in the absence of thermal activation.

2. A catalyst acts by forming transient, reversible complexes with substrate molecules, binding them in a manner that facilitates their interaction and stabilizes the intermediate transition state.
3. A catalyst changes only the *rate* at which equilibrium is achieved; it has no effect on the *position* of the equilibrium. This means that a catalyst can enhance the rate of exergonic reactions but cannot somehow change the $\Delta G'$ to allow an endergonic reaction to become spontaneous. Catalysts, in other words, are not thermodynamic wizards.

These properties are common to all catalysts, organic and inorganic alike. In terms of our example, they apply equally to ferric ions and to catalase molecules. However, biological systems rarely use inorganic catalysts. Instead, essentially all catalysis in cells is carried out by organic molecules (proteins, in most cases) called **enzymes**. Because enzymes are organic molecules, they are much more specific than inorganic catalysts, and their activities can be regulated much more carefully.

Most Enzymes Are Proteins

The capacity of cellular extracts to catalyze chemical reactions has been known since the fermentation studies of Eduard and Hans Buchner in 1897. In fact, one of the first terms for what we now call enzymes was *ferments*. However, it was not until 1926 that a specific enzyme, *urease*, was crystallized (from jack beans, by James B. Sumner) and shown to be a protein. This established the protein nature of enzymes and put to rest the belief that biochemical reactions in cells occurred via some unknown “vital force.” However, since the early 1980s, biologists have recognized that in addition to proteins, certain RNA molecules, known as *ribozymes*, also have catalytic activity. Ribozymes will be discussed in a later section. Here, we will consider enzymes as proteins—which, in fact, most are.

The Active Site. One of the most important concepts to emerge from our understanding of enzymes as proteins is the **active site**. Every enzyme contains a characteristic cluster of amino acids that form the active site where the substrates bind and the catalytic event occurs. Usually, the active site is an actual groove or pocket with chemical and structural properties that accommodate the intended substrate or substrates with high specificity. The active site consists of a small number of amino acids that are not necessarily adjacent to one another along the primary sequence of the protein. Instead, they are brought together in just the right arrangement by the specific three-dimensional folding of the polypeptide chain as it assumes its characteristic tertiary structure.

Figure 6-2 shows the unfolded and folded structures of the enzyme *lysozyme*, which hydrolyzes the peptido-

glycan polymer that makes up bacterial cell walls. The active site of lysozyme is a small groove in the enzyme surface into which the peptidoglycan fits. Lysozyme is a single polypeptide with 129 amino acid residues, but relatively few of these are directly involved in substrate binding and catalysis. Four of these are highlighted in Figure 6-2a. Substrate binding depends on amino acid residues from various positions along the polypeptide, including residues from positions 33–36, 46, 60–64, and 102–110. Catalysis involves two specific residues: a glutamate at position 35 (Glu-35) and an aspartic acid at position 52 (Asp-52). The acid side chain of Glu-35 donates an H⁺ to the bond about to be hydrolyzed, and Asp-52 stabilizes the transition state, enhancing cleavage of this bond by an OH⁻ ion from water. Only as the lysozyme molecule folds to attain its stable three-dimensional conformation are these specific amino acids brought together to form the active site (Figure 6-2b).

Of the 20 different amino acids that make up proteins, only a few are actually involved in the active sites of the many proteins that have been studied. Often, these are cysteine, histidine, serine, aspartate, glutamate, and lysine. All of these residues can participate in binding the substrate to the active site during catalysis, and several also serve as donors or acceptors of protons.

Some enzymes contain specific nonprotein cofactors that are located at the active site and are indispensable for catalytic activity. These cofactors, also called **prosthetic groups**, are usually either metal ions or small organic molecules known as *coenzymes* that are derivatives of vitamins. Frequently, prosthetic groups (especially positively charged metal ions) function as electron acceptors because none of the amino acid side chains are good electron acceptors.

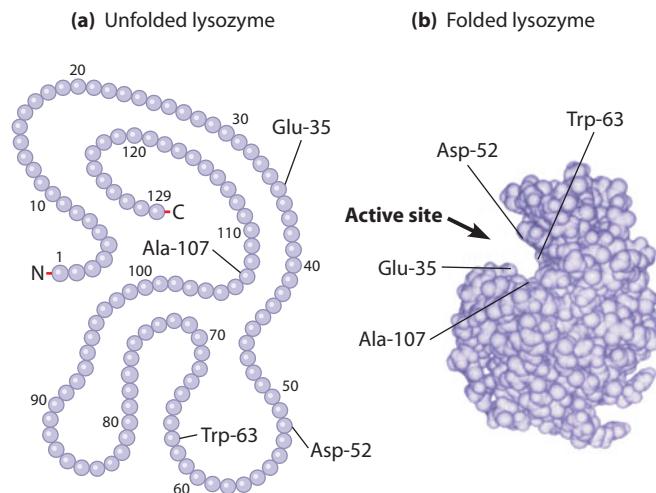

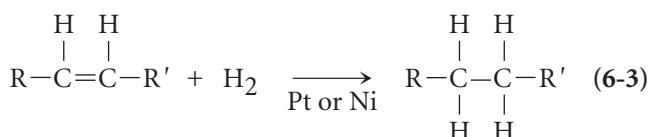

FIGURE 6-2 The Active Site of Lysozyme. (a) Four amino acid residues that are important for substrate binding and catalysis are far apart in the primary structure of unfolded lysozyme. (b) These residues are brought together to form part of the active site as lysozyme folds into its active tertiary structure.

Where present, prosthetic groups often are located at the active site and are indispensable for the catalytic activity of the enzyme. For example, each catalase enzyme molecule contains a multiring structure known as a *porphyrin* ring, to which an iron atom necessary for catalysis is bound (see Figure 10-13).

The requirement for various prosthetic groups on some enzymes explains our nutritional requirements for trace amounts of vitamins and certain metals. As we will see in Chapters 9 and 10, oxidation of glucose for energy requires two specific coenzymes that are derivatives of the vitamins niacin and riboflavin. Both niacin and riboflavin are essential nutrients in the human diet because our cells cannot synthesize them. These coenzymes, which are bound to the active site of certain enzymes, accept electrons and hydrogen ions from glucose as it is oxidized. Likewise, carboxypeptidase A, a digestive enzyme that degrades proteins, requires a single zinc atom bound to the active site, as we will see later in the chapter. Other enzymes may require atoms of iron, copper, molybdenum, or even lithium. Like enzymes, prosthetic groups are not consumed during chemical reactions, so cells require only minute, catalytic amounts of them.

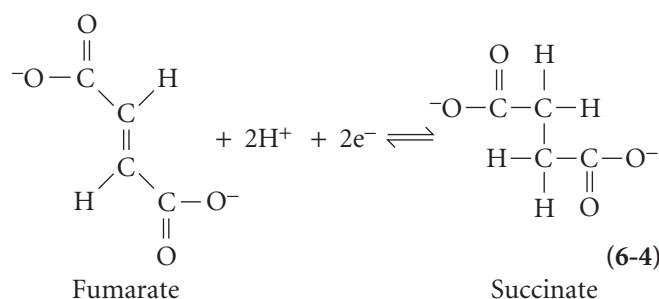

Enzyme Specificity. Due to the structure of the active site, enzymes display a very high degree of **substrate specificity**, which is the ability to discriminate between very similar molecules. Specificity is one of the most characteristic properties of living systems, and enzymes are excellent examples of biological specificity.

We can illustrate their specificity by comparing enzymes with inorganic catalysts. Most inorganic catalysts are quite nonspecific in that they will act on a variety of compounds that share some general chemical feature. Consider, for example, the *hydrogenation* of (addition of hydrogen to) an unsaturated C=C bond:

This reaction can be carried out in the laboratory using a platinum (Pt) or nickel (Ni) catalyst, as indicated. These inorganic catalysts are very nonspecific, however; they can catalyze the hydrogenation of a wide variety of unsaturated compounds. In practice, nickel and platinum are used commercially to hydrogenate polyunsaturated vegetable oils in the manufacture of solid cooking fats or shortenings. Regardless of the exact structure of the unsaturated compound, it can be effectively hydrogenated in the presence of nickel or platinum. This lack of specificity of inorganic catalysts during hydrogenation is responsible for the formation of certain *trans* fats (see Chapter 7) that are rare in nature.

In contrast, consider the biological example of hydrogenation as fumarate is converted to succinate, a reaction we will encounter again in Chapter 10:

This particular reaction is catalyzed in cells by the enzyme *succinate dehydrogenase* (so named because it normally functions in the opposite direction during energy metabolism). This dehydrogenase, like most enzymes, is highly specific. It will not add or remove hydrogen atoms from any compounds except those shown in Reaction 6-4. In fact, this particular enzyme is so specific that it will not even recognize maleate, which is an isomer of fumarate (**Figure 6-3**).

Not all enzymes are quite that specific. Some accept a number of closely related substrates, and others accept any of a whole group of substrates as long as they possess some common structural feature. Such **group specificity** is seen most often with enzymes involved in the synthesis or degradation of polymers. Since the purpose of carboxypeptidase A is to degrade dietary polypeptide chains by removing the C-terminal amino acid, it makes sense for the enzyme to accept any of a wide variety of polypeptides as substrates. It would be needlessly extravagant of the cell to require a separate enzyme for every different amino acid residue that has to be removed during polypeptide degradation.

In general, however, enzymes are highly specific with respect to substrate, such that a cell must possess almost as many different kinds of enzymes as it has reactions to catalyze. For a typical cell, this means that thousands of different enzymes are necessary to carry out its full metabolic

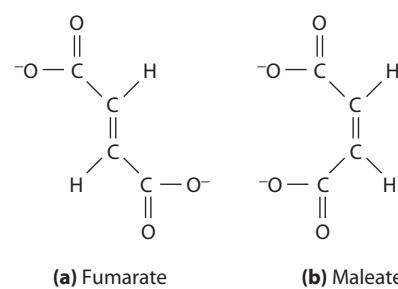

FIGURE 6-3 Specificity in Enzyme-Catalyzed Reactions.

Unlike most inorganic catalysts, enzymes can distinguish between closely related isomers. For example, the enzyme succinate dehydrogenase uses (a) fumarate as a substrate but not (b) its isomer, maleate.

program. At first, that may seem wasteful in terms of proteins to be synthesized, genetic information to be stored and read out, and enzyme molecules to have on hand in the cell. But you should also be able to see the tremendous regulatory possibilities this suggests—a point we will return to later.

Enzyme Diversity and Nomenclature. Given the specificity of enzymes and the large number of reactions occurring within a cell, it is not surprising that thousands of different enzymes have been identified. This enormous diversity of enzymes led to a variety of schemes for naming enzymes as they were discovered and characterized. Some were given names based on the substrate; *ribonuclease*, *protease*, and *amylase* are examples. Others, such as *succinate dehydrogenase*, were named to describe their function. Still other enzymes have names like *trypsin* and *catalase* that tell us little about either their substrates or their functions.

The resulting confusion prompted the International Union of Biochemistry to appoint an Enzyme Commission (EC) to devise a rational system for naming enzymes. Using the EC system, enzymes are divided into the following six major classes based on their general functions: *oxidoreductases*, *transferases*, *hydrolases*, *lyases*, *isomerases*, and *ligases*. The EC system assigns every known enzyme a unique four-part number based on its function—for example, EC 3.2.1.17 is the number for lysozyme. **Table 6-1** provides one representative example of each class of enzymes and the reaction it catalyzes.

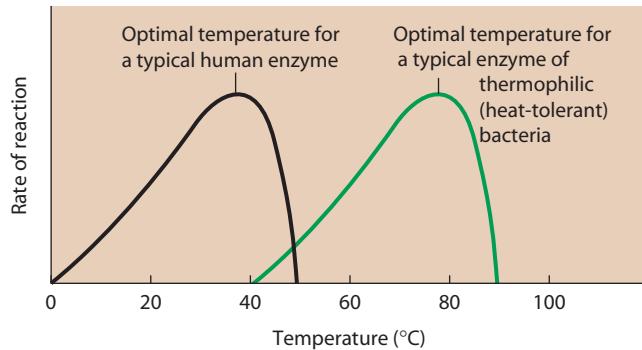

Sensitivity to Temperature. Besides their specificity and diversity, enzymes are characterized by their sensitivity to temperature. This temperature dependence is not usually a practical concern for enzymes in the cells of mammals or birds because these organisms are *homeotherms*, “warm-blooded” organisms that are capable of regulating body temperature independent of the environment. However, many organisms (e.g., insects, reptiles, worms, plants, protozoa, algae, and bacteria) function at the temperature of their environment, which can vary greatly. For these organisms, the dependence of enzyme activity on temperature is significant.

At low temperatures, the rate of an enzyme-catalyzed reaction increases with temperature. This occurs because the greater kinetic energy of both enzyme and substrate molecules ensures more frequent collisions, thereby increasing the likelihood of correct substrate binding and sufficient energy to undergo reaction. At some point, however, further increases in temperature result in *denaturation* of the enzyme molecule. It loses its defined tertiary shape as hydrogen and ionic bonds are broken and the native polypeptide assumes a random, extended conformation. During denaturation, the structural integrity of the active site is destroyed, causing a loss of enzyme activity.

The temperature range over which an enzyme denatures varies from enzyme to enzyme and especially from

organism to organism. **Figure 6-4a** contrasts the temperature dependence of a typical enzyme from the human body with that of a typical enzyme from a thermophilic bacterium. Not surprisingly, the reaction rate of the human enzyme is maximum at about 37°C (the *optimal temperature* for the enzyme), which is normal body temperature. The sharp decrease in activity at higher temperatures reflects the denaturation of the enzyme molecules. Most enzymes of homeotherms are inactivated by temperatures above about 50–55°C. However, some enzymes are remarkably sensitive to heat. They are denatured and inactivated at temperatures lower than this—in some cases, even by body temperatures encountered in people with high fevers (40°C). This is thought to be part of the beneficial effect of

(a) Temperature dependence. This panel shows how reaction rate varies with temperature for a typical human enzyme (black) and a typical enzyme from a thermophilic bacterium (green). The reaction rate is highest at the optimal temperature, which is about 37°C (body temperature) for the human enzyme and about 75°C (the temperature of a typical hot spring) for the bacterial enzyme. Above the optimal temperature, the enzyme is rapidly inactivated by denaturation.

(b) pH dependence. This panel shows how reaction rate varies with pH for the gastric enzyme pepsin (black) and the intestinal enzyme trypsin (red). The reaction rate is highest at the optimal pH, which is about 2.0 for pepsin (stomach pH) and near 8.0 for trypsin (intestinal pH). At the pH optimum for an enzyme, ionizable groups on both the enzyme and the substrate molecules are in the most favorable form for reactivity.

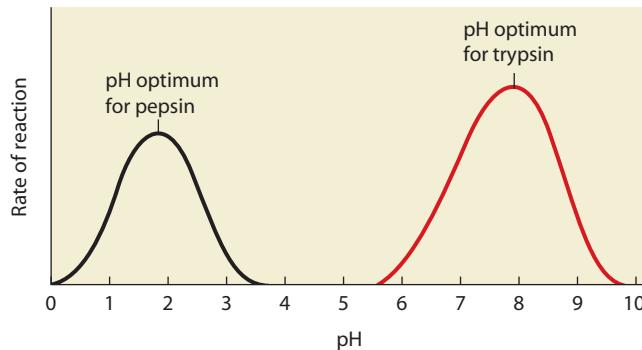

FIGURE 6-4 The Effect of Temperature and pH on the Reaction Rate of Enzyme-Catalyzed Reactions. Every enzyme has an optimum temperature and pH that usually reflect the environment where that enzyme is found in nature.

Table 6-1 The Major Classes of Enzymes with an Example of Each

Class	Reaction Type	Enzyme Name	Example	Reaction Catalyzed
1. Oxidoreductases	Oxidation-reduction reactions	Alcohol dehydrogenase (oxidation with NAD ⁺)	$\text{CH}_3\text{—CH}_2\text{—OH} \xrightarrow[\text{Ethanol}]{\text{NAD}^+ \text{ reduced}} \text{CH}_3\text{—C}(=\text{O})\text{—H}$	NAD ⁺ NADH + H ⁺ Acetaldehyde
2. Transferases	Transfer of functional groups from one molecule to another	Glycerokinase (phosphorylation)	$\text{HO—CH}_2\text{—CH(OH)—CH}_2\text{—OH} \xrightarrow[\text{Glycerol}]{\text{ATP} \text{ reduced}} \text{HO—CH}_2\text{—CH(OH)—CH}_2\text{—O—PO}_3^{2-}$	ADP Glycerol phosphate
3. Hydrolases	Hydrolytic cleavage of one molecule into two molecules	Carboxypeptidase A (peptide bond cleavage)	$\text{—NH—CH(}\overset{\text{R}_{n-1}}{\underset{\text{O}}{\text{ }}\text{)C—NH—CH(}\overset{\text{R}_n}{\underset{\text{O}}{\text{ }}\text{)C—O}^- \xrightarrow[\text{C-terminus of polypeptide}]{\text{H}_2\text{O}} \text{—NH—CH(}\overset{\text{R}_{n-1}}{\underset{\text{O}}{\text{ }}\text{)C—O}^- + \text{H}_3\text{N}^+—\text{CH(}\overset{\text{R}_n}{\underset{\text{O}}{\text{ }}\text{)C—O}^-$	Shortened polypeptide C-terminal amino acid
4. Lyases	Removal of a group from, or addition of a group to, a molecule with rearrangement of electrons	Pyruvate decarboxylase (decarboxylation)	$\text{CH}_3\text{—C}(=\text{O})\text{—C}(=\text{O})\text{—O}^- + \text{H}^+ \longrightarrow \text{CH}_3\text{—C}(=\text{O})\text{—H} + \text{CO}_2$	Pyruvate Acetaldehyde
5. Isomerases	Movement of a functional group within a molecule	Maleate isomerase (<i>cis-trans</i> isomerization)	$\begin{array}{ccc} \text{—O—C} & & \text{—O—C} \\ & \diagdown & \diagup \\ & \text{C} = \text{C} & \\ & \diagup & \diagdown \\ \text{—O—C} & & \text{—C} = \text{C} \end{array} \rightleftharpoons \begin{array}{ccc} \text{—O—C} & & \text{—O—C} \\ & \diagup & \diagdown \\ & \text{C} = \text{C} & \\ & \diagdown & \diagup \\ \text{—O—C} & & \text{—C} = \text{C} \end{array}$	Maleate Fumarate
6. Ligases	Joining of two molecules to form a single molecule	Pyruvate carboxylase (carboxylation)	$\text{CH}_3\text{—C}(=\text{O})\text{—C}(=\text{O})\text{—O}^- + \text{CO}_2 \xrightarrow[\text{Pyruvate}]{\text{ATP} \text{ reduced}} \text{—O—C}(=\text{O})\text{—CH}_2\text{—C}(=\text{O})\text{—O}^-$	Oxaloacetate

fever when you are ill—the denaturation of heat-sensitive pathogen enzymes.

Some enzymes, however, retain activity at unusually high temperatures. The green curve in Figure 6-4a depicts the temperature dependence of an enzyme from one of the thermophilic archaea mentioned in Chapter 4. Some of these organisms thrive in acidic hot springs at temperatures as high as 80°C, with optimal temperatures close to the boiling point of water, and others live in deep-sea hydrothermal vents at temperatures over 100°C. Other enzymes, such as those of cryophilic (“cold-loving”) *Listeria* bacteria and certain yeasts and molds, can function at low temperatures, allowing these organisms to grow slowly even at refrigerator temperatures (4–6°C).

Sensitivity to pH. Enzymes are also sensitive to pH. In fact, most of them are active only within a pH range of about 3–4 pH units. This pH dependence is usually due to the presence of one or more charged amino acids at the active site and/or on the substrate itself. Activity is usually dependent on having such groups present in a specific, either charged or uncharged form. For example, the active site of carboxypeptidase A includes the carboxyl groups from two glutamate residues. These carboxyl groups must be present in the charged (ionized) form, so the enzyme becomes inactive if the pH is decreased to the point where the glutamate carboxyl groups on the enzyme molecules are protonated and therefore uncharged. Extreme changes in pH also disrupt ionic and hydrogen bonds, altering tertiary structure and function.

As you might expect, the pH dependence of an enzyme usually reflects the environment in which that enzyme is normally active. Figure 6-4b shows the pH dependence of two protein-degrading enzymes found in the human digestive tract. Pepsin (black line) is present in the stomach, where the pH is usually about 2, whereas trypsin (red line) is secreted into the small intestine, which has a pH between 7 and 8. Both enzymes are active over a range of almost 4 pH units but differ greatly in their pH optima, consistent with the conditions in their respective locations within the body.

Sensitivity to Other Factors. In addition to temperature and pH, enzymes are sensitive to other factors, including molecules and ions that act as inhibitors or activators of the enzyme. For example, several enzymes involved in energy production via glucose degradation are inhibited by ATP, which inactivates them when energy is plentiful. Other enzymes in glucose breakdown are activated by adenosine monophosphate (AMP) and ADP, which act as signals that energy supplies are low and more glucose should be degraded.

Most enzymes are also sensitive to the ionic strength (concentration of dissolved ions) of the environment, which affects the hydrogen bonding and ionic interactions that help to maintain the tertiary conformation of the enzyme. Because these same interactions are often involved in the interaction between the substrate and the active site, the ionic environment may also affect binding

of the substrate. Several magnesium-requiring chloroplast enzymes required for photosynthetic carbon fixation are active only in the presence of the high levels of magnesium ions that occur when leaves are illuminated.

Substrate Binding, Activation, and Catalysis Occur at the Active Site

Because of the precise chemical fit between the active site of an enzyme and its substrates, enzymes are highly specific and much more effective than inorganic catalysts. As we noted previously, enzyme-catalyzed reactions proceed 10^7 to 10^{17} times more quickly than uncatalyzed reactions do, versus a rate increase of 10^3 to 10^4 times for inorganic catalysts. As you might guess, most of the interest in enzymes focuses on the active site, where binding, activation, and chemical transformation of the substrate occur.

Substrate Binding. Initial contact between the active site of an enzyme and a potential substrate molecule depends on their collision. Once in the active site, the substrate molecules are bound to the enzyme surface in just the right orientation so that specific catalytic groups on the enzyme can facilitate the reaction. Substrate binding usually involves hydrogen bonds or ionic bonds (or both) to charged or polar amino acids. These are generally weak bonds, but several bonds may hold a single molecule in place. The strength of the bonds between an enzyme and a substrate molecule is often in the range of 3–12 kcal/mol. This is less than one-tenth the strength of a single covalent bond (see Figure 2-2). Substrate binding is therefore readily reversible.

For many years, enzymologists regarded an enzyme as a rigid structure, with a specific substrate fitting into the active site like a key fits into a lock. This *lock-and-key model*, first suggested in 1894 by the German biochemist Emil Fischer, explained enzyme specificity but did little to enhance our understanding of the catalytic event. A more refined view of the enzyme-substrate interaction is provided by the **induced-fit model**, first proposed in 1958 by Daniel Koshland. According to this model, substrate binding at the active site distorts both the enzyme and the substrate, thereby stabilizing the substrate molecules in their transition state and rendering certain substrate bonds more susceptible to catalytic attack. In the case of lysozyme, substrate binding induces a conformational change in the enzyme that distorts the peptidoglycan substrate and weakens the bond about to be broken in the reaction.

As shown in **Figure 6-5**, induced fit involves a conformational change in the shape of the enzyme molecule following substrate binding. This alters the configuration of the active site and positions the proper reactive groups of the enzyme optimally for the catalytic reaction. Evidence of such conformational changes upon binding of substrate has come from X-ray diffraction studies of crystallized proteins and nuclear magnetic resonance (NMR) studies of proteins in solution, which can determine the shape of an enzyme molecule with and without bound substrate. Figure 6-5 illustrates the conformational change that

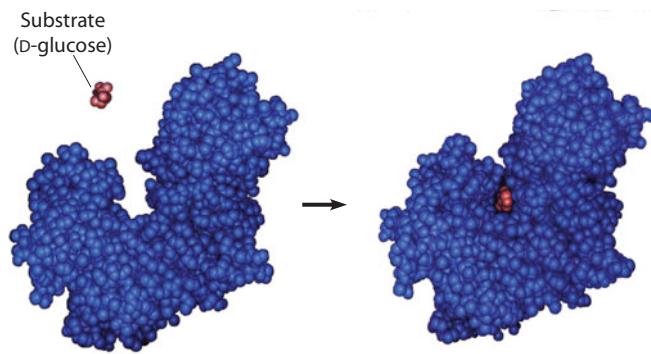

FIGURE 6-5 The Conformational Change in Enzyme Structure Induced by Substrate Binding. This figure shows a space-filling model for the enzyme hexokinase along with its substrate, a molecule of D-glucose. Substrate binding induces a conformational change in hexokinase, known as induced fit, that improves the catalytic activity of the enzyme.

 [VIDEOS www.thecellplace.com](http://www.thecellplace.com) Closure of hexokinase via induced fit

occurs upon substrate binding to hexokinase, which adds a phosphate group to D-glucose. As glucose binds to the active site, the two domains of hexokinase fold toward each other, closing the binding site cleft about the substrate to facilitate catalysis.

Often, the induced conformational change brings critical amino acid side chains into the active site even if they are not nearby in the absence of substrate. In the active site of carboxypeptidase A (**Figure 6-6**), a zinc ion is tightly bound to three residues of the enzyme (Glu-72, His-69, and His-196) and also loosely binds a water molecule (not shown). Substrate binding to the zinc ion replaces the bound water molecule and induces a conformational change in the enzyme that brings other amino

acid side chains into the active site, including Arg-145, Tyr-248, and Glu-270. These amino acid residues are then in position to participate in catalysis.

Substrate Activation. The role of the active site is not just to recognize and bind the appropriate substrate but also to *activate* it by subjecting it to the right chemical environment for catalysis. A given enzyme-catalyzed reaction may involve one or more means of **substrate activation**. Three of the most common mechanisms are as follows:

1. **Bond distortion.** The change in enzyme conformation induced by initial substrate binding to the active site not only causes better complementarity and a tighter enzyme-substrate fit but also distorts one or more of its bonds, thereby weakening the bond and making it more susceptible to catalytic attack.
2. **Proton transfer.** The enzyme may also accept or donate protons, thereby increasing the chemical reactivity of the substrate. This accounts for the importance of charged amino acids in active-site chemistry, which in turn explains why enzyme activity is so often pH dependent.
3. **Electron transfer.** As a further means of substrate activation, enzymes may also accept or donate electrons, thereby forming temporary covalent bonds between the enzyme and its substrate.

The Catalytic Event. The sequence of events at the active site is illustrated in **Figure 6-7**, using the enzyme sucrase as an example. Sucrase (also known as invertase or β -fructofuranosidase) hydrolyzes the disaccharide sucrose

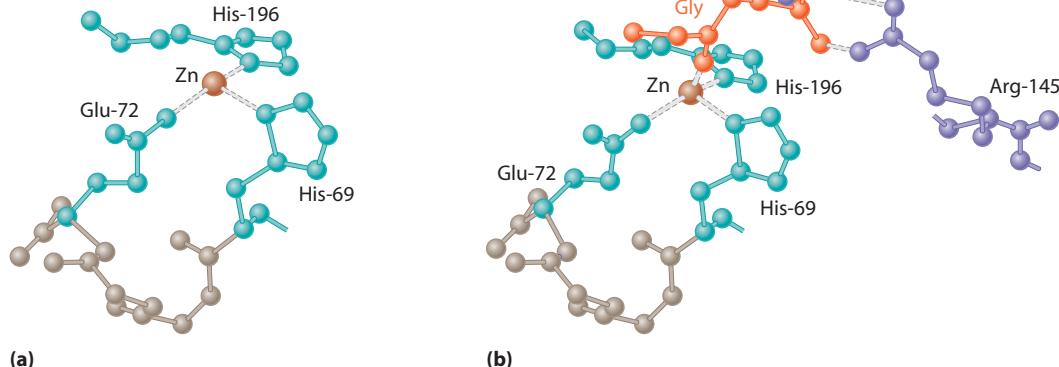

FIGURE 6-6 The Change in Active Site Structure Induced by Substrate Binding. (a) The unoccupied active site of carboxypeptidase A contains a zinc ion tightly bound to side chains of three amino acids (cyan). (b) Binding of the substrate (the dipeptide shown in orange) to this zinc ion induces a conformation change in the enzyme that brings other amino acid side chains (purple) into the active site to participate in catalysis.

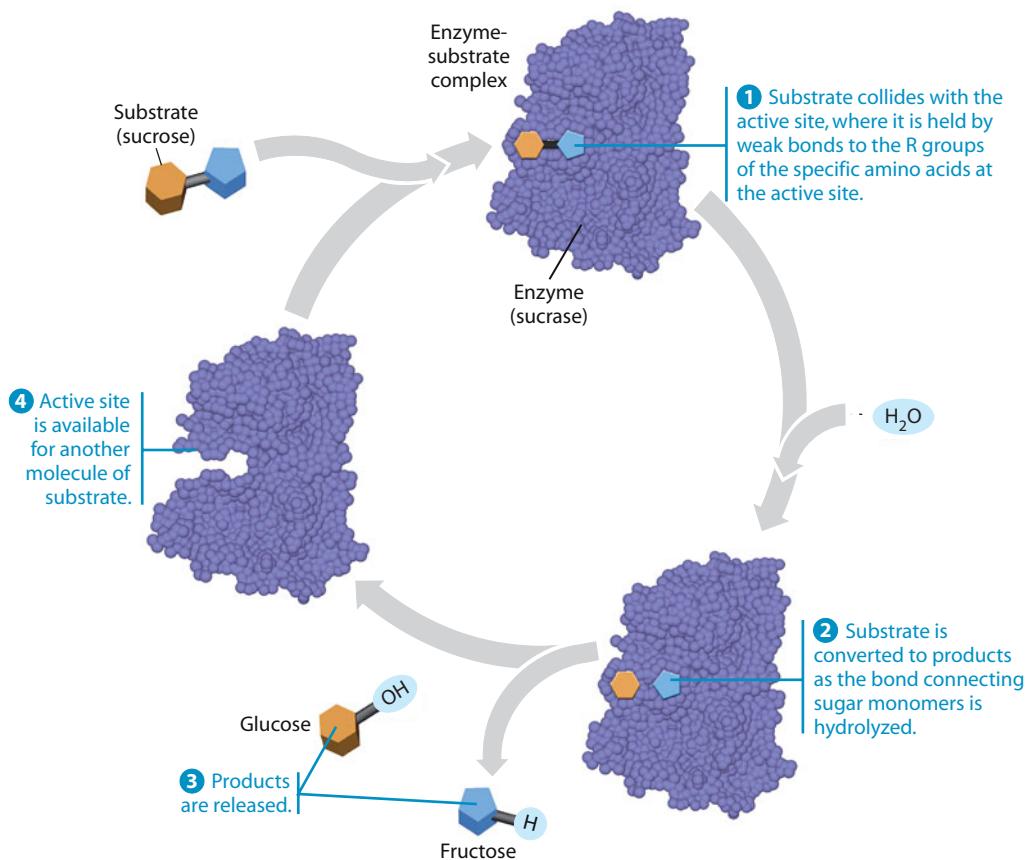

FIGURE 6-7 The Catalytic Cycle of an Enzyme. In this example, the enzyme sucrase catalyzes the hydrolysis of sucrose to glucose and fructose. The actual structure of this enzyme is shown, but the active site has been modified slightly to emphasize the close fit between enzyme and substrate.

[ACTIVITIES www.thecellplace.com](http://www.thecellplace.com) How enzymes work

into glucose and fructose. The initial random collision of a substrate molecule—sucrose, in this case—with the active site results in its binding to amino acid residues that are strategically positioned there (step ①). Substrate binding induces a change in the enzyme conformation that tightens the fit between the substrate molecule and the active site and lowers the free energy of the transition state. This facilitates the conversion of substrate into products—glucose and fructose, in this case (step ②). The products are then released from the active site (step ③), enabling the enzyme molecule to return to its original conformation, with the active site now available for another molecule of substrate (step ④). This entire sequence of events takes place in a sufficiently short time to allow hundreds or even thousands of such reactions to occur per second at the active site of a single enzyme molecule!

Enzyme Kinetics

So far, our discussion of enzymes has been basically descriptive. We have dealt with the activation energy requirement that prevents thermodynamically feasible reactions from occurring and with catalysts as a means of reducing the activation energy and thereby facilitating such reactions.

We have also encountered enzymes as biological catalysts and have examined their structure and function in some detail. Moreover, we realize that the only reactions likely to occur in cells at reasonable rates are those for which specific enzymes are on hand, such that the metabolic capability of a cell is effectively specified by the enzymes that are present.

Still lacking, however, is a means of assessing the actual rates at which enzyme-catalyzed reactions will proceed, as well as an appreciation for the factors that influence reaction rates. The mere presence of the appropriate enzyme in a cell does not ensure that a given reaction will occur at an adequate rate. We need to understand the cellular conditions that are favorable for activity of a particular enzyme. We have already seen how factors such as temperature and pH can affect enzyme activity. Now we are ready to appreciate how critically enzyme activity also depends on the concentrations of substrates, products, and inhibitors that prevail in the cell. In addition, we will see how at least some of these effects can be defined quantitatively.

We will begin with an overview of **enzyme kinetics**, which describes quantitative aspects of enzyme catalysis (the word *kinetics* is from the Greek word *kinetikos*, meaning “moving”) and the rate of substrate conversion into

products. Specifically, enzyme kinetics concerns reaction rates and the manner in which reaction rates are influenced by a variety of factors, including the concentrations of substrates, products, and inhibitors. Most of our attention here will focus on the effects of substrate concentration on the kinetics of enzyme-catalyzed reactions.

We will focus on *initial reaction rates*, the rates of reactions measured over a brief initial period of time during which the substrate concentration has not yet decreased enough to affect the rate of the reaction and the accumulation of product is still too small for the reverse reaction (conversion of product back into substrate) to occur at a significant rate. This resembles the steady-state situation in living cells, where substrates are continually replenished and products are continually removed, maintaining stable concentrations of each. Although this description is somewhat oversimplified compared to the situation in living cells, it nonetheless allows us to understand some important principles of enzyme kinetics.

Enzyme kinetics can seem quite complex at first. To help you understand the basic concepts, **Box 6A** explains how enzymes acting on substrate molecules can be compared to a roomful of monkeys shelling peanuts. You may find it useful to turn to the analogy at this point and then come back to this section.

Most Enzymes Display Michaelis–Menten Kinetics

Here we will consider how the **initial reaction velocity (v)** changes depending on the **substrate concentration ([S])**. The initial reaction velocity is rigorously defined as the rate of change in product concentration per unit time (e.g., mM/min). Often, however, reaction velocities are experimentally measured in a constant assay volume of 1 mL and are reported as μmol of product per minute. At low [S], a doubling of [S] will double v . But as [S] increases, each additional increment of substrate results in a smaller increase in reaction rate. As [S] becomes very large, increases in [S] increase only slightly, and the value of v reaches a maximum.

By determining v in a series of experiments at varying substrate concentrations, the dependence of v on [S] can be shown experimentally to be that of a hyperbola (Figure 6-8). An important property of this hyperbolic relationship is that as [S] tends toward infinity, v approaches an upper limiting value known as the **maximum velocity (V_{\max})**. This value depends on the number of enzyme molecules and can therefore be increased only by adding more enzyme. The inability of increasingly higher substrate concentrations to increase the reaction velocity beyond a finite upper value is called **saturation**. At saturation, all available enzyme molecules are operating at maximum capacity. Saturation is a fundamental, universal property of enzyme-catalyzed reactions. Catalyzed reactions always become saturated at high substrate concentrations, whereas uncatalyzed reactions do not.

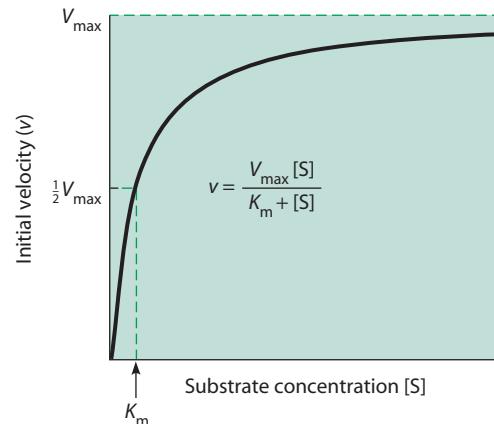

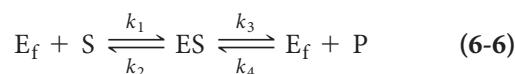

FIGURE 6-8 The Relationship Between Reaction Velocity and Substrate Concentration. For an enzyme-catalyzed reaction that follows Michaelis–Menten kinetics, the initial velocity tends toward an upper limiting velocity V_{\max} as the substrate concentration [S] tends toward infinity. The Michaelis constant K_m corresponds to that substrate concentration at which the reaction is proceeding at one-half of the maximum velocity.

Much of our understanding of the hyperbolic relationship between [S] and v is due to the pioneering work of two German enzymologists, Leonor Michaelis and Maud Menten. In 1913, they postulated a general theory of enzyme action that has turned out to be basic to the quantitative analysis of almost all aspects of enzyme kinetics. To understand their approach, consider one of the simplest possible enzyme-catalyzed reactions, a reaction in which a single substrate S is converted into a single product P:

According to the Michaelis–Menten hypothesis, the enzyme E that catalyzes this reaction first reacts with the substrate S, forming the transient enzyme-substrate complex ES, which then undergoes the actual catalytic reaction to form free enzyme and product P, as shown in the sequence

where E_f is the free form of the enzyme, S is the substrate, ES is the enzyme-substrate complex, P is the product, and k_1 , k_2 , k_3 , and k_4 are the rate constants for the indicated reactions.

Starting with this model and several simplifying assumptions, including the steady-state conditions we described near the end of Chapter 5, Michaelis and Menten arrived at the relationship between the velocity of an enzyme-catalyzed reaction and the substrate concentration, as follows:

$$v = \frac{V_{\max}[S]}{K_m + [S]} \quad (6-7)$$

Monkeys and Peanuts

If you found the Mexican jumping beans helpful in understanding free energy in Chapter 5, you might appreciate an approach to enzyme kinetics based on the analogy of a roomful of monkeys (“enzymes”) shelling peanuts (“substrates”), with the peanuts present in varying abundance. Try to understand each step first in terms of monkeys shelling peanuts and then in terms of an actual enzyme-catalyzed reaction.

The Peanut Gallery

For our model, we need a troop of ten monkeys, all equally adept at finding and shelling peanuts. We shall assume that the monkeys are too full to eat any of the peanuts they shell but nonetheless have an irresistible compulsion to go on shelling.

Next, we need the Peanut Gallery, a room of fixed floor space with peanuts scattered equally about on the floor. The number of peanuts will be varied as we proceed, but in all cases there will be vastly more peanuts than monkeys in the room. Moreover, because we know the number of peanuts and the total floor space, we can always calculate the “concentration” (more accurately, the density) of peanuts in the room. In each case, the monkeys start out in an adjacent room. To start an assay, we simply open the door and allow the eager monkeys to enter the Peanut Gallery.

The Shelling Begins

Now we are ready for our first assay. We start with an initial peanut concentration of 1 peanut per square meter, and we assume that, at this concentration of peanuts, the average monkey spends 9 seconds looking for a peanut to shell and 1 second shelling it. This means that each monkey requires 10 seconds per peanut and can thus shell peanuts at the rate of 0.1 peanut per second. Then, since there are ten monkeys in the gallery, the rate (let’s call it the velocity v) of peanut-shelling for all the monkeys is 1 peanut per second at this particular concentration of peanuts (which we will call $[S]$ to remind ourselves that the peanuts are really the substrate of the shelling action). All of this can be tabulated as follows:

$[S]$ = Concentration of peanuts (peanuts/m ²)	1
Time required per peanut:	
To find (sec/peanut)	9
To shell (sec/peanut)	1
Total (sec/peanut)	10
Rate of shelling:	
Per monkey (peanut/sec)	0.10
Total (v) (peanut/sec)	1.0

The Peanuts Become More Abundant

For our second assay, we herd all the monkeys back into the waiting room, sweep up the debris, and arrange peanuts about the Peanut Gallery at a concentration of 3 peanuts per square meter. Since peanuts are now three times more abundant than previously, the average monkey should find a peanut three times more quickly than before, such that the time spent finding the average peanut is now only 3 seconds. But each peanut, once found, still takes 1

second to shell, so the total time per peanut is now 4 seconds and the velocity of shelling is 0.25 peanut per second for each monkey, or 2.5 peanuts per second for the roomful of monkeys. This generates another column of entries for our data table:

$[S]$ = Concentration of peanuts (peanuts/m ²)	1	3
Time required per peanut:		
To find (sec/peanut)	9	3
To shell (sec/peanut)	1	1
Total (sec/peanut)	10	4
Rate of shelling:		
Per monkey (peanut/sec)	0.10	0.25
Total (v) (peanut/sec)	1.0	2.5

What Happens to v as $[S]$ Continues to Increase?

To find out what eventually happens to the velocity of peanut-shelling as the peanut concentration in the room gets higher and higher, all you need do is extend the data table by assuming ever-increasing values for $[S]$ and calculating the corresponding v . For example, you should be able to convince yourself that a further tripling of the peanut concentration (from 3 to 9 peanuts/m²) will bring the time required per peanut down to 2 seconds (1 second to find and another second to shell), which will result in a shelling rate of 0.5 peanut per second for each monkey, or 5.0 peanuts per second overall.

Already you should begin to see a trend. The first tripling of peanut concentration increased the rate 2.5-fold, but the next tripling resulted in only a further doubling of the rate. There seems, in other words, to be a diminishing return on additional peanuts. You can see this clearly if you choose a few more peanut concentrations and then plot v on the y-axis (suggested scale: 0–10 peanuts/sec) versus $[S]$ on the x-axis (suggested scale: 0–100 peanuts/m²).

What you should find is that the data generate a hyperbolic curve that looks strikingly like Figure 6-8. If you look at your data carefully, you should also see the reason your curve continues to “bend over” as $[S]$ gets higher (i.e., why you get less and less additional velocity for each further increment of peanuts): The shelling time is fixed and therefore becomes a more and more prominent component of the total processing time per peanut as the finding time gets smaller and smaller. You should also appreciate that it is this fixed shelling time that ultimately sets the upper limit on the overall rate of peanut processing because, even when $[S]$ is infinite (i.e., in a world flooded with peanuts), there will still be a finite time of 1 second required to process each peanut. This means that the overall maximum velocity, V_{max} , for the ten monkeys would be 10 peanuts per second.

Finally, you should realize that there is something special about the peanut concentration at which the finding time is exactly equal to the shelling time (it turns out to be 9 peanuts/m²); this is the point along the curve at which the rate of peanut processing is exactly one-half of the maximum rate. In fact, it is such an important benchmark along the concentration scale that you might even be tempted to give it a special name, particularly if your name were Michaelis and you were monkeying around with enzymes instead of peanuts!

Here, v is the initial reaction velocity, $[S]$ is the initial substrate concentration, V_{\max} is the maximum velocity, and K_m is the concentration of substrate that gives exactly half the maximum velocity. V_{\max} and K_m (also known as the **Michaelis constant**) are important kinetic parameters that we will consider in more detail in the next section. Equation 6-7 is known as the **Michaelis–Menten equation**, a central relationship of enzyme kinetics. (Problem 6-12 at the end of the chapter gives you an opportunity to derive the Michaelis–Menten equation yourself.)

What Is the Meaning of V_{\max} and K_m ?

To appreciate the implications of the relationship between v and $[S]$ and to examine the meaning of the parameters V_{\max} and K_m , we can consider three special cases of substrate concentration: very low substrate concentration, very high substrate concentration, and the special case of $[S] = K_m$.

Case 1: Very Low Substrate Concentration ($[S] \ll K_m$).

At very low substrate concentration, $[S]$ becomes negligibly small compared with the constant K_m in the denominator of the Michaelis–Menten equation and can be ignored, so we can write

$$v = \frac{V_{\max}[S]}{K_m + [S]} \approx \frac{V_{\max}[S]}{K_m} \quad (6-8)$$

Thus, at very low substrate concentration, the initial reaction velocity is roughly proportional to the substrate concentration. This can be seen at the extreme left side of the graph in Figure 6-8. As long as the substrate concentration is much lower than the K_m value, the velocity of an enzyme-catalyzed reaction increases linearly with substrate concentration.

Case 2: Very High Substrate Concentration ($[S] \gg K_m$).

At very high substrate concentration, K_m becomes negligibly small compared with $[S]$ in the denominator of the Michaelis–Menten equation, so we can write

$$v = \frac{V_{\max}[S]}{K_m + [S]} \approx \frac{V_{\max}[S]}{[S]} = V_{\max} \quad (6-9)$$

Therefore, at very high substrate concentrations, the velocity of an enzyme-catalyzed reaction is essentially independent of the variation in $[S]$ and is approximately constant at a value close to V_{\max} (see the right side of Figure 6-8).

This provides us with a mathematical definition of V_{\max} , which is one of the two kinetic parameters in the Michaelis–Menten equation. V_{\max} is the upper limit of v as the substrate concentration $[S]$ approaches infinity. In other words, V_{\max} is the velocity at saturating substrate concentrations. Under these conditions, every enzyme molecule is occupied in the actual process of catalysis

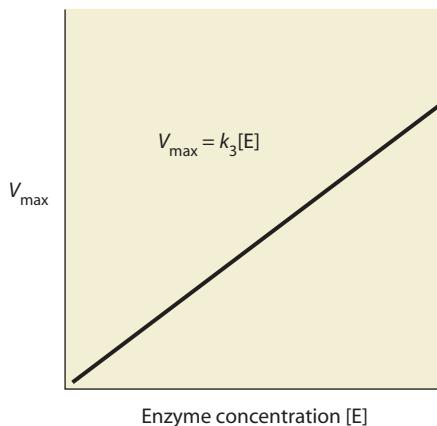

FIGURE 6-9 The Linear Relationship Between V_{\max} and Enzyme Concentration. The linear increase in reaction velocity with enzyme concentration provides the basis for determining enzyme concentrations experimentally.

almost all of the time because the substrate concentration is so high that, as soon as a product molecule is released, another substrate molecule arrives at the active site.

V_{\max} is therefore an upper limit determined by (1) the time required for the actual catalytic reaction and (2) how many such enzyme molecules are present. Because the actual reaction rate is fixed, the only way that V_{\max} can be increased is to increase enzyme concentration. In fact, V_{\max} is linearly proportional to the amount of enzyme present, as shown in Figure 6-9, where k_3 represents the reaction rate constant.

Case 3: ($[S] = K_m$). To explore the meaning of K_m more precisely, consider the special case where $[S]$ is exactly equal to K_m . Under these conditions, the Michaelis–Menten equation can be written as

$$v = \frac{V_{\max}[S]}{K_m + [S]} \approx \frac{V_{\max}[S]}{2[S]} = \frac{V_{\max}}{2} \quad (6-10)$$

This equation demonstrates mathematically that K_m is that specific substrate concentration at which the reaction proceeds at one-half of its maximum velocity. The K_m is a constant value for a given enzyme-substrate combination catalyzing a reaction under specified conditions. Figure 6-8 illustrates the meaning of both V_{\max} and K_m .

Why Are K_m and V_{\max} Important to Cell Biologists?

Now that we understand what K_m and V_{\max} mean, it is fair to ask why these kinetic parameters are important to cell biologists. The K_m value is useful because it allows us to estimate where along the Michaelis–Menten plot of Figure 6-8 an enzyme is functioning in a cell (providing, of course, that the normal substrate concentration in the cell is known). We can then estimate at what fraction of the maximum velocity the enzyme-catalyzed reaction is likely to be proceeding in

Table 6-2 K_m and k_{cat} Values for Some Enzymes

Enzyme Name	Substrate	K_m (M)	k_{cat} (s ⁻¹)
Acetylcholinesterase	Acetylcholine	9×10^{-5}	1.4×10^4
Carbonic anhydrase	CO ₂	1×10^{-2}	1×10^6
Fumarase	Fumarate	5×10^{-6}	8×10^2
Triose phosphate isomerase	Glyceraldehyde-3-phosphate	5×10^{-4}	4.3×10^3
β -lactamase	Benzylpenicillin	2×10^{-5}	2×10^3

the cell. The lower the K_m value for a given enzyme and substrate, the lower the substrate concentration range in which the enzyme is effective. As we will soon see, enzyme activity in the cell can be modulated by regulatory molecules that bind to the enzyme and alter the K_m for a particular substrate. K_m values for several enzyme-substrate combinations are given in **Table 6-2** and, as you can see, can vary over several orders of magnitude.

The V_{max} for a particular reaction is important because it provides a measure of the potential maximum rate of the reaction. Few enzymes actually encounter saturating substrate concentrations in cells, so enzymes are not likely to be functioning at their maximum rate under cellular conditions. However, by knowing the V_{max} value, the K_m value, and the substrate concentration *in vivo*, we can at least estimate the likely rate of the reaction under cellular conditions.

V_{max} can also be used to determine another useful parameter called the **turnover number** (k_{cat}), which expresses the rate at which substrate molecules are converted to product by a single enzyme molecule when the enzyme is operating at its maximum velocity. The constant k_{cat} has the units of reciprocal time (s⁻¹, for example) and is calculated as the quotient of V_{max} over [E_t], the concentration of the enzyme:

$$k_{cat} = \frac{V_{max}}{[E_t]} \quad (6-11)$$

Turnover numbers vary greatly among enzymes, as is clear from the examples given in Table 6-2.

The Double-Reciprocal Plot Is a Useful Means of Linearizing Kinetic Data

The classic Michaelis–Menten plot of v versus [S] shown in Figure 6-8 illustrates the dependence of velocity on substrate concentration. However, it is not an especially useful tool for the quantitative determination of the key kinetic parameters K_m and V_{max} . Its hyperbolic shape makes it difficult to extrapolate accurately to infinite substrate concentration in order to determine the critical parameter V_{max} . Also, if V_{max} is not known accurately, K_m cannot be determined.

To circumvent this problem and provide a more useful graphic approach, Hans Lineweaver and Dean Burk in

1934 converted the hyperbolic relationship of the Michaelis–Menten equation into a linear function by inverting both sides of Equation 6-7 and simplifying the resulting expression into the form of an equation for a straight line:

$$\begin{aligned} \frac{1}{v} &= \frac{K_m + [S]}{V_{max}[S]} = \frac{K_m}{V_{max}[S]} + \frac{[S]}{V_{max}[S]} \\ &= \frac{K_m}{V_{max}} \left(\frac{1}{[S]} \right) + \frac{1}{V_{max}} \end{aligned} \quad (6-12)$$

Equation 6-12 is known as the **Lineweaver–Burk equation**. When it is plotted as $1/v$ versus $1/[S]$, as in **Figure 6-10**, the resulting **double-reciprocal plot** is linear in the general algebraic form $y = mx + b$, where m is the slope and b is the y -intercept. Therefore, it has a slope (m) of K_m/V_{max} , a y -intercept (b) of $1/V_{max}$, and an x -intercept ($y = 0$) of $-1/K_m$. (You should be able to convince yourself of these intercept values by setting first $1/[S]$ and then $1/v$ equal to zero in Equation 6-12 and solving for the other value.) Therefore, once the double-reciprocal plot has been constructed, V_{max} can be determined directly from the reciprocal of the y -intercept and K_m from the negative reciprocal of the x -intercept. Furthermore, the slope can be used to check both values.

Thus, the Lineweaver–Burk plot is useful experimentally because it allows us to determine the parameters V_{max}

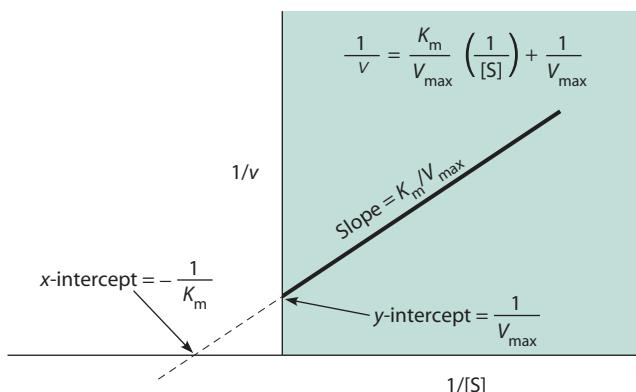

FIGURE 6-10 The Lineweaver–Burk Double-Reciprocal Plot. The reciprocal of the initial velocity, $1/v$, is plotted as a function of the reciprocal of the substrate concentration, $1/[S]$. K_m can be calculated from the x -intercept and V_{max} from the y -intercept.

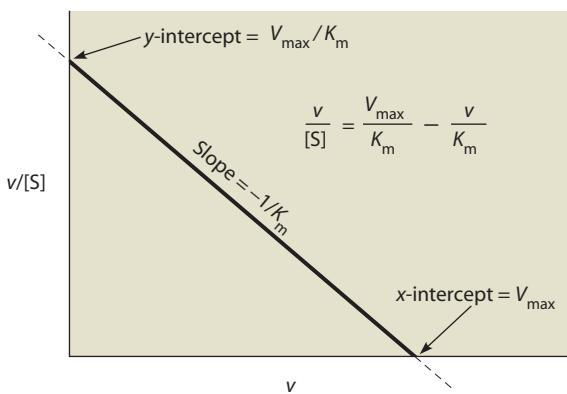

FIGURE 6-11 The Eadie–Hofstee Plot. The ratio $v/[S]$ is plotted as a function of v . K_m can be determined from the slope and V_{\max} from the x -intercept.

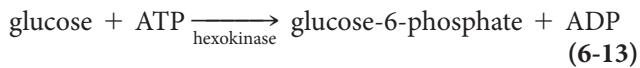

and K_m without the complication of a hyperbolic shape. It also serves as a useful diagnostic in analyzing enzyme inhibition because the several different kinds of reversible inhibitors affect the shape of the plot in characteristic ways.

The Lineweaver–Burk equation has some limitations, however. The main problem is that a long extrapolation is often necessary to determine K_m , and this may introduce uncertainty in the result. Moreover, the most crucial data points for determining the slope of the curve are the farthest from the y -axis. Because those points represent the samples with the lowest substrate concentrations and lowest levels of enzyme activity, they are the most difficult to measure accurately.

To circumvent these disadvantages, several alternatives to the Lineweaver–Burk equation have come into use to linearize kinetic data. One such alternative is the **Eadie–Hofstee equation**, which is represented graphically as a plot of $v/[S]$ versus v . As Figure 6-11 illustrates, V_{\max} is determined from the x -intercept and K_m from the slope of this plot. (To explore the Eadie–Hofstee plot and another alternative to the Lineweaver–Burk plot further, see Problem 6-13 at the end of this chapter.)

Determining K_m and V_{\max} : An Example

To illustrate the value of the double-reciprocal plot in determining V_{\max} and K_m , consider a specific example involving the enzyme hexokinase, as illustrated in Figures 6-12 and 6-13. Hexokinase is an important enzyme in cellular energy metabolism because it catalyzes the first reaction in the glycolytic pathway, which is discussed in detail in Chapter 9. Using the hydrolysis of ATP as a source of both the phosphate group and the free energy needed for the reaction, hexokinase catalyzes the phosphorylation of glucose on carbon atom 6:

To analyze this reaction kinetically, we must determine the initial velocity at each of several substrate concentrations.

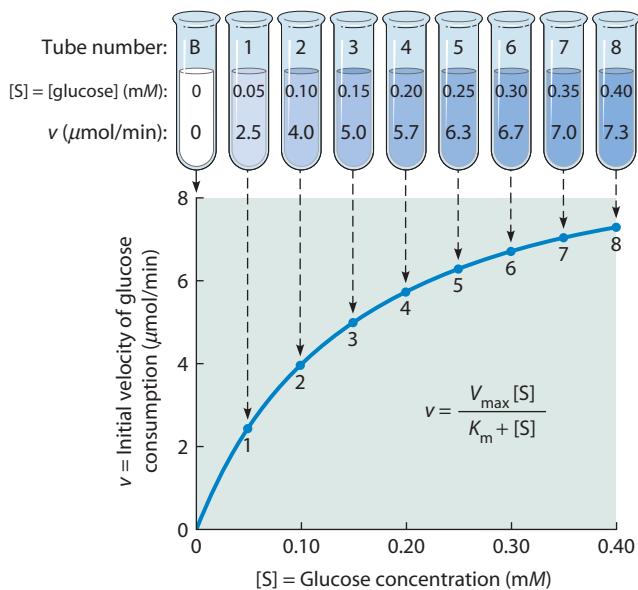

FIGURE 6-12 Experimental Procedure for Studying the Kinetics of the Hexokinase Reaction. Test tubes containing graded concentrations of glucose and a saturating concentration of ATP were incubated with a standard amount of hexokinase. The initial rate of product appearance, v , was then plotted as a function of the substrate concentration $[S]$. The curve is hyperbolic, approaching V_{\max} as the substrate concentration gets higher and higher. For the double-reciprocal plot derived from these data, see Figure 6-13.

When an enzyme has two substrates, the usual approach is to vary the concentration of one substrate at a time while holding that of the other one constant at a level near saturation to ensure that it does not become rate limiting. The velocity determination must be made before either the substrate concentration drops appreciably or the product accumulates to the point that the reverse reaction becomes significant.

In the experimental approach shown in Figure 6-12, glucose is the variable substrate, with ATP present at a saturating concentration in each tube. Of the nine reaction mixtures set up for this experiment, one tube is a negative control designated the reagent blank (B) because it contains no glucose. The other tubes contain concentrations of glucose ranging from 0.05 to 0.40 mM. With all tubes prepared and maintained at some favorable temperature (25°C is often used), the reaction in each is initiated by adding a fixed amount of hexokinase.

The rate of product formation in each of the reaction mixtures can then be determined either by continuous spectrophotometric monitoring of the reaction mixture (provided that one of the reactants or products absorbs light of a specific wavelength) or by allowing each reaction mixture to incubate for some short, fixed period of time, followed by chemical assay for either substrate depletion or product accumulation.

As Figure 6-12 indicates, the initial velocity of the glucose consumption reaction for tubes 1–8 ranged from 2.5 to 7.3 μmol of glucose consumed per minute, with no

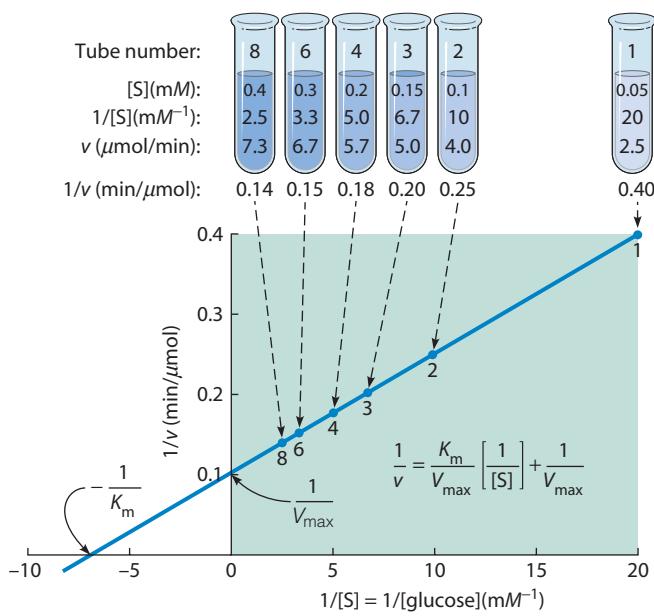

FIGURE 6-13 Double-Reciprocal Plot for the Hexokinase Data of Figure 6-12. For each test tube in Figure 6-12, $1/v$ and $1/[S]$ were calculated, and $1/v$ was then plotted as a function of $1/[S]$. The y -intercept of 0.1 corresponds to $1/V_{\max}$, so V_{\max} is 10 $\mu\text{M}/\text{min}$. The x -intercept of -6.7 corresponds to $-1/K_m$, so K_m is 0.15 mM. (Some of the tubes depicted in Figure 6-12 are not shown here due to lack of space.)

detectable reaction in the blank. When these reaction velocities are plotted as a function of glucose concentration, the eight data points generate the hyperbolic curve shown in Figure 6-12. Although the data of Figure 6-12 are idealized for illustrative purposes, most kinetic data generated by this approach do, in fact, fit a hyperbolic curve unless the enzyme has some special properties that cause departure from Michaelis–Menten kinetics.

The hyperbolic curve of Figure 6-12 illustrates the need for some means of linearizing the analysis because neither V_{\max} nor K_m can be easily determined from the values as plotted. This need is met by the linear double-reciprocal plot shown in Figure 6-13. To obtain the data plotted here, reciprocals were calculated for each value of $[S]$ and v in Figure 6-12. Thus, the $[S]$ values of 0.05–0.40 mM generate reciprocals of 20–2.5 mM^{-1} , and the v values of 2.5–7.3 $\mu\text{mol}/\text{min}$ give rise to reciprocals of 0.4–0.14 min/ μmol . Because these are reciprocals, the data point representing the lowest concentration (tube 1) is farthest from the origin, and each successive tube is represented by a point closer to the origin.

When these data points are connected by a straight line, the y -intercept is found to be 0.1 min/ μmol , and the x -intercept is -6.7 mM^{-1} . From these intercepts, we can calculate that $V_{\max} = 1/0.1 = 10 \mu\text{mol}/\text{min}$ and $K_m = -(1/-6.7) = 0.15 \text{ mM}$. If we now go back to the Michaelis–Menten plot of Figure 6-12, we can see that both of these values are quite reasonable because we can readily imagine that the plot is rising hyperbolically to a maximum of 10 $\mu\text{M}/\text{min}$. Note that using your eyes

alone, you might estimate the V_{\max} to be only 8 or 9 $\mu\text{mol}/\text{min}$. Moreover, the graph reaches one-half of this value at a substrate concentration of 0.15 mM. Therefore, this is the K_m of hexokinase for glucose.

The enzyme also has a K_m value for the other substrate, ATP. The K_m for ATP can be determined by varying the ATP concentration while holding the glucose concentration at a high, fixed level. Interestingly, hexokinase phosphorylates not only glucose but also other hexoses and has a distinctive K_m value for each. The K_m for fructose, for example, is 1.5 mM, which means that it takes ten times more fructose than glucose to sustain the reaction at one-half of its maximum velocity.

Enzyme Inhibitors Act Either Irreversibly or Reversibly

Thus far, we have assumed that substrates are the only substances in cells that affect the activities of enzymes in cells. However, enzymes are also influenced by products, alternative substrates, substrate analogues, drugs, toxins, and a very important class of regulators called *allosteric effectors*. Most of these substances have an inhibitory effect on enzyme activity, reducing the reaction rate with the desired substrate or sometimes blocking the reaction completely.

This **inhibition** of enzyme activity is important for several reasons. First and foremost, enzyme inhibition plays a vital role as a control mechanism in cells. Many enzymes are subject to regulation by specific small molecules other than their substrates. Often this is a means of sensing their immediate environment to respond to specific cellular conditions.

Enzyme inhibition is also important in the action of drugs and poisons, which frequently exert their effects by inhibiting specific enzymes. Inhibitors are also useful to enzymologists as tools in their studies of reaction mechanisms and to doctors for treatment of disease. Especially important inhibitors are *substrate analogues* and *transition state analogues*. These are compounds that resemble the real substrate or transition state closely enough to bind to the active site but cannot undergo reaction to create a functional product.

Substrate analogs are important tools in fighting infectious disease, and many have been developed to inhibit specific enzymes in pathogenic bacteria and viruses, usually targeting enzymes that we humans lack. For example, sulfa drugs resemble the folic acid precursor, PABA. They can bind to and block the active site of the bacterial enzyme used to synthesize folic acid, which is required in DNA synthesis. Likewise, azidothymidine (AZT), which is an antiviral medication, resembles the deoxythymidine molecule normally used by the human immunodeficiency virus (HIV) to synthesize DNA using viral reverse transcriptase. However, after binding to the active site, AZT is incorporated into a growing strand of DNA but forms a “dead-end” molecule of DNA that cannot be elongated.

Inhibitors may be either *reversible* or *irreversible*. An **irreversible inhibitor** binds to the enzyme covalently, causing permanent loss of catalytic activity. Not surprisingly, irreversible inhibitors are usually toxic to cells. Ions of heavy metals are often irreversible inhibitors, as are nerve gas poisons and some insecticides. These substances can bind irreversibly to enzymes such as *acetylcholinesterase*, an enzyme that is vital to the transmission of nerve impulses (see Chapter 13). Inhibition of acetylcholinesterase activity leads to rapid paralysis of vital functions and therefore to death. One such inhibitor is *diisopropyl fluorophosphate*, a nerve gas that binds covalently to the hydroxyl group of a critical serine at the active site of the enzyme, thereby rendering the enzyme molecule permanently inactive.

Some irreversible inhibitors of enzymes can be used as therapeutic agents. For example, aspirin binds irreversibly to the enzyme cyclooxygenase-1 (COX-1), which produces prostaglandins and other signaling chemicals that cause inflammation, constriction of blood vessels, and platelet aggregation. Thus, aspirin is effective in relieving minor inflammation and headaches, and has been recommended in low doses as a cardiovascular protectant. The antibiotic *penicillin* is an irreversible inhibitor of the enzyme needed for bacterial cell wall synthesis. Penicillin is therefore effective in treating bacterial infections because it prevents the bacterial cells from forming cell walls, thus blocking their growth and division. And because our cells lack a cell wall (and the enzyme that synthesizes it), penicillin is nontoxic to humans.

In contrast, a **reversible inhibitor** binds to an enzyme in a noncovalent, dissociable manner, such that the free

and bound forms of the inhibitor exist in equilibrium with each other. We can represent such binding as

with E as the active free enzyme, I as the inhibitor, and EI as the inactive enzyme-inhibitor complex. Clearly, the fraction of the enzyme that is available to the cell in active form depends on the concentration of the inhibitor and the strength of the enzyme-inhibitor complex.

The two most common forms of reversible inhibitors are called *competitive inhibitors* and *noncompetitive inhibitors*. A competitive inhibitor binds to the active site of the enzyme and therefore competes directly with substrate molecules for the same site on the enzyme (**Figure 6-14a**). This reduces enzyme activity because many of the active sites of the enzyme molecules are blocked by bound inhibitor molecules and thus cannot bind substrate molecules at the active site. A noncompetitive inhibitor, on the other hand, binds to the enzyme surface at a location *other* than the active site. It does not block substrate binding directly but inhibits enzyme activity indirectly by causing a change in protein conformation that can either inhibit substrate binding to the active site or greatly reduce the catalytic activity at the active site (Figure 6-14b).

Considerable progress has been made in the field of computer-aided drug design. In this approach, the three-dimensional structure of an enzyme active site is analyzed to predict what types of molecules are likely to bind tightly to it and act as inhibitors. Scientists can then design a number of hypothetical inhibitors and test their binding using complex computer models. In this way, we do not have to rely only upon those inhibitors we can discover in

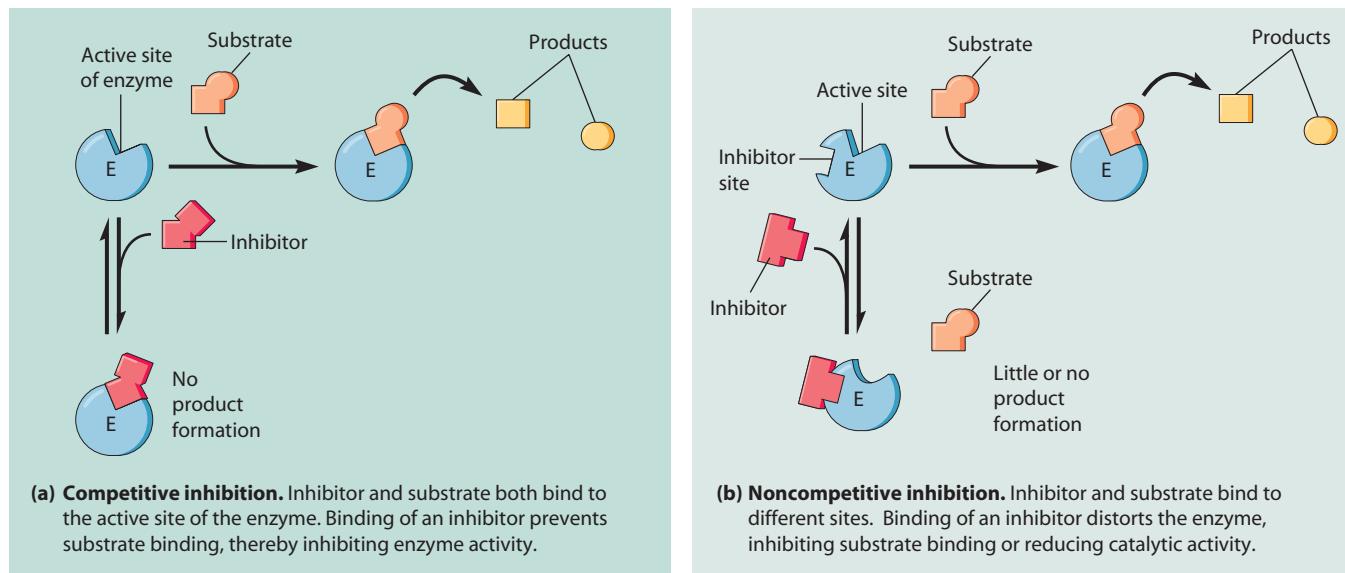

FIGURE 6-14 Modes of Action of Competitive and Noncompetitive Inhibitors. Both (a) competitive and (b) noncompetitive inhibitors bind reversibly to the enzyme (E), thereby inhibiting its activity. The two kinds of inhibitors differ in which site on the enzyme they bind to.

nature. Hundreds or even thousands of potential inhibitors can be designed and tested, and only the most promising are actually synthesized and evaluated experimentally.

Enzyme Regulation

To understand the role of enzymes in cellular function, we need to recognize that it is rarely in the cell's best interest to allow an enzyme to function at an indiscriminately high rate. Instead, the rates of enzyme-catalyzed reactions must be continuously adjusted to keep them finely tuned to the needs of the cell. An important aspect of that adjustment lies in the cell's ability to control enzyme activities with specificity and precision.

We have already encountered a variety of regulatory mechanisms, including changes in substrate and product concentrations, alterations in temperature and pH, and the presence and concentration of inhibitors. Regulation that depends directly on the interactions of substrates and products with the enzyme is called **substrate-level regulation**. As the Michaelis–Menten equation makes clear, increases in substrate concentration result in higher reaction rates (see Figure 6–8). Conversely, increases in product concentration reduce the rate at which substrate is converted to product. (This inhibitory effect of product concentration is why v needs to be identified as the *initial* reaction velocity in the Michaelis–Menten equation, as given by Equation 6–7.)

Substrate-level regulation is an important control mechanism in cells, but it is not sufficient for the regulation of most reactions or reaction sequences. For most pathways, enzymes are regulated by other mechanisms as well. Two of the most important of these are *allosteric regulation* and *covalent modification*. These mechanisms allow cells to turn enzymes on or off or to fine-tune their reaction rates by modulating enzyme activities appropriately.

Almost invariably, an enzyme that is regulated by such a mechanism catalyzes the first step of a multistep sequence. By increasing or reducing the rate at which the first step functions, the whole sequence is effectively controlled. Pathways that are regulated in this way include those required to break down large molecules (such as sugars, fats, or amino acids) and pathways that lead to the synthesis of substances needed by the cell (such as amino acids and nucleotides). For now, we will discuss allosteric regulation and covalent modification at an introductory level. We will return to these mechanisms as we encounter specific examples in later chapters.

Allosteric Enzymes Are Regulated by Molecules Other than Reactants and Products

The single most important control mechanism whereby the rates of enzyme-catalyzed reactions are adjusted to meet cellular needs is *allosteric regulation*. To understand this mode of regulation, consider the pathway by which a cell

converts some precursor A into some final product P via a series of intermediates B, C, and D in a sequence of reactions catalyzed respectively by enzymes E₁, E₂, E₃, and E₄:

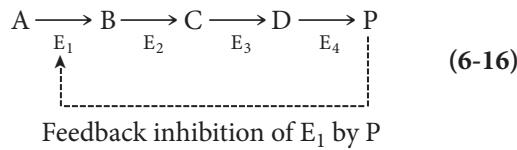

Product P could, for example, be an amino acid needed by the cell for protein synthesis, and A could be some common cellular component that serves as the starting point for the specific reaction sequence leading to P.

Feedback Inhibition. If allowed to proceed at a constant, unrestrained rate, the pathway shown in Reaction Sequence 6–15 can convert large amounts of A to P, with possible adverse effects resulting from a depletion of A or an excessive accumulation of P. Clearly, the best interests of the cell are served when the pathway is functioning not at its maximum rate or even some constant rate, but at a rate that is carefully tuned to the cellular need for P.

Somehow, the enzymes of this pathway must be responsive to the cellular level of the product P in somewhat the same way that a furnace needs to be responsive to the temperature of the rooms it is intended to heat. In the latter case, a thermostat provides the necessary regulatory link between the furnace and its “product,” heat. If there is too much heat, the thermostat turns the furnace off, inhibiting heat production. If heat is needed, this inhibition is relieved due to the lack of heat. In our enzyme example, the desired regulation is possible because the product P is a specific inhibitor of E₁, the enzyme that catalyzes the first reaction in the sequence.

This phenomenon is called **feedback (or end-product) inhibition** and is represented by the dashed arrow that connects the product P to enzyme E₁ in the following reaction sequence:

Feedback inhibition is one of the most common mechanisms used by cells to ensure that the activities of reaction sequences are adjusted to cellular needs.

Figure 6–15 provides a specific example of such a pathway—the five-step sequence whereby the amino acid *isoleucine* is synthesized from *threonine*, another amino acid. In this case, the first enzyme in the pathway, *threonine deaminase*, is regulated by the concentration of isoleucine within the cell. If isoleucine is being used by the cell (in the synthesis of proteins, most likely), the isoleucine concentration will be low and the cell will need more. Under these conditions, threonine deaminase is active, and the pathway functions to produce more isoleucine. If the need for isoleucine decreases, isoleucine will begin to accumulate in the cell. This increase in its

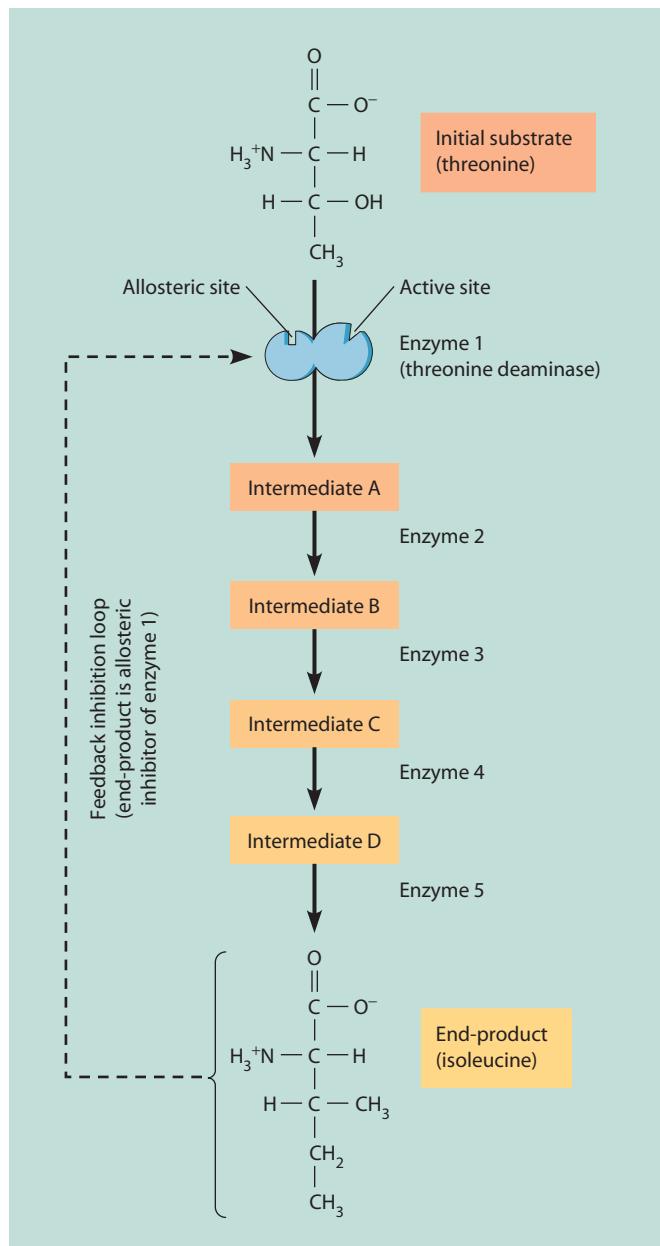

FIGURE 6-15 Allosteric Regulation of Enzyme Activity.

A specific example of feedback inhibition is seen in the pathway by which the amino acid isoleucine is synthesized from threonine, another amino acid. The first enzyme in the sequence, threonine deaminase, is allosterically inhibited by isoleucine, which binds to the enzyme at a site other than the active site.

concentration will lead to inhibition of threonine deaminase and hence to a reduced rate of isoleucine synthesis.

Allosteric Regulation. How can the first enzyme in a pathway (e.g., enzyme E₁ in Reaction Sequence 6-16) be sensitive to the concentration of a substance P that is neither its substrate nor its immediate product? The answer to this question was first proposed in 1963 by Jacques Monod, Jean-Pierre Changeux, and François Jacob. Their model was quickly substantiated and went on to become

the foundation for our understanding of **allosteric regulation**. The term *allosteric* derives from the Greek for “another shape (or form),” thereby indicating that all enzymes capable of allosteric regulation can exist in two different forms.

In one of the two forms, the enzyme has a high affinity for its substrate(s), leading to high activity. In the other form, it has little or no affinity for its substrate, giving little or no catalytic activity. Enzymes with this property are called **allosteric enzymes**. The two different forms of an allosteric enzyme are readily interconvertible and are, in fact, in equilibrium with each other.

Whether the active or inactive form of an allosteric enzyme is favored depends on the cellular concentration of the appropriate regulatory substance, called an **allosteric effector**. In the case of isoleucine synthesis, the allosteric effector is isoleucine and the allosteric enzyme is threonine deaminase. More generally, *an allosteric effector is a small organic molecule that regulates the activity of an enzyme for which it is neither the substrate nor the immediate product.*

An allosteric effector influences enzyme activity by binding to one of the two interconvertible forms of the enzyme, thereby stabilizing it in that state. The effector binds to the enzyme because of the presence on the enzyme surface of an **allosteric (or regulatory) site** that is distinct from the active site at which the catalytic event occurs. Thus, a distinguishing feature of all allosteric enzymes (and other allosteric proteins, as well) is the presence on the enzyme surface of an *active site* to which the substrate binds and an *allosteric site* to which the effector binds. In fact, some allosteric enzymes have multiple allosteric sites, each capable of recognizing a different effector.

An effector may be either an **allosteric inhibitor** or an **allosteric activator**, depending on the effect it has when bound to the allosteric site on the enzyme—that is, depending on whether the effector is bound to the low-affinity or high-affinity form of the enzyme (**Figure 6-16**). The binding of an allosteric inhibitor shifts the equilibrium between the two forms of the enzyme to favor the low-affinity state (Figure 6-16a). The binding of an allosteric activator, on the other hand, shifts the equilibrium in favor of the high-affinity state (Figure 6-16b). In either case, binding of the effector to the allosteric site stabilizes the enzyme in one of its two interconvertible forms, thereby either decreasing or increasing the likelihood of substrate binding.

Most allosteric enzymes are large, multisubunit proteins with an active site or an allosteric site on each subunit. Thus, quaternary protein structure is important for these enzymes. Typically, the active sites and allosteric sites are on different subunits of the protein, which are referred to as **catalytic subunits** and **regulatory subunits**, respectively (notice the C and R subunits of the enzyme molecules shown in Figure 6-16). This means, in turn, that the binding of effector molecules to the allosteric sites affects not just the shape of the regulatory subunits but that of the catalytic subunits as well.

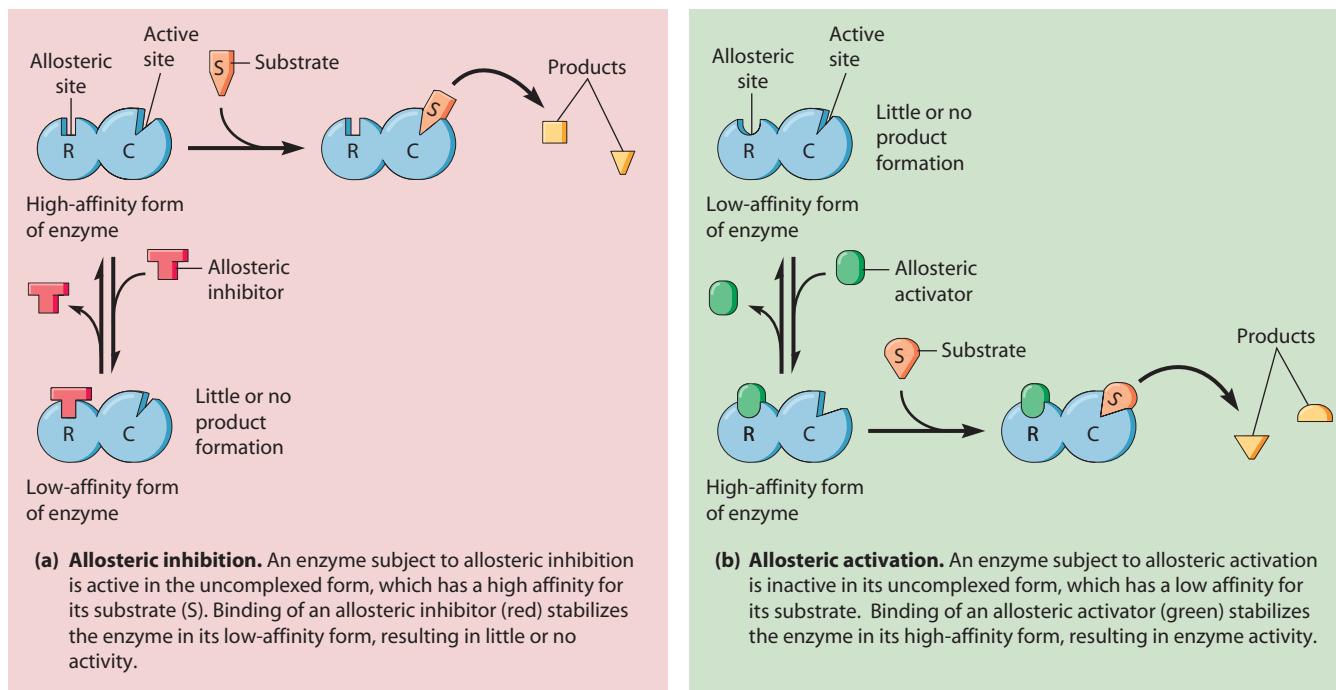

FIGURE 6-16 Mechanisms of Allosteric Inhibition and Activation. An allosteric enzyme consists of one or more catalytic subunits (C) and one or more regulatory subunits (R), each with an active site or an allosteric site, respectively. The enzyme exists in two forms, one with a high affinity for its substrate (and therefore a high likelihood of product formation) and the other with a low affinity (and a correspondingly low likelihood of product formation). The predominant form of the enzyme depends on the concentration of its allosteric effector(s).

Allosteric Enzymes Exhibit Cooperative Interactions Between Subunits

Many allosteric enzymes exhibit a property known as **cooperativity**. This means that, as the multiple catalytic sites on the enzyme bind substrate molecules, the enzyme undergoes conformational changes that affect the affinity of the remaining sites for substrate. Some enzymes show *positive cooperativity*, in which the binding of a substrate molecule to one catalytic subunit increases the affinity of other catalytic subunits for substrate. Other enzymes show *negative cooperativity*, in which the substrate binding to one catalytic subunit reduces the affinity of the other catalytic sites for substrate.

The cooperativity effect enables cells to produce enzymes that are more sensitive or less sensitive to changes in substrate concentration than would otherwise be predicted by Michaelis–Menten kinetics. Positive cooperativity causes an enzyme's catalytic activity to increase faster than normal as the substrate concentration is increased, whereas negative cooperativity means that enzyme activity increases more slowly than expected.

Enzymes Can Also Be Regulated by the Addition or Removal of Chemical Groups

In addition to allosteric regulation, many enzymes are subject to control by **covalent modification**. In this form of regulation, an enzyme's activity is affected by the addition or removal of specific chemical groups via covalent bonding.

Common modifications include the addition of phosphate groups, methyl groups, acetyl groups, or derivatives of nucleotides. Some of these modifications can be reversed, whereas others cannot. In each case, the effect of the modification is to activate or to inactivate the enzyme—or at least to adjust its activity upward or downward.

Phosphorylation/Dephosphorylation. One of the most frequently encountered and best understood covalent modifications involves the reversible addition of phosphate groups. The addition of phosphate groups is called **phosphorylation** and occurs most commonly by transfer of the phosphate group from ATP to the hydroxyl group of a serine, threonine, or tyrosine residue in the protein. Enzymes that catalyze the phosphorylation of other enzymes (or of other proteins) are called **protein kinases**. The reversal of this process, **dephosphorylation**, involves the removal of a phosphate group from a phosphorylated protein, catalyzed by enzymes called **protein phosphatases**. Depending on the particular enzyme, phosphorylation may activate or inhibit the enzyme.

Enzyme regulation by reversible phosphorylation/dephosphorylation was discovered by Edmond Fischer and Edwin Krebs (not Hans Krebs, namesake of the Krebs cycle) at the University of Washington in the 1950s. They were awarded the 1992 Nobel Prize in Physiology or Medicine for their groundbreaking work with *glycogen phosphorylase*, a glycogen-degrading enzyme found in liver and skeletal muscle cells (Figure 6-17). In muscle cells, it provides glucose as an energy source for muscle

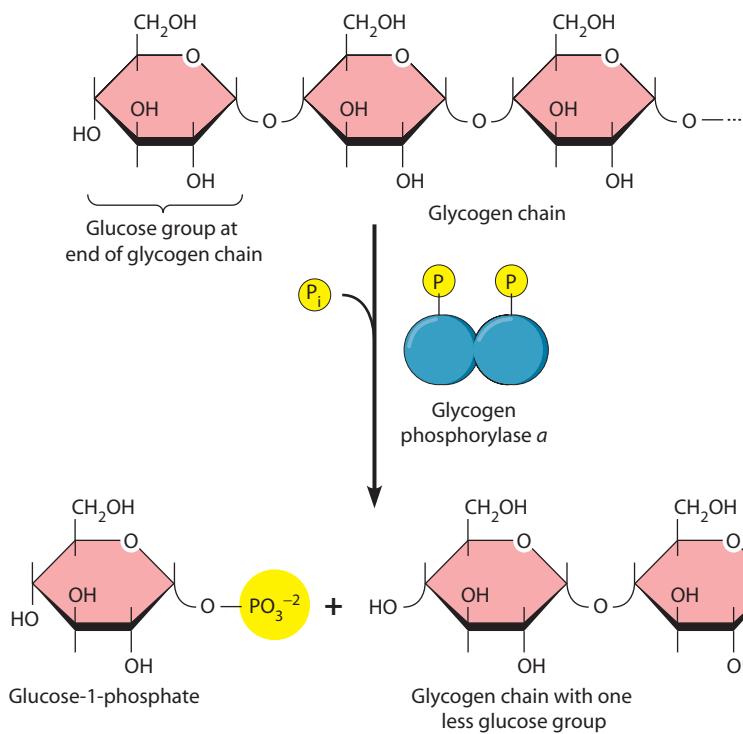

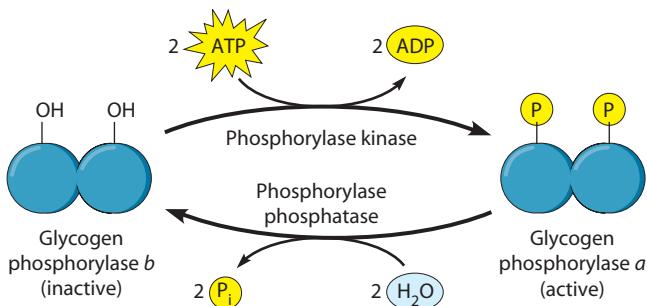

FIGURE 6-17 The Regulation of Glycogen Phosphorylase by Phosphorylation

Phosphorylation. The activity of glycogen phosphorylase is regulated by reversible phosphorylation and dephosphorylation reactions catalyzed by phosphorylase kinase and phosphorylase phosphatase, respectively.

(a) Glycogen phosphorylase is a dimeric enzyme that releases glucose units from glycogen molecules as glucose-1-phosphate. Glucose-1-phosphate is then used by muscle cells as an energy source and by liver cells to regulate blood glucose levels.

(b) Glycogen phosphorylase is regulated in part by a phosphorylation/dephosphorylation mechanism. The inactive form of the enzyme, phosphorylase *b*, can be converted to the active form, phosphorylase *a*, by a dual phosphorylation reaction catalyzed by the enzyme phosphorylase kinase. Removal of the phosphate groups by phosphorylase phosphatase returns the phosphorylase molecule to the inactive *b* form.

contraction and in liver cells it provides glucose for secretion to help maintain a constant blood glucose level. Glycogen phosphorylase breaks down glycogen by successive removal of glucose units as glucose-1-phosphate (Figure 6-17a). Regulation of this dimeric enzyme is achieved in part by the presence of two interconvertible forms of the enzyme—an active form called *phosphorylase a* and an inactive form called *phosphorylase b* (Figure 6-17b).

When glycogen breakdown is required in the cell, the inactive *b* form of the enzyme is converted into the active *a* form by the addition of a phosphate group to a particular serine on each of the two subunits of the phosphorylase molecule. The reaction is catalyzed by *phosphorylase kinase* and results in a conformational change of phosphorylase to the active form. When glycogen breakdown is no longer needed, the phosphate groups are removed from phosphorylase *a* by the enzyme *phosphorylase phosphatase*.

The muscle and liver forms of glycogen phosphorylase, known as isozymes, have subtle differences in their manner of regulation. Besides being regulated by the

phosphorylation/dephosphorylation mechanism shown in Figure 6-17, liver glycogen phosphorylase, an allosteric enzyme, is inhibited by glucose and ATP and activated by AMP. Glucose binding to active liver glycogen phosphorylase *a* will inactivate it, blocking glycogen breakdown when glucose accumulates faster than needed. The existence of two levels of regulation for glycogen phosphorylase illustrates an important aspect of enzyme regulation. Many enzymes are controlled by two or more regulatory mechanisms, thereby enabling the cell to make appropriate responses to a variety of situations.

Proteolytic Cleavage. A different kind of covalent activation of enzymes involves the one-time, irreversible removal of a portion of the polypeptide chain by an appropriate proteolytic (protein-degrading) enzyme. This kind of modification, called **proteolytic cleavage**, is exemplified especially well by the proteolytic enzymes of the pancreas, which include trypsin, chymotrypsin, and carboxypeptidase. After being synthesized in the pancreas, these enzymes are secreted in an inactive form into

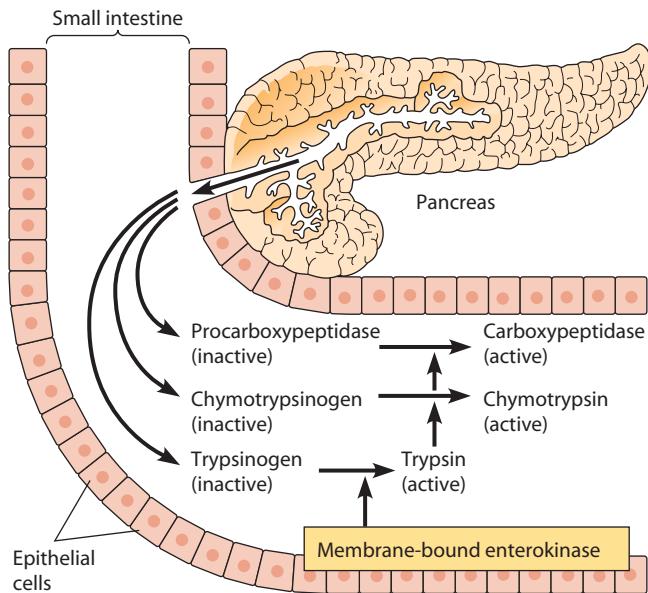

FIGURE 6-18 Activation of Pancreatic Zymogens by Proteolytic Cleavage.

Pancreatic proteases are synthesized and secreted into the small intestine as inactive precursors known as zymogens. Procarboxypeptidase, trypsinogen, and chymotrypsinogen are zymogens. Activation of trypsinogen to trypsin requires removal of a hexapeptide segment by enterokinase, a membrane-bound duodenal enzyme. Trypsin then activates other zymogens by proteolytic cleavage. Procarboxypeptidase is activated by a single cleavage event, whereas the activation of chymotrypsinogen is a somewhat more complicated two-step process, the details of which are not shown here.

the duodenum of the small intestine in response to a hormonal signal (Figure 6-18). These proteases can digest almost all ingested proteins into free amino acids, which are then absorbed by the intestinal epithelial cells.

Pancreatic proteases are not synthesized in their active form. That would likely cause problems for the cells of the pancreas, which must protect themselves against their own proteolytic enzymes. Instead, each of these enzymes is synthesized as a slightly larger, catalytically inactive molecule called a *zymogen*. Zymogens must themselves be cleaved proteolytically to yield active enzymes. For example, trypsin is synthesized initially as a zymogen called *trypsinogen*. When trypsinogen reaches the duodenum, it is activated by the removal of a hexapeptide (a string of six amino acids) from its N-terminus by the action of *enterokinase*, a membrane-bound protease produced by the duodenal cells. The active trypsin then activates other zymogens by specific proteolytic cleavages.

RNA Molecules as Enzymes: Ribozymes

Until the early 1980s, it was thought that all enzymes were proteins. Indeed, that statement was regarded as a fundamental truth of cellular biology and was found in every textbook. Cell biologists became convinced that all enzymes were proteins because every enzyme isolated in

the 55 years following Sumner's purification of urease in 1926 turned out to be a protein. But biology is full of surprises, and this statement has been revised to include RNA catalysts called **ribozymes**. In fact, many scientists now believe that the earliest enzymes were molecules of catalytic, self-replicating RNA and that these molecules were present in primitive cells even before the existence of DNA.

The first evidence came in 1981, when Thomas Cech and his colleagues at the University of Colorado discovered an apparent exception to the “all enzymes are proteins” rule. They were studying the removal of an internal segment of RNA known as an intron from a specific ribosomal RNA precursor (pre-rRNA) in *Tetrahymena thermophila*, a single-celled eukaryote. In the course of their work, the researchers made the remarkable observation that the process proceeded without the presence of proteins! They showed that the removal of a 413-nucleotide internal segment of RNA from the *Tetrahymena* pre-rRNA is catalyzed by the pre-rRNA molecule itself and is therefore an example of *autocatalysis*.

Two years later, another RNA-based catalyst was discovered in the laboratory of Sidney Altman at Yale University, which was studying *ribonuclease P*, an enzyme that cleaves transfer RNA precursors (pre-tRNAs) to yield functional RNA molecules. It had been known that ribonuclease P consisted of a protein component and an RNA component, and it was generally assumed that the active site was on the protein component. By isolating the components and studying them separately, however, Altman and his colleagues showed unequivocally that only the isolated RNA component was capable of catalyzing the specific cleavage of tRNA precursors on its own. Furthermore, the RNA-catalyzed reaction followed Michaelis–Menten kinetics, further evidence that the RNA component was acting like a true enzyme. (The protein component enhances activity but is not required for either substrate binding or cleavage.)

The significance of these findings was recognized by the Nobel Prize that Cech and Altman shared in 1989 for their discovery of ribozymes. Since these initial discoveries, additional examples of ribozymes have been reported. Of special significance is the active site for a crucial step in protein synthesis by ribosomes. The large ribosomal subunit (see Figure 4-22) is the site of the peptidyl transferase activity that catalyzes peptide bond formation.

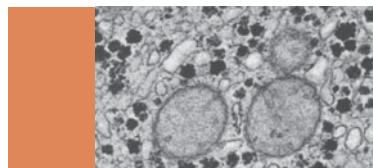

The active site for this peptidyl transferase activity was for a long time assumed to be located on one of the protein molecules of the large subunit, with the rRNA providing a scaffold for structural support. However, in 1992, Harry Noller and his colleagues at the University of California, Santa Cruz, demonstrated that, despite the removal of at least 95% of the protein from the large ribosomal subunit, it retained 80% of the peptidyl transferase of the intact subunit. This strongly suggested that one of the rRNA molecules was the catalyst.

Furthermore, the activity was destroyed by treatment with ribonuclease, an enzyme that degrades RNA, but was

not affected by proteinase K, an enzyme that degrades protein. Thus, the peptidyl transferase activity responsible for peptide bond formation in ribosomal protein synthesis is due to the rRNA, now known to be a ribozyme. It appears the function of the ribosomal proteins is to provide support and stabilization for the catalytic RNA, not the other way around! This supports the idea that RNA-based catalysis preceded protein-based catalysis.

The discovery of ribozymes has markedly changed the way we think about the origin of life on Earth. For many years, scientists had speculated that the first

catalytic macromolecules must have been amino acid polymers resembling proteins. But this concept immediately ran into difficulty because there was no obvious way for a primitive protein to carry information or to replicate itself, which are two primary attributes of life. However, if the first catalysts were RNA rather than protein molecules, it becomes conceptually easier to imagine an “RNA world” in which RNA molecules acted both as catalysts and as replicating systems capable of transferring information from generation to generation.

SUMMARY OF KEY POINTS

Activation Energy and the Metastable State

- While thermodynamics allows us to assess the feasibility of a reaction, it says nothing about the likelihood that the reaction will actually occur at a reasonable rate in the cell.
- For a given chemical reaction to occur in the cell, substrates must reach the transition state, which has a higher free energy than either the substrates or products. Reaching the transition state requires the input of activation energy.
- Because of this activation energy barrier, most biological compounds exist in an unreactive, metastable state. To ensure that the activation energy requirement is met and the transition state is achieved, a catalyst is required, which is always an enzyme in biological systems.

Enzymes as Biological Catalysts

- Catalysts, whether inorganic or organic, act by forming transient complexes with substrate molecules that lower the activation energy barrier and rapidly increase the rate of the particular reaction.
- Chemical reactions in cells are catalyzed by enzymes, which in some cases require organic or inorganic cofactors for activity. The vast majority of enzymes are proteins, but a few are composed of RNA and are known as ribozymes.
- Enzymes are exquisitely specific, either for a single specific substrate or for a class of closely related compounds. This is because the actual catalytic process takes place at the active site—a pocket or groove on the enzyme surface that only the correct substrates will fit into.
- The active site is composed of specific, noncontiguous amino acids that become positioned near each other as the protein folds into its tertiary structure. These amino acids are responsible for substrate binding, substrate activation, and catalysis.
- Binding of the appropriate substrate at the active site causes a change in the shape of the enzyme and substrate known as induced fit. This facilitates substrate activation, often by

distorting one or more bonds in the substrate, by bringing necessary amino acid side chains into the active site, or by transferring protons and/or electrons between the enzyme and substrate.

Enzyme Kinetics

- An enzyme-catalyzed reaction proceeds via an enzyme-substrate intermediate. Most reactions follow Michaelis-Menten kinetics, characterized by a hyperbolic relationship between the initial reaction velocity v and the substrate concentration $[S]$.
- The upper limit on velocity is called V_{max} , and the substrate concentration needed to reach one-half of this maximum velocity is termed the Michaelis constant, K_m . The hyperbolic relationship between v and $[S]$ can be linearized by a double-reciprocal equation and plot, from which V_{max} and K_m can be determined graphically.
- Enzyme activity is sensitive to temperature, pH, and the ionic environment. Enzyme activity is also influenced by substrate availability, products, alternative substrates, substrate analogues, drugs, and toxins, most of which have an inhibitory effect.
- Irreversible inhibition involves covalent bonding of the inhibitor to the enzyme surface, permanently disabling the enzyme. A reversible inhibitor, on the other hand, binds noncovalently to an enzyme in a reversible manner, either at the active site (competitive inhibition) or elsewhere on the enzyme surface (noncompetitive inhibition).

Enzyme Regulation

- Enzymes must be regulated to adjust their activity levels to cellular needs. Substrate-level regulation involves the effects of substrate and product concentrations on the reaction rate. Additional control mechanisms include allosteric regulation and covalent modification.

- Most allosterically regulated enzymes catalyze the first step in a reaction sequence and are multisubunit proteins with both catalytic subunits and regulatory subunits. Each of the catalytic subunits has an active site that recognizes substrates, whereas each regulatory subunit has one or more allosteric sites that recognize specific effector molecules.
- Allosteric enzymes exist in an equilibrium between a low-activity and a high-activity form. A given effector binds to and stabilizes one of these two forms and therefore will either inhibit or activate the enzyme, depending on which form of the enzyme is bound by the effector.
- Enzyme inhibitors can act either irreversibly or reversibly. Irreversible inhibitors bind covalently to the enzyme, causing a permanent loss of activity. Reversible inhibitors bind noncovalently either to the active site (competitive inhibitors such as substrate analogs) or to a separate site on the enzyme (noncompetitive inhibition).
- Enzymes can also be regulated by covalent modification. The most common covalent modifications include

phosphorylation, as seen with glycogen phosphorylase, and proteolytic cleavage, as occurs in the activation of proteolytic pancreatic zymogens.

RNA Molecules as Enzymes: Ribozymes

- Although it was long thought that all enzymes were proteins, we now recognize the catalytic properties of certain RNA molecules called ribozymes.
- These include some rRNA molecules that are able to catalyze the removal of their own introns, RNA components of enzymes that also contain protein components, and the rRNA component of the large ribosomal subunit.
- The discovery of ribozymes has changed the way we think about the origin of life on Earth because RNA molecules, unlike proteins, can both carry information and replicate themselves.

MAKING CONNECTIONS

In Chapter 5, we learned that thermodynamic principles can be used to tell us whether a particular cellular reaction is feasible but not whether or at what rate the reaction will happen. In this chapter, we have just learned how enzymes make these reactions happen. All the macromolecules we studied in earlier chapters, and most of the cellular components we will learn about later, are produced using enzymes. In the next two chapters, we will take a detailed look at cell membranes and will see that many membranes contain enzymes as integral components. Also, many membrane transporters have enzymatic activities, such as the ATPases that provide energy for moving materials across membranes. We will use our knowledge of enzyme structure, function, and regulation extensively in Chapters 9 through 11 when we study glycolysis, fermentation, aerobic respiration, and photosynthesis in detail. Each of these biochemical pathways is an ordered sequence of highly regulated, enzyme-catalyzed steps. Each step

involves the recognition, binding, and activation of specific substrates and the subsequent conversion of substrates to specific products. Throughout the rest of this text, we will encounter enzymes everywhere we look. We will see how they are involved in protein and lipid synthesis, processing, and packaging in Chapter 12, and learn details of their involvement in cell signaling mechanisms in the following two chapters. Later, we will see how assembly of the cytoskeleton and cellular motility likewise depend on enzymatic activities, as do synthesis of the extracellular matrix of animal cells and the cell walls of plants. When we study DNA replication and gene expression, we will see how a number of enzymes are highly regulated to ensure proper transmission of genetic information and precise control of cell function. Finally, when we study the development of cancer, we will see that often it is the result of defects in cellular enzymes such as proteases, protein kinases, and DNA repair enzymes.

PROBLEM SET

More challenging problems are marked with a •.

6-1 The Need for Enzymes. You should now be in a position to appreciate the difference between the thermodynamic feasibility of a reaction and the likelihood that it will actually proceed.

(a) Many reactions that are thermodynamically possible do not occur at an appreciable rate because of the activation energy required for the reactants to achieve the transition state. In molecular terms, what does this mean?

- (b) One way to meet this requirement is by an input of heat, which in some cases need only be an initial, transient input. Give an example, and explain what this accomplishes in molecular terms.
- (c) An alternative solution is to lower the activation energy. What does it mean in molecular terms to say that a catalyst lowers the activation energy of a reaction?
- (d) Organic chemists often use inorganic catalysts such as nickel, platinum, or cations in their reactions, whereas cells

use proteins called enzymes. What advantages can you see to the use of enzymes? Can you think of any disadvantages?

- (e) Some enzymes can transfer a hydrogen atom without lowering the activation energy barrier. How is this possible?

6-2 Activation Energy. As shown in Reaction 6-2, hydrogen peroxide, H_2O_2 , decomposes to H_2O and O_2 . The activation energy, E_A , for the uncatalyzed reaction at 20°C is 18 kcal/mol. The reaction can be catalyzed either by ferric ions ($E_A = 13$ kcal/mol) or by the enzyme *catalase* ($E_A = 7$ kcal/mol).

- (a) Draw an activation energy diagram for this reaction under catalyzed and uncatalyzed conditions, and explain what it means for the activation energy to be lowered from 18 to 13 kcal/mol by ferric ions but from 18 to 7 kcal/mol by catalase.
 (b) Suggest two properties of catalase that make it a more suitable intracellular catalyst than ferric ions.
 (c) Suggest yet another way that the rate of hydrogen peroxide decomposition can be accelerated. Is this a suitable means of increasing reaction rates within cells? Why or why not?

6-3 Rate Enhancement by Catalysts. The decomposition of H_2O_2 to H_2O and O_2 shown in Reaction 6-2 can be catalyzed either by an inorganic catalyst (ferric ions) or by the enzyme catalase. Compared with the uncatalyzed rate, this reaction proceeds about 30,000 times faster in the presence of ferric ions but about 100,000,000 times faster in the presence of catalase, an iron-containing enzyme. Assume that 1 μg of catalase can decompose a given quantity of H_2O_2 in 1 minute at 25°C and that all reactions are carried out under sterile conditions.

- (a) How long would it take for the same quantity of H_2O_2 to be decomposed in the presence of an amount of ferric ions equivalent to the iron content of 1 μg of catalase?
 (b) How long would it take for the same quantity of H_2O_2 to decompose in the absence of a catalyst?
 (c) Explain how these calculations illustrate the indispensability of catalysts and the superiority of enzymes over inorganic catalysts.

6-4 Temperature and pH Effects. Figure 6-4 illustrates enzyme activities as functions of temperature and pH. In general, the activity of a specific enzyme is highest at the temperature and pH that are characteristic of the environment in which the enzyme normally functions.

- (a) Explain the shapes of the curves in Figure 6-4 in terms of the major chemical or physical factors that affect enzyme activity.
 (b) For each enzyme in Figure 6-4, suggest the adaptive advantage of having the enzyme activity profile shown in the figure.
 (c) Some enzymes have a very flat pH profile—that is, they have essentially the same activity over a broad pH range. How might you explain this observation?

6-5 Michaelis–Menten Kinetics. Figure 6-19 represents a Michaelis–Menten plot for a typical enzyme, with initial reaction velocity plotted as a function of substrate concentration. Three regions of the curve are identified by the letters A, B, and C.

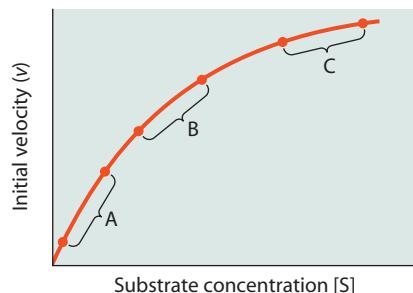

FIGURE 6-19 Analysis of the Michaelis–Menten Plot. See Problem 6-5.

For each of the statements that follow, indicate with a single letter which one of the three regions of the curve fits the statement best. A given letter can be used more than once.

- (a) The active site of an enzyme molecule is occupied by substrate most of the time.
 (b) The active site of an enzyme molecule is free most of the time.
 (c) This is the range of substrate concentration in which most enzymes usually function in normal cells.
 (d) This includes the point (K_m , $V_{max}/2$).
 (e) Reaction velocity is limited mainly by the number of enzyme molecules present.
 (f) Reaction velocity is limited mainly by the number of substrate molecules present.

6-6 Enzyme Kinetics. The enzyme β -galactosidase catalyzes the hydrolysis of the disaccharide lactose into its component monosaccharides:

To determine V_{max} and K_m of β -galactosidase for lactose, the same amount of enzyme (1 μg per tube) was incubated with a series of lactose concentrations under conditions where product concentrations remained negligible. At each lactose concentration, the initial reaction velocity was determined by assaying for the amount of lactose remaining at the end of the assay. The following data were obtained:

Lactose concentration (mM)	Rate of lactose consumption ($\mu\text{mol}/\text{min}$)
1	10.0
2	16.7
4	25.0
8	33.3
16	40.0
32	44.4

- (a) Why is it necessary to specify that product concentrations remained negligible during the course of the reaction?
 (b) Plot v (rate of lactose consumption) versus $[S]$ (lactose concentration). Why is it that when the lactose concentration is doubled, the increase in velocity is always less than twofold?
 (c) Calculate $1/v$ and $1/[S]$ for each entry on the data table, and plot $1/v$ versus $1/[S]$.

- (d) Determine K_m and V_{max} from your double-reciprocal plot.
 (e) On the same graph as part b, plot the results you would expect if each tube contained only 0.5 μg of enzyme. Explain your graph.

6-7 More Enzyme Kinetics. The galactose formed in Reaction 6-17 can be phosphorylated by the transfer of a phosphate group from ATP, a reaction catalyzed by the enzyme galactokinase:

Assume that you have isolated the galactokinase enzyme and have determined its kinetic parameters by varying the concentration of galactose in the presence of a constant, high (i.e., saturating) concentration of ATP. The double-reciprocal (Lineweaver–Burk) plot of the data is shown as **Figure 6-20**.

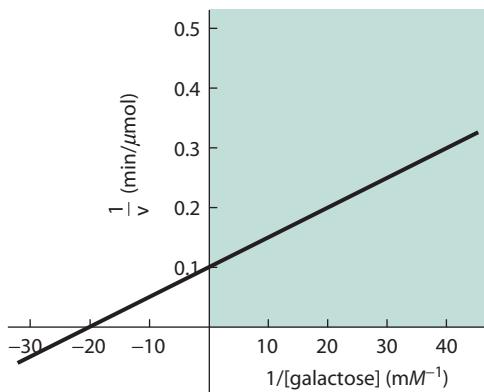

FIGURE 6-20 Double-Reciprocal Plot for the Enzyme Galactokinase. See Problem 6-7.

- (a) What is the K_m of galactokinase for galactose under these assay conditions? What does K_m tell us about the enzyme?
 (b) What is the V_{max} of the enzyme under these assay conditions? What does V_{max} tell us about the enzyme?
 (c) Assume that you now repeat the experiment, but with the ATP concentration varied and galactose present at a constant, high concentration. Assuming that all other conditions are maintained as before, would you expect to get the same V_{max} value as in part b? Why or why not?
 (d) In the experiment described in part c, the K_m value turned out to be very different from the value determined in part b. Can you explain why?

6-8 Turnover Number. Carbonic anhydrase catalyzes the reversible hydration of carbon dioxide to form bicarbonate ion:

As we will discover in Chapter 8, this reaction is important in the transport of carbon dioxide from body tissues to the lungs by red blood cells. Carbonic anhydrase has a molecular weight of 30,000 and a turnover number (k_{cat} value) of $1 \times 10^6 \text{ sec}^{-1}$. Assume that you are given 1 mL of a solution containing 2.0 μg of pure carbonic anhydrase.

- (a) At what rate (in millimoles of CO_2 consumed per second) will you expect this reaction to proceed under optimal conditions?
 (b) Assuming standard temperature and pressure, how much CO_2 is that in mL per second?

6-9 Inhibitors: Wrong Again. For each of the following false statements, change the statement to make it true and explain your reasoning.

- (a) Diisopropyl fluorophosphate binds covalently to the hydroxyl group of a specific amino acid residue of the target enzyme and is therefore almost certainly an allosteric effector.
 (b) The enzyme hexokinase is inhibited by its own product, glucose-6-phosphate, and is therefore an example of feedback inhibition.
 (c) Glycogen synthase, like glycogen phosphorylase, is active in the phosphorylated form and inactive in the dephosphorylated form.
 (d) An enzyme that is subject to allosteric activation is most likely to catalyze the final reaction in a biosynthetic pathway.
 (e) If researchers claim that an enzyme is allosterically activated by compound A and allosterically inhibited by compound B, one of these claims must be wrong.

6-10 What Type of Inhibition? A new mucinase enzyme was recently discovered that breaks down a glycoprotein in mucous membranes and contributes to bacterial vaginosis (*J. Clin. Microbiol.* 43:5504). You are a research pathologist testing a new inhibitor of this enzyme that you have discovered and want to design experiments to understand the nature of this inhibition. You have a supply of the normal glycoprotein substrate, the inhibitor, and an assay to measure product formation.

- (a) How might you determine whether inhibition is reversible or irreversible?
 (b) If you find that the inhibition is reversible, how would you determine whether the inhibition is competitive or noncompetitive?

6-11 Biological Relevance. Explain the biological relevance of each of the following observations concerning enzyme regulation.

- (a) When you need a burst of energy, the hormones epinephrine and glucagon are secreted into your bloodstream and circulated to your muscle cells, where they initiate a cascade of reactions that leads to the phosphorylation of the inactive *b* form of glycogen phosphorylase, thereby converting the enzyme into the active *a* form.
 (b) Even in the *a* form, glycogen phosphorylase is allosterically inhibited by a high concentration of glucose or ATP within a specific liver cell.
 (c) Your pancreas synthesizes and secretes the proteolytic enzyme carboxypeptidase in the form of an inactive precursor called procarboxypeptidase, which is activated as a result of proteolytic cleavage by the enzyme trypsin in the duodenum of your small intestine.

• 6-12 Derivation of the Michaelis–Menten Equation. For the enzyme-catalyzed reaction in which a substrate S is converted into a product P (see Reaction 6-5), velocity can be defined as the disappearance of substrate or the appearance of product per unit time:

$$v = -\frac{d[S]}{dt} = +\frac{d[P]}{dt} \quad (6-20)$$

Beginning with this definition and restricting your consideration to the initial stage of the reaction when [P] is essentially zero,

derive the Michaelis–Menten equation (see Equation 6-7). The following points may help you in your derivation:

- (a) Begin by expressing the rate equations for $d[S]/dt$, $d[P]/dt$, and $d[ES]/dt$ in terms of concentrations and rate constants.
- (b) Assume a steady state at which the enzyme-substrate complex of Reaction 6-6 is being broken down at the same rate as it is being formed such that the net rate of change, $d[ES]/dt$, is zero.
- (c) Note that the total amount of enzyme present, E_t , is the sum of the free form, E_f , plus the amount of complexed enzyme ES: $E_t = E_f + ES$.
- (d) When you get that far, note that V_{max} and K_m can be defined as follows:

$$V_{max} = k_3[E_t] \quad K_m = \frac{k_2 + k_3}{k_1} \quad (6-21)$$

• **6-13 Linearizing Michaelis and Menten.** In addition to the Lineweaver–Burk plot (see Figure 6-10), two other straight-line forms of the Michaelis–Menten equation are sometimes used. The Eadie–Hofstee plot is a graph of $v/[S]$ versus v (see Figure 6-11), and the Hanes–Woolf plot graphs $[S]/v$ versus $[S]$.

- (a) In both cases, show that the equation being graphed can be derived from the Michaelis–Menten equation by simple arithmetic manipulation.
- (b) In both cases, indicate how K_m and V_{max} can be determined from the resulting graph.
- (c) Make a Hanes–Woolf plot, with the intercepts and slope labeled as for the Lineweaver–Burk and Eadie–Hofstee plots (see Figures 6-10 and 6-11). Can you suggest why the Hanes–Woolf plot is the most statistically satisfactory of the three?

Membranes: Their Structure, Function, and Chemistry

An essential feature of every cell is the presence of **membranes** that define the boundaries of the cell and its various internal compartments. Even the casual observer of electron micrographs is likely to be struck by the prominence of membranes around and within cells, especially those of eukaryotic organisms (Figure 7-1). In Chapter 3, we encountered the structural molecules that allow membranes to be formed and began to study membranes and membrane-bounded organelles in Chapter 4. Now we are ready to look at membrane structure and function in greater detail. In this chapter, we will examine the molecular structure of membranes and explore the multiple roles that membranes play in the life of the cell. In Chapter 8, we will discuss the transport of solutes across membranes, with an emphasis on the mechanisms involved.

The Functions of Membranes

We begin our discussion by noting that biological membranes play five related yet distinct roles, as illustrated in Figure 7-2. ① They define the boundaries of the cell and its organelles and act as permeability barriers. ② They serve as sites for specific biochemical functions, such as electron transport during mitochondrial respiration or protein processing in the ER. ③ Membranes also possess transport proteins that regulate the movement of substances into and out of the cell and its organelles. ④ In addition, membranes contain the protein molecules that act as receptors to detect external signals. ⑤ Finally, they provide mechanisms for cell-to-cell contact, adhesion, and communication. Each of these functions is described briefly in the following five sections.

Membranes Define Boundaries and Serve as Permeability Barriers

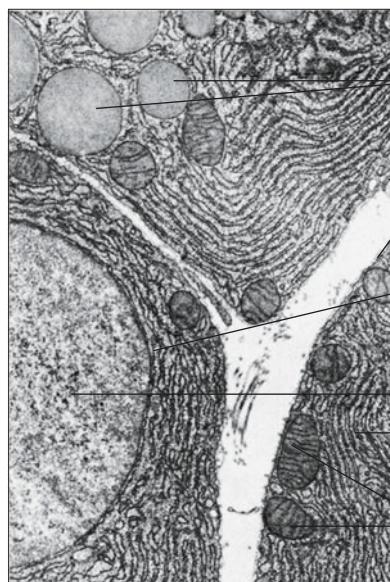

One of the most obvious functions of membranes is to define the boundaries of the cell and its compartments

and to serve as permeability barriers. The interior of the cell must be physically separated from the surrounding environment, not only to keep desirable substances in the cell but also to keep undesirable substances out. Membranes serve this purpose well because the hydrophobic interior of the membrane is an effective permeability barrier for hydrophilic molecules and ions. The permeability barrier for the cell as a whole is the **plasma** (or **cell**) **membrane**, a membrane that surrounds the cell and regulates the passage of materials both into and out of cells. In addition to the plasma membrane, various **intracellular membranes** serve to compartmentalize functions within eukaryotic cells.

Recently, there has been much interest in a class of *antimicrobial peptides* (AMPs), which are small molecules of 10–50 amino acids that can affect this permeability barrier. Over 1200 different AMPs are known, with more than 20 being produced by human skin alone. One class of AMPs consists of cationic, amphipathic molecules that disrupt bacterial membrane structure by interacting with the negatively charged phospholipids in their cell membranes. These AMPs thus act like detergents and disrupt the membrane structure, causing holes to form that destroy the cell's permeability barrier and kill the cells. Some AMPs have shown promise as antiviral agents in disrupting the outer covering of membrane-enclosed viruses such as the human immunodeficiency virus (HIV).

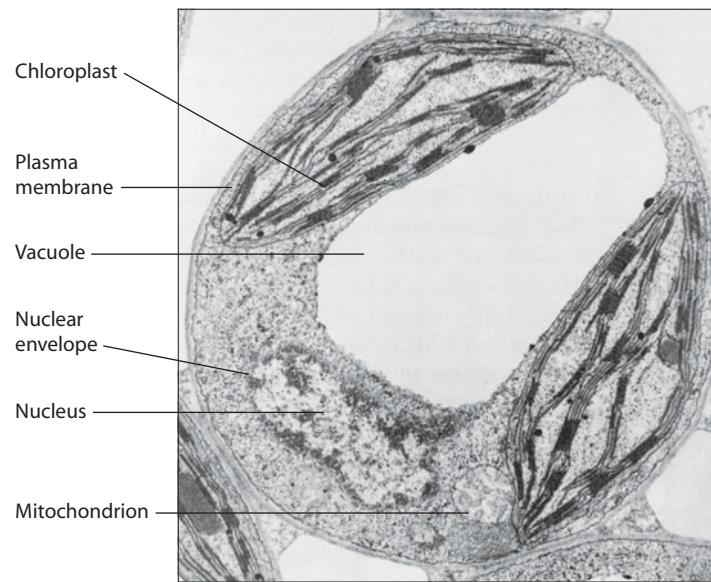

Membranes Are Sites of Specific Proteins and Therefore of Specific Functions

Membranes have specific functions associated with them because the molecules and structures responsible for those functions—proteins, in most cases—are either embedded in or localized on membranes. One of the most useful ways to characterize a specific membrane, in fact, is to describe the particular enzymes, transport proteins, receptors, and other molecules associated with it.

(a) Rat pancreas cells

5 μm

(b) Plant leaf cell

5 μm

FIGURE 7-1 The Prominence of Membranes Around and Within Eukaryotic Cells. Among the structures of eukaryotic cells that involve membranes are the plasma membrane, nucleus, chloroplasts, mitochondria, endoplasmic reticulum (ER), secretory granules, and vacuoles. These structures are shown here in (a) portions of three cells from a rat pancreas and (b) a plant leaf cell (TEMs).

For example, many distinctive enzymes are present in or on the plasma membrane or the membranes of particular organelles. Such enzymes are often useful as *markers* to identify particular membranes during the isolation of organelles and organelle membranes from suspensions of disrupted cells (see Box 12A, pages 327–329). For example, *glucose-6-phosphatase* is a membrane-bound enzyme found in the endoplasmic reticulum, and its presence in,

say, a preparation of mitochondria would demonstrate contamination with ER membranes.

Other functions associated with specific membranes are a direct result of the particular proteins present in these membranes. For example, the plasma membrane contains the enzymes that synthesize the cell wall of plants, fungi, and bacteria. In vertebrate cells, the plasma membrane contains enzymes that secrete the materials that make up the extracellular matrix. Other membrane proteins, such as those in chloroplast and mitochondrial membranes or in the bacterial plasma membrane, are critical for energy-generating processes such as photosynthesis and respiration.

Membrane Proteins Regulate the Transport of Solutes

Another function of membrane proteins is to carry out and regulate the *transport* of substances into and out of cells and their organelles. Nutrients, ions, gases, water, and other substances are taken up into various compartments, and various products and wastes must be removed. While lipophilic molecules, very small molecules, and gases can typically diffuse directly across cellular membranes, most substances needed by the cell require transport proteins that recognize and transport a specific molecule or a group of similar molecules.

For example, cells may have specific transporters for glucose, amino acids, or other nutrients. Your nerve cells transmit electrical signals as Na^+ and K^+ ions are transported across the plasma membrane of neurons by specific ion channel proteins. Transport proteins in muscle cells move calcium ions across membranes to assist in muscle

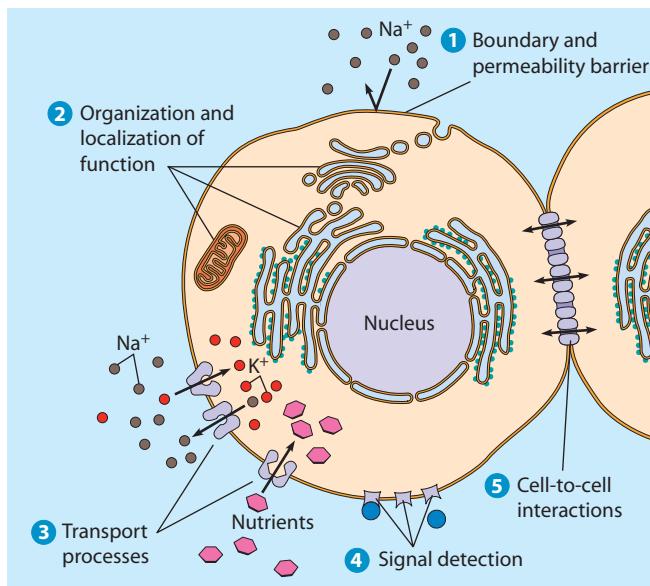

FIGURE 7-2 Functions of Membranes. Membranes not only define the cell and its organelles but also have a number of important functions, including transport, signaling, and adhesion.

contraction. The chloroplast membrane has a transporter specific for the phosphate ions needed for ATP synthesis, and the mitochondrion has transporters for intermediates involved in aerobic respiration. There is even a specific transporter for water—known as an aquaporin—that can rapidly transport water molecules through membranes of kidney cells to facilitate urine production.

Molecules as large as proteins and RNA can be transferred across membranes by transport proteins. Proteins form the nuclear pore complexes in the nuclear envelope through which mRNA molecules and partially assembled ribosomes can move from the nucleus to the cytosol. In some cases, proteins that are synthesized on the endoplasmic reticulum or in the cytosol can be imported into lysosomes, peroxisomes, or mitochondria via transport proteins. In other cases, proteins in the membranes of intracellular vesicles facilitate the movement of molecules such as neurotransmitters either into the cell or out of the cell.

Membrane Proteins Detect and Transmit Electrical and Chemical Signals

Cells receive information from their environment, usually in the form of electrical or chemical signals that impinge on the outer surface of the cell. The nerve impulses being sent from your eyes to your brain as you read these words are examples of such signals, as are the various hormones present in your circulatory system. *Signal transduction* is the term used to describe the specific mechanisms used to transmit such signals from the outer surface of cells to the cell interior.

Many chemical signal molecules bind to specific membrane proteins known as *receptors* on the outer surface of the plasma membrane. Binding of these signal molecules to their receptors triggers specific chemical events on the inner surface of the membrane that lead to changes in cell function. For example, muscle and liver cell membranes contain insulin receptors and can therefore respond to this hormone, which helps cells take in glucose. White blood cells have specific receptors that recognize chemical signals from bacteria and initiate a cellular defense response.

Many plant cells have a transmembrane receptor protein that detects the gaseous hormone ethylene and transmits a signal to the cell that can affect a variety of processes including seed germination, fruit ripening, and defense against pathogens. Bacteria often have plasma membrane receptors that sense nutrients in the environment and can signal the cell to move toward these nutrients. Thus, membrane receptors allow cells to recognize, transmit, and respond to a variety of specific signals in nearly all types of cells.

Membrane Proteins Mediate Cell Adhesion and Cell-to-Cell Communication

Membrane proteins also mediate adhesion and communication between adjacent cells. Although textbooks often depict cells as separate, isolated entities, most cells in multicellular

organisms are in contact with other cells. During embryonic development, specific cell-to-cell contacts are critical and, in animals, are often mediated by membrane proteins known as *cadherins*. Cadherins have extracellular sequences of amino acids that bind calcium ions and stimulate adhesion between similar cells in a tissue. However, some pathogenic bacteria, such as some species of *Listeria* and *Shigella*, take advantage of adhesive membrane proteins to attach to and invade intestinal cells and cause disease.

Other types of membrane proteins in animal tissues form *adhesive junctions*, which hold cells together, and *tight junctions*, which form seals that block the passage of fluids between cells. Membrane proteins such as *ankyrin* can also be points of attachment to the cell cytoskeleton, lending rigidity to tissues. In addition, cells within a particular tissue often have direct cytoplasmic connections that allow the exchange of at least some cellular components. This intercellular communication is provided by *gap junctions* in animal cells and by *plasmodesmata* in plant cells. We will learn about all these structures when we move “beyond the cell” in Chapter 17.

All the functions we have just considered—compartmentalization, localization of function, transport, signal detection, and intercellular communication—depend on the chemical composition and structural features of membranes. It is to these topics that we now turn as we consider how our present understanding of membrane structure developed.

Models of Membrane Structure: An Experimental Perspective

Until electron microscopy was applied to the study of cell structure in the early 1950s, no one had ever seen a membrane. Yet indirect evidence led biologists to postulate the existence of membranes long before they could actually be seen. In fact, researchers have been trying to understand the molecular organization of membranes for more than a century. The intense research effort paid off, however, because it led eventually to the *fluid mosaic model* of membrane structure. This model, which is now thought to be descriptive of all biological membranes, envisions a membrane as two quite fluid layers of lipids, with proteins localized within and on the lipid layers and oriented in a specific manner with respect to the inner and outer membrane surfaces. Although the lipid layers are turning out to be much more complex than originally thought, the basic model is almost certainly correct as presently envisioned.

Before looking at the model in detail, we will describe some of the central experiments leading to this view of membrane structure and function. As we do so, you may also gain some insight into how such developments come about, as well as a greater respect for the diversity of approaches and techniques that are often important in advancing our understanding of biological phenomena. **Figure 7-3** presents a chronology of membrane studies

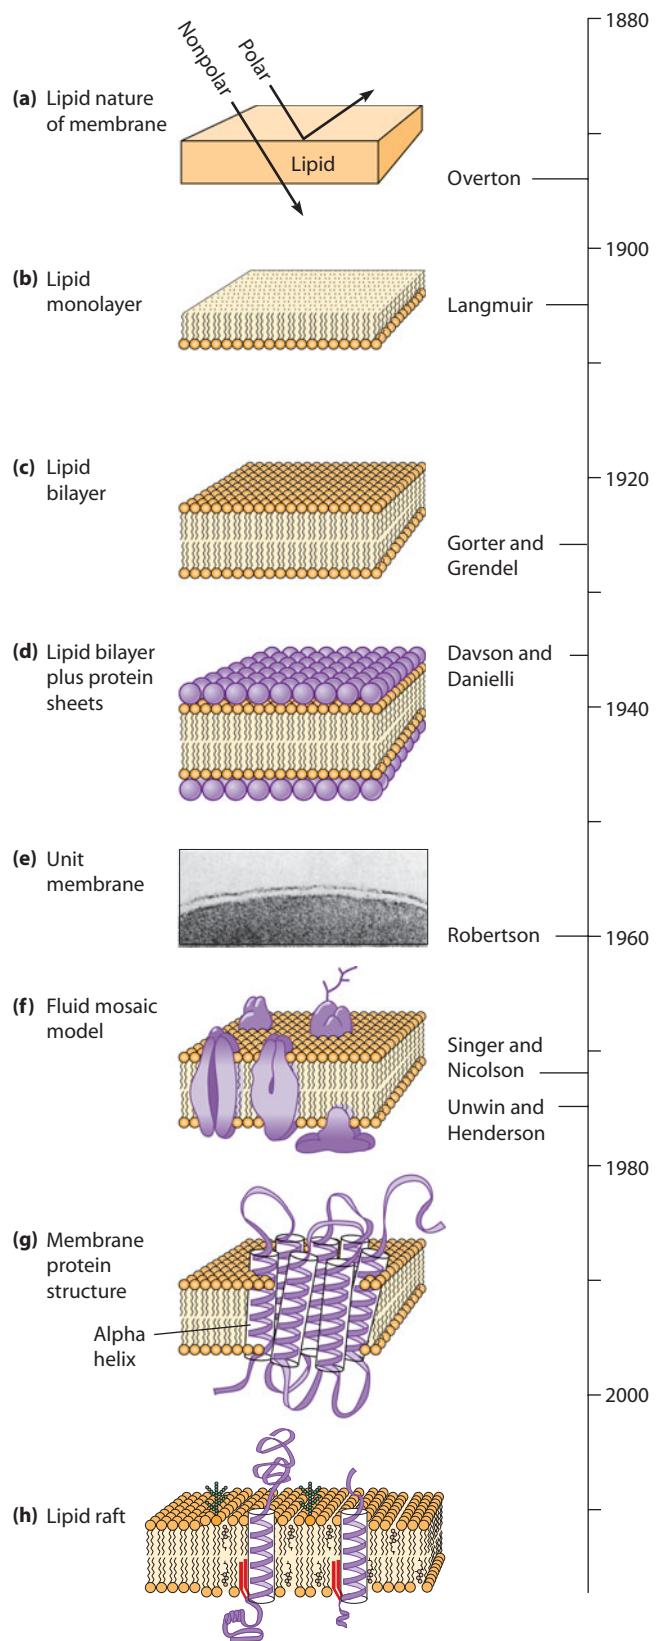

FIGURE 7-3 Timeline for Development of the Fluid Mosaic Model. The fluid mosaic model of membrane structure that Singer and Nicolson proposed in 1972 was the culmination of studies dating back to the 1890s (a)–(e). This model (f) has been significantly refined by subsequent studies (g and h).

that began over a century ago and led eventually to our current understanding of membranes as fluid mosaics.

Overton and Langmuir: Lipids Are Important Components of Membranes

A good starting point for our experimental overview is the pioneering work of German scientist Charles Ernest Overton in the 1890s. Working with cells of plant root hairs, he observed that lipid-soluble substances penetrate readily into cells, whereas water-soluble substances do not. From his studies, Overton concluded that lipids are present on the cell surface as some sort of “coat” (Figure 7-3a). He even suggested that cell coats are probably mixtures of cholesterol and lecithin, an insight that proved to be remarkably farsighted in light of what we now know about the prominence of sterols and phospholipids as membrane components.

A second important advance came about a decade later through the work of Irving Langmuir, who studied the behavior of purified phospholipids by dissolving them in benzene and layering samples of the benzene-lipid solution onto a water surface. As the benzene evaporated, the molecules were left as a lipid film one molecule thick—that is, a “monolayer.” Because phospholipids are *amphiphatic* molecules (see Figure 2-11), Langmuir reasoned that the phospholipids orient themselves on water such that their hydrophilic heads face the water and their hydrophobic tails protrude away from the water (Figure 7-3b). Langmuir’s lipid monolayer became the basis for further thought about membrane structure in the early years of the twentieth century.

Gorter and Grendel: The Basis of Membrane Structure Is a Lipid Bilayer

The next major advance came in 1925 when two Dutch physiologists, Evert Gorter and F. Grendel, extracted the lipids from a known number of erythrocytes (red blood cells) and used Langmuir’s method to spread the lipids as a monolayer on a water surface. They found that the area of the lipid film on the water was about twice the estimated total surface area of the erythrocyte. Therefore, they concluded that the erythrocyte plasma membrane consists of not one but *two* layers of lipids.

Hypothesizing a bilayer structure, Gorter and Grendel reasoned that it would be thermodynamically favorable for the nonpolar hydrocarbon chains of each layer to face inward, away from the aqueous milieu on either side of the membrane. The polar hydrophilic groups of each layer would then face outward, toward the aqueous environment on either side of the membrane (Figure 7-3c). Gorter and Grendel’s experiment and their conclusions were momentous because this work represented the first attempt to understand membranes at the molecular level. Moreover, the **lipid bilayer** they envisioned became the

basic underlying assumption for each successive refinement in our understanding of membrane structure.

Davson and Danielli: Membranes Also Contain Proteins

Shortly after Gorter and Grendel proposed their bilayer model in 1925, it became clear that a simple lipid bilayer, could not explain all the properties of membranes—particularly those related to *surface tension*, *solute permeability*, and *electrical resistance*. For example, the surface tension of a lipid film was significantly higher than that of cellular membranes but could be lowered by adding protein to the lipid film. Moreover, sugars, ions, and other hydrophilic solutes readily moved into and out of cells even though pure lipid bilayers are nearly impermeable to water-soluble substances.

To explain such differences, Hugh Davson and James Danielli suggested that proteins are present in membranes. They proposed in 1935 that biological membranes consist of lipid bilayers that are coated on both sides with thin sheets of protein (Figure 7-3d). Their model, a protein-lipid-protein “sandwich,” was the first detailed representation of membrane organization and dominated the thinking of cell biologists for the next several decades.

The original model was later modified to accommodate additional findings. Particularly notable was the suggestion, made in 1954, that hydrophilic proteins might penetrate into the membrane in places to provide polar pores through an otherwise hydrophobic bilayer. These proteins could then allow water-soluble substances to cross the cell membrane. Specifically, the lipid interior accounted for the hydrophobic properties of membranes, and the protein components explained their hydrophilic properties.

The real significance of the Davson–Danielli model, however, was that it recognized the importance of proteins in membrane structure. This feature, more than any other, made the Davson–Danielli sandwich the basis for much subsequent research on membrane structure.

Robertson: All Membranes Share a Common Underlying Structure

With the advent of electron microscopy in the 1950s, cell biologists could finally verify the presence of a plasma membrane around each cell. They could also observe that most subcellular organelles are bounded by similar membranes. Furthermore, when membranes were stained with osmium, a heavy metal, and then examined closely at high magnification, they were found to have extensive regions of “railroad track” structure that appeared as two dark lines separated by a lightly stained central zone, with an overall thickness of 6–8 nm. This pattern is seen in **Figure 7-4** for the plasma membranes of two adjacent cells that are separated from each other by a thin intercellular space. Because this same staining pattern was observed with many different kinds of

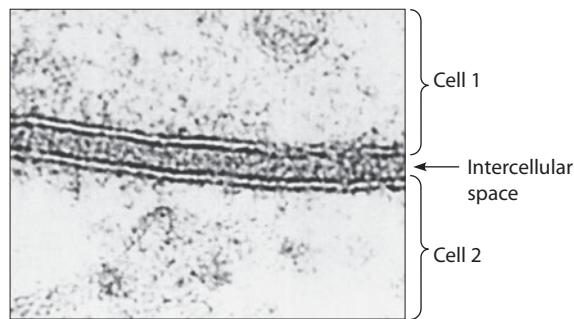

FIGURE 7-4 Trilaminar Appearance of Cellular Membranes.

This electron micrograph of a thin section through two adjacent cells shows their plasma membranes separated by a small intercellular space. Each membrane appears as two dark lines separated by a lightly stained central zone in a staining pattern that gives each membrane a trilaminar, or “railroad track,” appearance (TEM).

membranes, J. David Robertson suggested that all cellular membranes share a common underlying structure, which he called the *unit membrane* (see Figure 7-3e).

When first proposed, the unit membrane structure seemed to agree remarkably well with the Davson–Danielli model. Robertson suggested that the lightly stained space (between the two dark lines of the trilaminar pattern) contains the hydrophobic region of the lipid molecules, which do not readily stain. Conversely, the two dark lines were thought to represent phospholipid head groups and the thin sheets of protein bound to the membrane surfaces, which appear dark because of their affinity for heavy metal stains. This interpretation appeared to provide strong support for the Davson–Danielli view that a membrane consists of a lipid bilayer coated on both surfaces with thin sheets of protein.

Further Research Revealed Major Shortcomings of the Davson–Danielli Model

Despite its apparent confirmation by electron microscopy and its extension to all membranes by Robertson, the Davson–Danielli model encountered difficulties in the 1960s as more and more data emerged that could not be reconciled with their model. Based on electron microscopy, most membranes were reported to be about 6–8 nm thick—and, of this, the lipid bilayer accounted for about 4–5 nm. That left only about 1–2 nm of space on either surface of the bilayer for the membrane protein, a space that could at best accommodate a thin monolayer of protein. Yet after membrane proteins were isolated and studied, it became apparent that most of them were globular proteins with sizes and shapes that are inconsistent with the concept of thin sheets of protein on the two surfaces of the membrane.

As a further complication, the Davson–Danielli model did not readily account for the distinctiveness of different kinds of membranes. Depending on their source, membranes vary considerably in chemical composition and

Table 7-1 Protein, Lipid, and Carbohydrate Content of Biological Membranes

Membrane	Approximate Percentage by Weight			
	Protein	Lipid	Carbohydrate	Protein/Lipid Ratio
Plasma membrane				
Human erythrocyte	49	43	8	1.14
Mammalian liver cell	54	36	10	1.50
Amoeba	54	42	4	1.29
Myelin sheath of nerve axon	18	79	3	0.23
Nuclear envelope	66	32	2	2.06
Endoplasmic reticulum	63	27	10	2.33
Golgi complex	64	26	10	2.46
Chloroplast thylakoids	70	30	0	2.33
Mitochondrial outer membrane	55	45	0	1.22
Mitochondrial inner membrane	78	22	0	3.54
Gram-positive bacterium	75	25	0	3.00

especially in the ratio of protein to lipid (**Table 7-1**), which can vary from 3 or more in some bacterial cells to only 0.23 for the myelin sheath surrounding nerve axons. Even the two membranes of the mitochondrion differ significantly: The protein/lipid ratio is about 1.2 for the outer membrane and about 3.5 for the inner membrane, which contains all the enzymes and proteins related to electron transport and ATP synthesis. Yet all of these membranes look essentially the same when visualized using electron microscopy.

The Davson–Danielli model was also called into question by studies in which membranes were exposed to *phospholipases*, enzymes that degrade phospholipids by removing their head groups. According to the model, the hydrophilic head groups of membrane lipids should be covered by a layer of protein and therefore protected from phospholipase digestion. However, up to 75% of the membrane phospholipid can be degraded when the membrane is exposed to phospholipases, suggesting that many of the phospholipid head groups are exposed at the membrane surface and not covered by a layer of protein.

Moreover, the surface localization of membrane proteins specified by the Davson–Danielli model was not supported by the experience of scientists who tried to isolate such proteins. Most membrane proteins turned out to be quite insoluble in water and could be extracted only by using organic solvents or detergents. These observations indicated that many membrane proteins are hydrophobic (or at least amphipathic) and suggested that they are located, at least partially, within the hydrophobic interior of the membrane rather than on either of its surfaces.

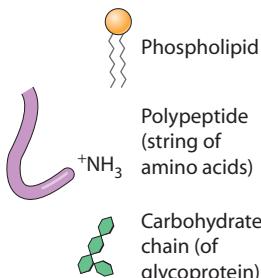

Singer and Nicolson: A Membrane Consists of a Mosaic of Proteins in a Fluid Lipid Bilayer

The preceding problems with the Davson–Danielli model stimulated considerable interest in the development of new ideas about membrane organization, culminating in

1972 with the **fluid mosaic model** proposed by S. Jonathan Singer and Garth Nicolson. This model, which now dominates our view of membrane organization, has two key features, both implied by its name. Simply put, the model envisions a membrane as a *mosaic* of proteins embedded in, or at least attached to, a *fluid* lipid bilayer (Figure 7-3f). This model retained the basic lipid bilayer structure of earlier models but viewed membrane proteins in an entirely different way—not as thin sheets on the membrane surface but as discrete globular entities within the lipid bilayer (Figure 7-5a).

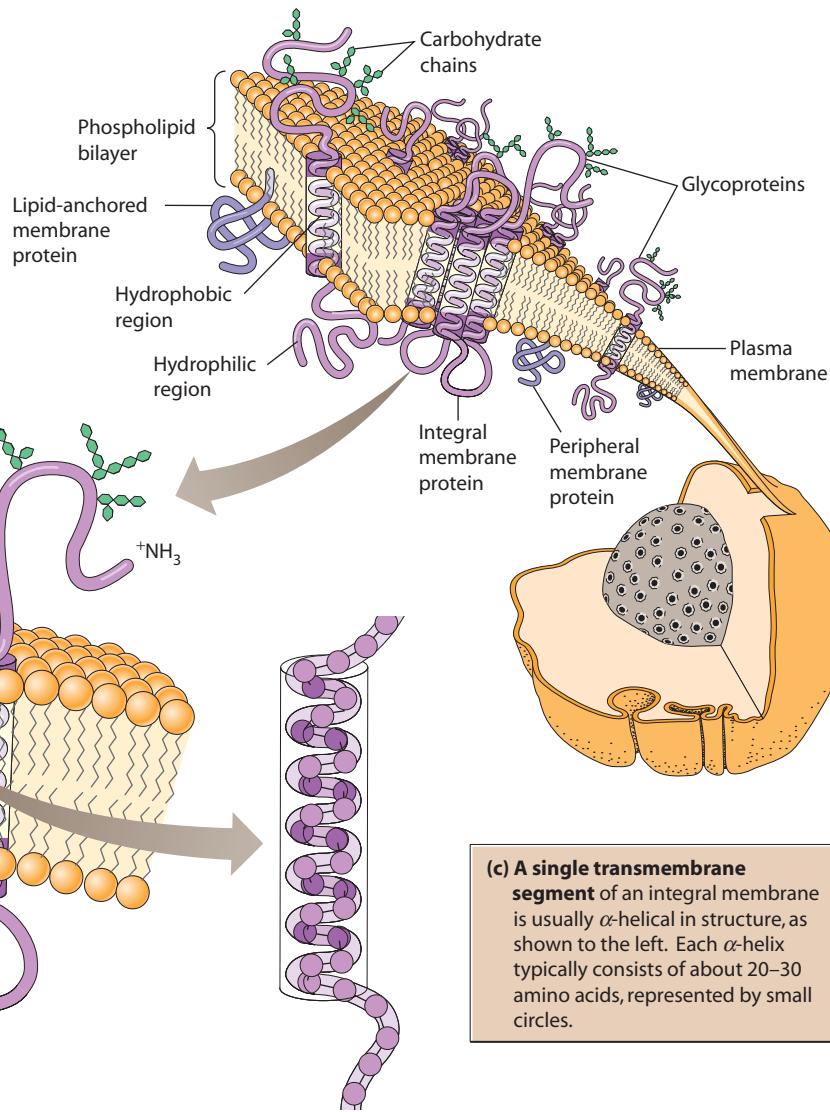

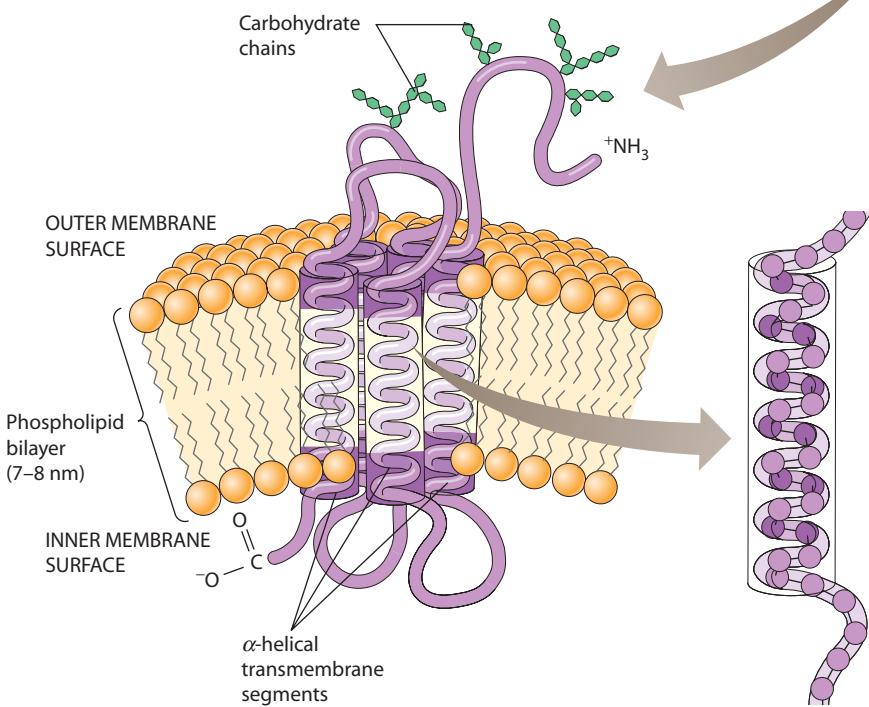

This way of thinking about membrane proteins was revolutionary when Singer and Nicolson first proposed it, but it turned out to fit the data quite well. Three classes of membrane proteins are now recognized based on differences in how the proteins are linked to the bilayer. *Integral membrane proteins* are embedded within the lipid bilayer, where they are held in place by the affinity of hydrophobic segments of the protein for the hydrophobic interior of the lipid bilayer. *Peripheral proteins* are much more hydrophilic and are therefore located on the surface of the membrane, where they are linked noncovalently to the polar head groups of phospholipids and/or to the hydrophilic parts of other membrane proteins. *Lipid-anchored proteins* are essentially hydrophilic proteins and therefore reside on membrane surfaces, but they are covalently attached to lipid molecules that are embedded within the bilayer.

The fluid nature of the membrane is the second critical feature of the Singer–Nicolson model. Rather than being rigidly locked in place, most of the lipid components of a membrane are in constant motion, capable of lateral mobility (i.e., movement parallel to the membrane surface). Many membrane proteins are also able to move laterally within the membrane, although some proteins are anchored to structural elements such as the cytoskeleton on one side of the membrane or the other and are therefore restricted in their mobility.

(a) Singer and Nicolson's fluid mosaic model envisions the membrane as a fluid bilayer of lipids with a mosaic of associated proteins, as shown below. Integral membrane proteins are anchored to the hydrophobic interior of the membrane by hydrophobic transmembrane segments (light purple), while hydrophilic segments (dark purple) extend outward on one or both sides of the membrane. Peripheral membrane proteins are associated with the membrane surface by weak electrostatic forces.

(b) An integral membrane protein with multiple α -helical transmembrane segments is shown below. Many integral membrane proteins of the plasma membrane have carbohydrate side chains attached to the hydrophilic segments on the outer membrane surface.

(c) A single transmembrane segment of an integral membrane is usually α -helical in structure, as shown to the left. Each α -helix typically consists of about 20–30 amino acids, represented by small circles.

FIGURE 7-5 The Fluid Mosaic Model of Membrane Structure. These drawings show (a) representative phospholipids and proteins in a typical plasma membrane, with closeups of (b) an integral membrane protein and (c) one of its transmembrane segments.

 **ACTIVITIES** www.thecellplace.com Membrane structure

The major strength of the fluid mosaic model is that it readily explains most of the criticisms of the Davson–Danielli model. For example, the concept of proteins partially embedded within the lipid bilayer accords well with the hydrophobic nature and globular structure of most membrane proteins and eliminates the need to accommodate membrane proteins in thin surface layers of unvarying thickness. Moreover, the variability in the

protein/lipid ratios of different membranes simply means that different membranes vary in the amount of protein they contain. Also, the exposure of lipid head groups at the membrane surface is obviously compatible with their susceptibility to phospholipase digestion, while the fluidity of the lipid layers and the intermingling of lipids and proteins within the membrane make it easy to envision the mobility of both lipids and proteins.

Unwin and Henderson: Most Membrane Proteins Contain Transmembrane Segments

The next illustration in the timeline (see Figure 7-3g) depicts an important property of integral membrane proteins that cell biologists began to understand in the 1970s: Most such proteins have in their primary structure one or more hydrophobic sequences that span the lipid bilayer (Figure 7-5b, c). These *transmembrane segments* anchor the protein to the membrane and hold it in proper alignment within the lipid bilayer.

The example in Figure 7-3g is *bacteriorhodopsin*, the first membrane protein shown to possess this structural feature. Bacteriorhodopsin is a plasma membrane protein found in archaea of the genus *Halobacterium*, where its presence allows cells to obtain energy directly from sunlight, as we will see in Chapter 8. Nigel Unwin and Richard Henderson used electron microscopy to determine the three-dimensional structure of bacteriorhodopsin and to reveal its orientation in the membrane. Their remarkable finding, reported in 1975, was that bacteriorhodopsin consists of a single peptide chain folded back and forth across the lipid bilayer a total of seven times. Each of the seven transmembrane segments of the protein is a closely packed α helix composed mainly of hydrophobic amino acids. Successive transmembrane segments are linked to each other by short loops of hydrophilic amino acids that extend into or protrude from the polar surfaces of the membrane. (For the detailed three-dimensional structure of bacteriorhodopsin, see Figure 8-14.) Based on subsequent work in many laboratories, membrane biologists currently believe that all transmembrane proteins are anchored in the lipid bilayer by one or more transmembrane segments.

Recent Findings Further Refine Our Understanding of Membrane Structure

Almost from the moment Singer and Nicolson proposed it, the fluid mosaic model revolutionized the way scientists think about membrane structure. The model launched a new era in membrane research that not only confirmed the basic model but also refined and extended it. Moreover, our understanding of membrane structure continues to expand as new research findings further refine and modify the basic model.

Recent developments emphasize the concept that membranes are not homogenous, freely mixing structures. Both lipids and proteins are ordered within membranes, and this ordering often occurs in dynamic microdomains known as *lipid rafts* (Figure 7-3h), which we will discuss later in this chapter. In fact, most cellular processes that involve membranes depend critically on specific structural complexes of lipids and proteins within the membrane. This interaction between a membrane protein and a particular lipid can be highly specific and is often critical for proper membrane protein structure and function.

So, to understand membrane-associated processes, we need more than the original fluid mosaic model with lipids and proteins simply floating around randomly. But the fluid mosaic model is still basic to our understanding of membrane structure, so it is important for us to closely examine its essential features. These features include the chemistry, the asymmetric distribution, and the fluidity of membrane lipids; the relationship of membrane proteins to the bilayer; and the mobility of proteins within the bilayer. We will discuss each of these features in turn, focusing on both the supporting evidence and the implications of each feature for membrane function.

Membrane Lipids: The “Fluid” Part of the Model

We will begin our detailed look at membranes by considering membrane lipids, which are important components of the “fluid” part of the fluid mosaic model.

Membranes Contain Several Major Classes of Lipids

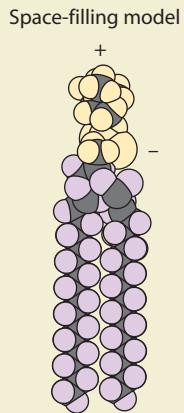

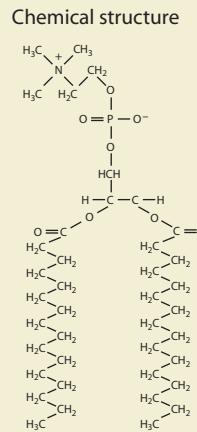

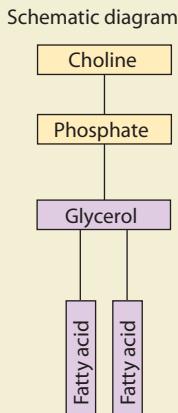

One feature of Singer and Nicolson’s fluid mosaic model is that it retains the lipid bilayer initially proposed by Gorter and Grendel, though with a greater diversity and fluidity of lipid components than early investigators recognized. The main classes of membrane lipids are *phospholipids*, *glycolipids*, and *sterols*. **Figure 7-6** lists the main lipids in each of these categories and depicts the structures of several.

Phospholipids. As we already know from Chapter 3, the most abundant lipids found in membranes are the **phospholipids** (Figure 7-6a). Membranes contain many different kinds of phospholipids, including both the glycerol-based **phosphoglycerides** and the sphingosine-based **sphingolipids**. The most common phosphoglycerides are *phosphatidylcholine*, *phosphatidylethanolamine*, *phosphatidylserine*, and *phosphatidylinositol*. A common sphingolipid is *sphingomyelin* (Figure 7-6a), which is one of the main phospholipids of animal plasma membranes but is absent from the plasma membranes of plants and most bacteria. The kinds and relative proportions of phospholipids present vary significantly among membranes from different sources (**Figure 7-7**).

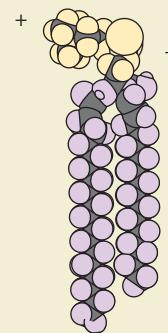

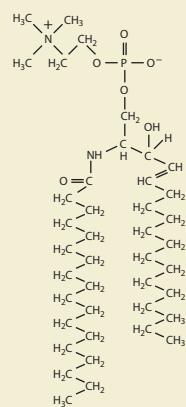

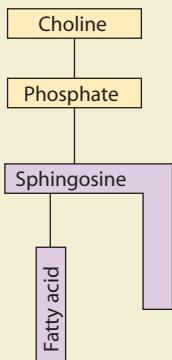

Glycolipids. As their name indicates, **glycolipids** are formed by adding carbohydrate groups to lipids. Some glycolipids are glycerol based, and others are derivatives of sphingosine and are therefore called *glycosphingolipids*. The most common examples are **cerebrosides** and **gangliosides**. Cerebrosides are called *neutral glycolipids* because each molecule has a single uncharged sugar as its head group—galactose, in the case of the galactocerebroside shown in Figure 7-6b. A ganglioside, on the other hand, always has an oligosaccharide head group that

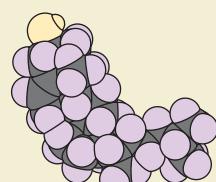

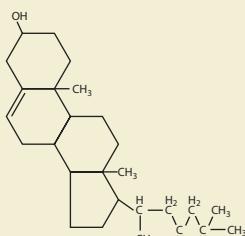

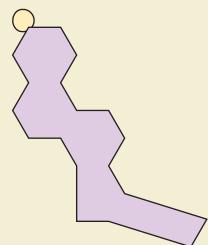

FIGURE 7-6 The Three Major Classes of Membrane Lipids. Each class of lipids is illustrated by a schematic diagram (on the left), a chemical structure (in the middle), and a space-filling model (on the right).
 (a) Phospholipids consist of a small polar head group (such as choline, ethanolamine, serine, or inositol) attached to a lipid backbone, forming either phosphoglycerides (glycerol-based) or sphingolipids (sphingosine-based). (For the structures of choline, ethanolamine, serine, and inositol, see Figure 3-29.)
 (b) Glycolipids are also either glycerol- or sphingosine-based, with the latter more common. A cerebroside has a neutral sugar as its head group, whereas a ganglioside has an oligosaccharide chain containing one or more sialic acid residues and therefore carries a negative charge. (c) The most common membrane sterols are cholesterol in animals and several related phytosterols in plants.

 [VIDEOS](http://www.thecellplace.com) www.thecellplace.com Space-filling model of phosphatidylcholine

contains one or more negatively charged sialic acid residues and gives the molecule a net negative charge.

Cerebrosides and gangliosides are especially prominent in the membranes of brain and nerve cells. Gangliosides exposed on the surface of the plasma membrane also function as antigens recognized by antibodies in immune reactions, including those responsible for blood group interactions. The human ABO blood groups, for example, involve glycosphingolipids known as A antigen and B antigen that serve as specific cell surface markers of the different groups of red blood cells. Cells of blood type A have the A antigen, and cells of blood type B have the B antigen. Type AB blood cells have both antigen types, and type O blood cells have neither.

Several serious human diseases are known to result from impaired metabolism of glycosphingolipids. The best-known example is *Tay-Sachs disease*, which is caused by the absence of a lysosomal enzyme, β -N-acetylhexosaminidase A, that is responsible for one of the steps in ganglioside degradation. As a result of the genetic defect, gangliosides accumulate in the brain and other nervous tissue, leading to impaired nerve and brain function and eventually to paralysis, severe mental deterioration, and death.

Two common glycolipids that do not contain sphingosine are derivatives of glycerol that are abundant in

plant and algal chloroplasts. Monogalactosyldiacylglycerol (MGDG) and digalactosyldiacylglycerol (DGDG) have either one or two galactose molecules, respectively, attached to a glycerol backbone that contains two polyunsaturated fatty acid groups (Figure 7-8). These two glycolipids constitute up to 75% of the total membrane lipids in leaves, where they are believed to play a role in stabilizing membrane proteins of the photosynthetic apparatus. Together, these two lipids are sometimes considered to be the most abundant glycolipids on Earth. Recently, several studies have shown that MGDG has an inhibitory effect on inflammation and cell proliferation in some human cells and tissues.

Sterols. Besides phospholipids and glycolipids, the membranes of most eukaryotic cells contain significant amounts of **sterols** (Figure 7-6c). The main sterol in animal cell membranes is **cholesterol**, which is necessary for maintaining and stabilizing membranes in our bodies by acting as a fluidity buffer. The membranes of plant cells contain small amounts of cholesterol and larger amounts of **phytosterols**, including campesterol, sitosterol, and stigmasterol. Fungal membranes contain a sterol known as ergosterol that is similar in structure to cholesterol but is not found in humans. Ergosterol is the target of antifungal

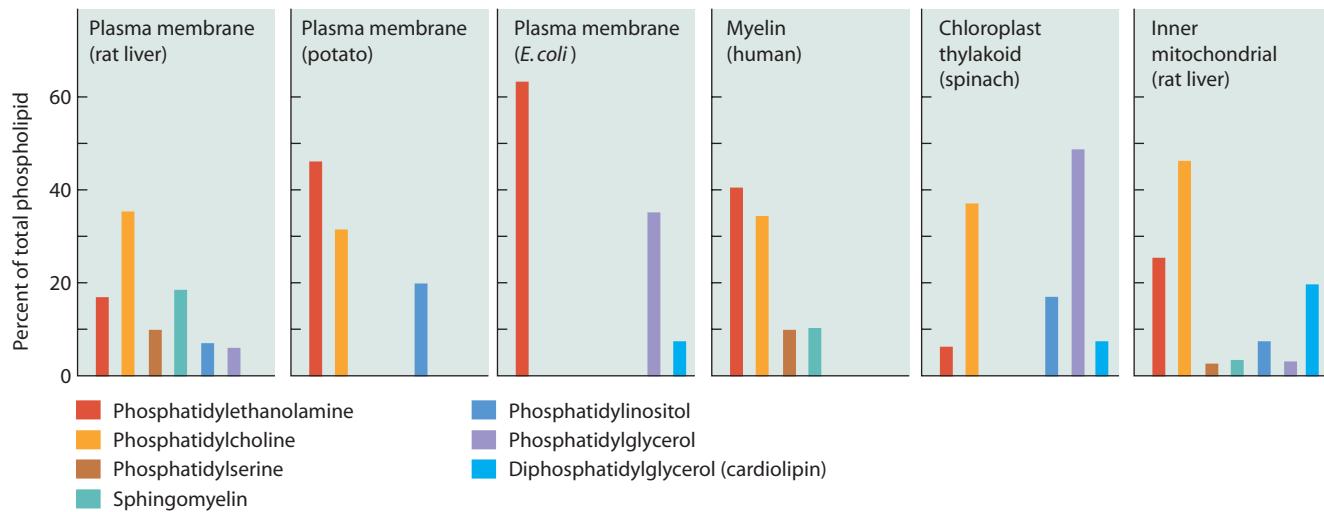

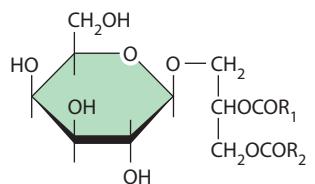

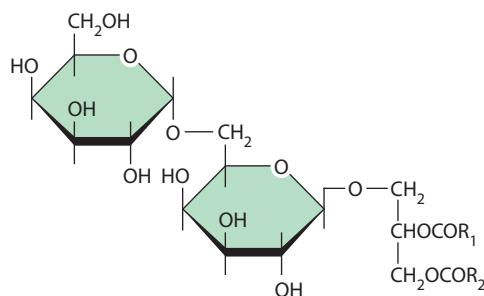

FIGURE 7-7 Phospholipid Composition of Several Kinds of Membranes. The relative abundance of different kinds of phospholipids in biological membranes varies greatly with the source of the membrane.

(a) Monogalactosyldiacylglycerol (MGDG)

(b) Digalactosyldiacylglycerol (DGDG)

FIGURE 7-8 The Structure of Two Common Glycolipids.

MGDG and DGDG are abundant in plant cell membranes, and are similar in structure to the animal fat triacylglycerol (see Figure 3-27b). They have one or two galactose molecules attached to glycerol in addition to the two fatty acid groups (R_1 and R_2)

medications such as nystatin, which selectively kill fungi but do not harm human cells because they lack ergosterol.

Sterols are not found in the membranes of most bacterial cells. They are, however, found in the plasma membrane of *Mycoplasma* species, which, unlike most bacteria, lack a cell wall. Presumably these *Mycoplasma* bacteria have sterols to add stability and strength to the membrane. Sterols are also absent from the inner membranes of both mitochondria and chloroplasts, which are believed to be derived evolutionarily from the plasma membranes of bacterial cells. However, the plasma membranes of at least some bacteria contain sterol-like molecules called *hopanoids* that appear to substitute for sterols in membrane structure. The hopanoid molecule is rigid and strongly hydrophobic, and it closely resembles cholesterol. Because hopanoids are abundant in petroleum deposits, these molecules might have been membrane components of ancient bacteria that presumably contributed to the formation of fossil fuels.

Thin-Layer Chromatography Is an Important Technique for Lipid Analysis

How do we know so much about the lipid components of membranes? As you may suspect, they are difficult to isolate and study due to their hydrophobic nature. However, using nonpolar solvents such as acetone and chloroform, biologists and biochemists have been isolating, separating, and studying membrane lipids for more than a century. One important technique for the analysis of lipids is **thin-layer chromatography (TLC)**, depicted schematically in **Figure 7-9**. This technique is used to

separate different kinds of lipids based on their relative polarities.

In this procedure, the lipids are solubilized from a membrane preparation using a mixture of nonpolar organic solvents and separated using a glass plate coated with silicic acid, a polar compound that dries to form a thin film on the glass plate. A sample of the extract is applied to one end of the TLC plate by spotting the extract onto a small area called the *origin* (Figure 7-9a). After the solvent in the sample has evaporated, the edge of the plate is dipped into a solvent system that typically consists of chloroform, methanol, and water. As the solvent moves past the origin and up the plate by capillary action, the lipids are separated based on their polarity—that is, by their relative affinities for the polar silicic acid plate and the less polar solvent.

Nonpolar lipids such as cholesterol have little affinity for the polar silicic acid (the stationary phase) and therefore move up the plate with the solvent system (the mobile phase). Lipids that are more polar, such as phospholipids, interact more strongly with the silicic acid, which slows their movement. In this way the various lipids are separated progressively as the leading edge of the mobile phase continues to move up the plate. When the leading edge, or *solvent front*, approaches the top, the plate is removed from the solvent system and dried. The separated lipids are then recovered from the plate by dissolving each spot or band in a nonpolar solvent such as chloroform for identification and further study.

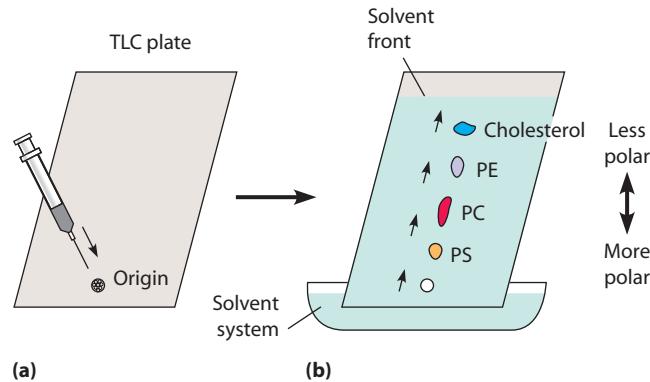

FIGURE 7-9 Using Thin-Layer Chromatography to Analyze Membrane Lipids.

Thin-layer chromatography (TLC) is a useful technique for analyzing membrane lipids. Lipids are extracted from a membrane preparation with a mixture of organic solvents and separated according to their degree of polarity. (a) A sample is spotted and dried onto a small area of a glass or metal plate coated with a thin layer of silicic acid. (b) Components of the sample are then carried upward by the solvent into which the TLC plate is placed. As the solvent moves up the plate by capillary action, the lipids are separated according to their polarity: Less polar lipids such as cholesterol do not adhere strongly to the silicic acid and move further up the plate, while more polar lipids remain closer to the origin. The pattern shown is for lipids of the erythrocyte plasma membrane. The main components are cholesterol, phosphatidylethanolamine (PE), phosphatidylcholine (PC), and phosphatidylserine (PS).

Figure 7-9b shows the TLC pattern seen for the lipids of the erythrocyte plasma membrane. The main components of this membrane are cholesterol (25%) and phospholipids (55%), with phosphatidylethanolamine (PE), phosphatidylcholine (PC), and phosphatidylserine (PS) as the most prominent phospholipids. Other minor components, such as phosphatidylinositol and sphingolipids, are not shown. Control plates are run simultaneously using the same methods and small amounts of known lipids for comparison and identification.

Fatty Acids Are Essential to Membrane Structure and Function

Fatty acids are components of all membrane lipids except the sterols. They are essential to membrane structure because their long hydrocarbon tails form an effective hydrophobic barrier to the diffusion of polar solutes. Most fatty acids in membranes are between 12 and 20 carbon atoms in length, with 16- and 18-carbon fatty acids especially common. This size range appears to be optimal for bilayer formation because chains with fewer than 12 or more than 20 carbons are less able to form a stable bilayer. Thus, the thickness of membranes (about 6–8 nm, depending on the source) is dictated primarily by the chain length of the fatty acids required for bilayer stability.

In addition to differences in length, the fatty acids found in membrane lipids vary considerably in the presence and number of double bonds. **Table 7-2** shows the structures of several fatty acids that are especially common in membrane lipids. *Palmitate* and *stearate* are saturated fatty acids with 16 and 18 carbon atoms, respectively. *Oleate* and *linoleate* are 18-carbon unsaturated fatty acids with one and two double bonds, respectively. Other common unsaturated fatty acids in membranes are *linolenate*, with 18 carbons and three double bonds, and *arachidonate*, with 20 carbons and four double bonds (see Table 3-5, page 68). All unsaturated fatty acids in membranes are in the *cis* configuration, resulting in a sharp bend, or kink, in the hydrocarbon chain at every double bond. Due to the bent nature of their side chains, fatty acids with double bonds do not pack tightly in the membrane.

Membrane Asymmetry: Most Lipids Are Distributed Unequally Between the Two Monolayers

Are the various lipids in a membrane randomly distributed between the two monolayers of lipid that constitute the lipid bilayer? Chemical studies involving membranes derived from a variety of cell types have revealed that most lipids are unequally distributed between the two monolayers. This **membrane asymmetry** includes differences in both the kinds of lipids present and the degree of unsaturation of the fatty acids in the phospholipid molecules.

For example, most of the glycolipids present in the plasma membrane of an animal cell are restricted to the

outer monolayer. As a result, their carbohydrate groups protrude from the outer membrane surface, where they are involved in various signaling and recognition events. Phosphatidylethanolamine, phosphatidylinositol, and phosphatidylserine, on the other hand, are more prominent in the inner monolayer, where they are involved in transmitting various kinds of signals from the plasma membrane to the interior of the cell. Further details of signal detection and transduction await us in Chapter 14.

Membrane asymmetry is established during membrane biogenesis by the insertion of different lipids, or different proportions of the various lipids, into each of the two monolayers. Once established, asymmetry tends to be maintained because the movement of lipids from one monolayer to the other requires their hydrophilic head groups to pass through the hydrophobic interior of the membrane—an event that is thermodynamically unfavorable. While such “flip-flop,” or **transverse diffusion**, of membrane lipids does occur occasionally, it is relatively rare. For instance, a typical phospholipid molecule flip-flops less than once a week in a pure phospholipid bilayer. This movement contrasts strikingly with the **rotation** of phospholipid molecules about their long axis and with the **lateral diffusion** of phospholipids in the plane of the membrane, both of which occur freely, rapidly, and randomly. **Figure 7-10** illustrates these three types of lipid movements.

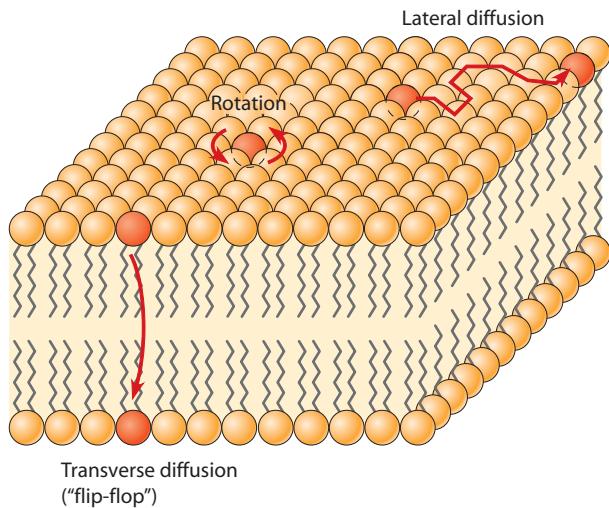

FIGURE 7-10 Movements of Phospholipid Molecules Within Membranes.

A phospholipid molecule is capable of three kinds of movement in a membrane: rotation about its long axis; lateral diffusion by exchanging places with neighboring molecules in the same monolayer; and transverse diffusion, or “flip-flop,” from one monolayer to the other. In a pure phospholipid bilayer at 37°C, a typical lipid molecule exchanges places with neighboring molecules about 10 million times per second and can move laterally at a rate of about several micrometers per second. By contrast, an individual phospholipid molecule flip-flops from one layer to the other at a rate ranging from less than once a week in a pure phospholipid bilayer to once every few hours in some natural membranes. The more rapid movement in natural membranes is due to the presence of enzymes called phospholipid translocators, or flippases, that catalyze the transverse diffusion of phospholipid molecules from one monolayer to the other.

Table 7-2 Structures of Some Common Fatty Acids Found in Lipid Bilayers

Name of Fatty Acid	Number of Carbon Atoms	Number of Double Bonds	Structural Formula	Space-Filling Model
Saturated				
Palmitate	16	0		
Stearate	18	0		
Unsaturated				
Oleate	18	1		
Linoleate	18	2		

While phospholipid flip-flop is relatively rare, it occurs more frequently in natural membranes than in artificial lipid bilayers. This is because some membranes—the smooth endoplasmic reticulum (ER), in particular—have proteins called **phospholipid translocators**, or **flippases**, that catalyze the flip-flop of membrane lipids from one monolayer to the other. Such proteins act only on specific kinds of lipids. For example, one of these proteins in the smooth ER membrane catalyzes the translocation of phosphatidylcholine from one side of the membrane to the other but does not recognize other phospholipids. This ability to move lipid molecules selectively from one side of the bilayer to the other contributes further to the asymmetric distribution of phospholipids across the membrane. The role of smooth ER in the synthesis and selective flip-flop of membrane phospholipids is a topic we will return to in Chapter 12.

The Lipid Bilayer Is Fluid

One of the most striking properties of membrane lipids is that rather than being fixed in place within the membrane, they form a fluid bilayer that permits lateral diffusion of membrane lipids as well as proteins. Lipid molecules move especially fast because they are much smaller than proteins. A typical phospholipid molecule, for example, has a molecular weight of about 800 and can travel the length of a bacterial cell (a few micrometers, in most cases) in one second or less! Proteins move much more slowly than lipids, partly because they are much larger molecules and partly due to their interactions with cytoskeletal proteins on the inside of the cell.

The lateral diffusion of membrane lipids can be demonstrated experimentally by a technique called **fluorescence recovery after photobleaching** (**Figure 7-11**). The investigator tags, or labels, lipid molecules in the membrane of a living cell by covalently linking them to a fluorescent dye. A

high-intensity laser beam is then used to bleach the dye in a tiny spot (a few square micrometers) on the cell surface. If the cell surface is examined immediately thereafter with a fluorescence microscope, a dark, nonfluorescent spot is seen on the membrane. Within seconds, however, the edges of the spot become fluorescent as bleached lipid molecules diffuse out of the laser-treated area and fluorescent lipid molecules from adjoining regions of the membrane diffuse in. Eventually, the spot is indistinguishable from the rest of the cell surface. This technique demonstrates that membrane lipids are in a fluid rather than a static state, and it provides a direct means of measuring the lateral movement of specific molecules.

Membranes Function Properly Only in the Fluid State

As you might guess, membrane fluidity changes with temperature, decreasing as the temperature drops and increasing as it rises. In fact, we know from studies with artificial lipid bilayers that every lipid bilayer has a characteristic **transition temperature (T_m)** at which it becomes fluid (“melts”) when warmed from a solid gel-like state. This change in the state of the membrane is called a **phase transition**, and you have probably seen this yourself if you have ever accidentally left a stick of butter on the stove! To function properly, a membrane must be maintained in the fluid state—that is, at a temperature above its T_m value. At a temperature below the T_m value, all functions that depend on the mobility or conformational changes of membrane proteins will be impaired or disrupted. This includes such vital processes as transport of solutes across the membrane, detection and transmission of signals, and cell-to-cell communication (see Figure 7-2).

The technique of **differential scanning calorimetry** is one means of determining the transition temperature of a given membrane. This procedure monitors the uptake of

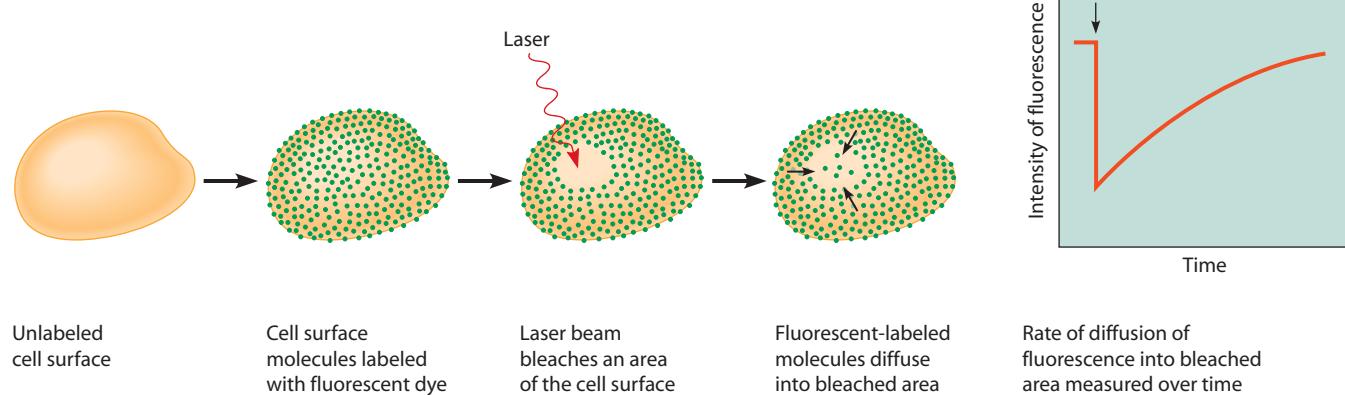

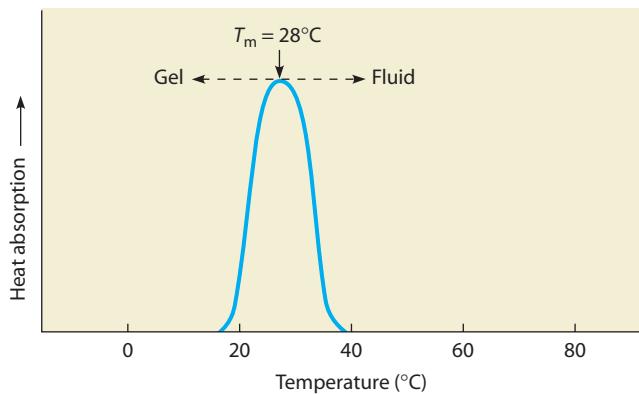

FIGURE 7-11 Measuring Lipid Mobility in Membranes by Fluorescence Recovery After Photobleaching.

Membrane lipids are labeled with a fluorescent compound, and the fluorescence in a local area is then bleached by irradiating the cell with a laser beam. As fluorescent molecules from surrounding regions diffuse into the bleached area, fluorescence will reappear in the laser-bleached spot. Membrane fluidity is measured by determining the rate of this reappearance of fluorescence. Similar experiments can be carried out to measure the mobility of membrane proteins, as shown in Figure 7-28.

(a) Normal membrane. When the temperature of a typical membrane preparation is increased slowly in a calorimeter chamber, a peak of heat absorption marks the gel-to-fluid transition temperature, T_m .

(b) Membranes enriched in unsaturated or saturated fatty acids. Membranes from cells grown in media enriched in the unsaturated fatty acid oleate (left) are more fluid than normal membranes (lower T_m). Membranes from cells grown in media enriched in the saturated fatty acid stearate (right) are less fluid than normal membranes (higher T_m).

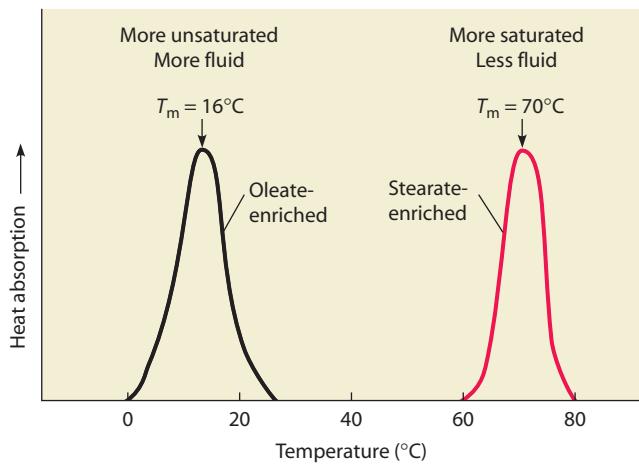

FIGURE 7-12 Determination of Membrane Transition Temperature by Differential Scanning Calorimetry. These graphs show T_m determinations for (a) a normal membrane from a homeotherm and (b) membranes enriched in specific unsaturated or saturated fatty acids.

heat that occurs during the transition from one physical state to another—the gel-to-fluid transition, in the case of membranes. The membrane of interest is placed in a sealed chamber, the *calorimeter*, and the uptake of heat is measured as the temperature is slowly increased. The point of maximum heat absorption corresponds to the T_m (Figure 7-12).

Effects of Fatty Acid Composition on Membrane Fluidity. A membrane's fluidity depends primarily on the kinds of lipids it contains. Two properties of a membrane's lipid makeup are especially important in determining

fluidity: the length of the fatty acid side chains and their degree of unsaturation. Long-chain fatty acids have higher transition temperatures than do short-chain fatty acids, which means that membranes enriched in long-chain fatty acids tend to be less fluid.

For example, as the chain length of saturated fatty acids increases from 10 to 20 carbon atoms, the T_m rises from 32°C to 76°C, and the membrane thus becomes progressively less fluid (Figure 7-13a). The presence of unsaturation affects the T_m even more markedly. For fatty acids with 18 carbon atoms, the transition temperatures are 70, 16, 5, and -11°C for zero, one, two, and three double bonds, respectively (Figure 7-13b). As a result, membranes containing many unsaturated fatty acids tend to have lower transition temperatures and thus are more fluid than membranes with many saturated fatty acids. Figure 7-12b illustrates this increased fluidity for membranes enriched in oleate (18 carbons, one double bond) versus membranes enriched in stearate (18 carbons, saturated).

The effect of unsaturation on membrane fluidity is so dramatic because the kinks caused by double bonds in fatty acids prevent the hydrocarbon chains from fitting together snugly. Membrane lipids with saturated fatty

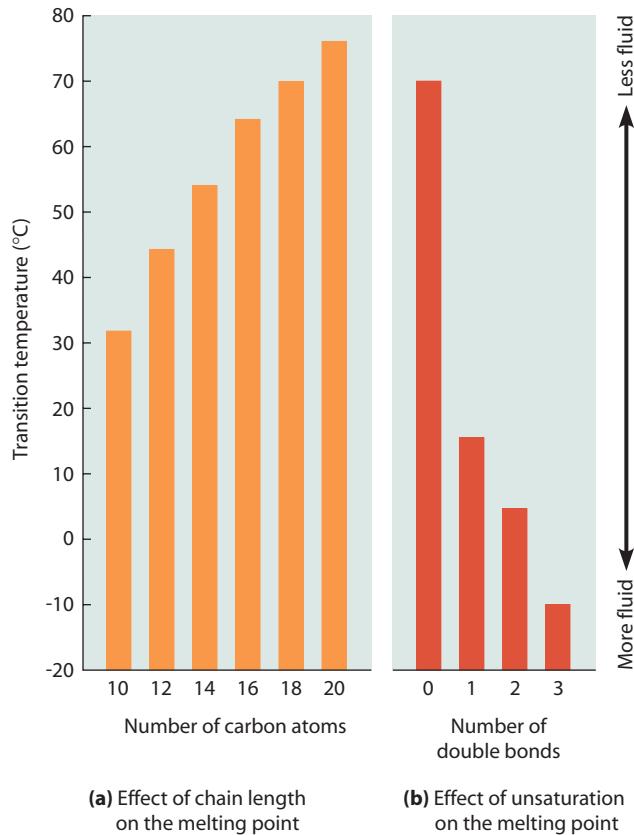

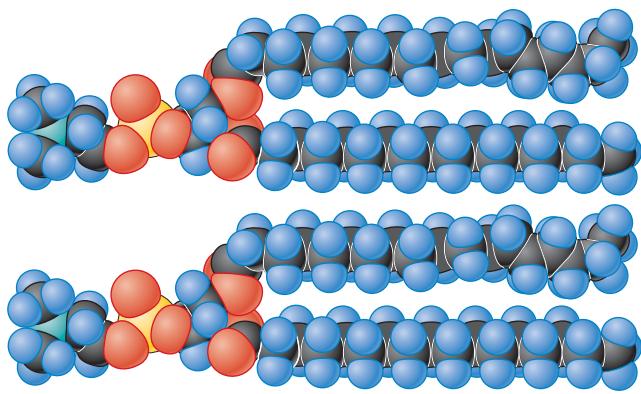

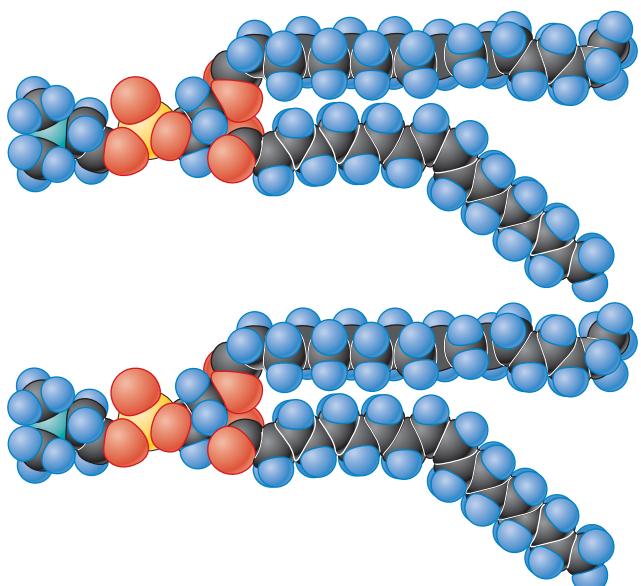

FIGURE 7-13 The Effect of Chain Length and the Number of Double Bonds on the Melting Point of Fatty Acids. The transition temperature of fatty acids (a) increases with chain length for saturated fatty acids, becoming less fluid with longer chains. (b) The transition temperature decreases dramatically with the number of double bonds for fatty acids with a fixed chain length, becoming more fluid as more double bonds are present.

(a) Lipids with saturated fatty acids pack together well in the membrane

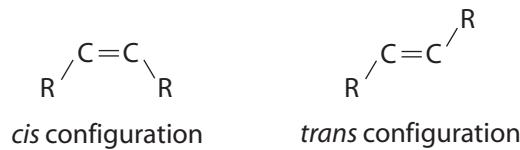

(b) Lipids with a mixture of saturated and unsaturated fatty acids do not pack together well in the membrane

FIGURE 7-14 The Effect of Unsaturated Fatty Acids on the Packing of Membrane Lipids. (a) Membrane phospholipids with no unsaturated fatty acids fit together tightly because the fatty acid chains are parallel to each other. (b) Membrane lipids with one or more unsaturated fatty acids do not fit together as tightly because the *cis* double bonds cause bends in the chains that interfere with packing. Each structure shown is a phosphatidylcholine molecule, with either two 18-carbon saturated fatty acids (stearate; part a) or two 18-carbon fatty acids, one saturated (stearate) and the other with one *cis* double bond (oleate; part b).

acids pack together tightly (Figure 7-14a), whereas lipids with unsaturated fatty acids do not (Figure 7-14b). The lipids of most plasma membranes contain fatty acids that vary in both chain length and degree of unsaturation. In fact, the variability is often intramolecular because membrane lipids commonly contain one saturated and one unsaturated fatty acid. This property helps to ensure that membranes are in the fluid state at physiological temperatures.

Most unsaturated fatty acids found in nature contain *cis* double bonds. In contrast, many commercially processed fats and hydrogenated oils contain significant numbers of *trans* double bonds. The *trans* double bond does not introduce as much of a bend in the fatty acid chain, as shown below (H atoms not shown):

Thus, in their overall shape and ability to pack together closely, *trans* fats resemble saturated fats more than *cis* unsaturated fats do. The presence of *trans* fats in membranes increases the transition temperature and decreases the membrane fluidity. As with saturated fats, consuming *trans* fats has been correlated with high blood cholesterol levels and increased risk of heart disease.

Effects of Sterols on Membrane Fluidity. For eukaryotic cells, membrane fluidity is also affected by the presence of sterols—mainly cholesterol in animal cell membranes and phytosterols in plant cell membranes. Sterols are prominent components in the membranes of many cell types. A typical animal cell, for example, contains large amounts of cholesterol—up to 50% of the total membrane lipid on a molar basis. Cholesterol molecules are usually found in both layers of the plasma membrane, but a given molecule is localized to one of the two layers (Figure 7-15a). The molecule orients itself in the layer with its single hydroxyl group—the only polar part of an otherwise hydrophobic molecule—close to the polar head group of a neighboring phospholipid molecule, where it can form a hydrogen bond (Figure 7-15b). The rigid hydrophobic steroid rings and the hydrocarbon side chain of the cholesterol molecule interact with the portions of adjacent hydrocarbon chains that are closest to the phospholipid head groups.

This intercalation of rigid cholesterol molecules into the membrane of an animal cell makes the membrane less fluid at higher temperatures than it would otherwise be. However, cholesterol also effectively prevents the hydrocarbon chains of phospholipids from fitting snugly together as the temperature is decreased, thereby reducing the tendency of membranes to gel upon cooling. Thus, cholesterol acts as a fluidity buffer: It has the moderating effect of *decreasing* membrane fluidity at temperatures above the T_m and *increasing* it at temperatures below the T_m . The sterols in the membranes of other eukaryotes and hopanoids in prokaryotes presumably function in the same way.

Besides their effects on membrane fluidity, sterols decrease the permeability of a lipid bilayer to ions and small polar molecules. They probably do so by filling in spaces between hydrocarbon chains of membrane phospholipids, thereby plugging small channels that ions and small molecules might otherwise pass through. In general, a lipid bilayer containing sterols is less permeable to ions and small molecules than is a bilayer lacking sterols.

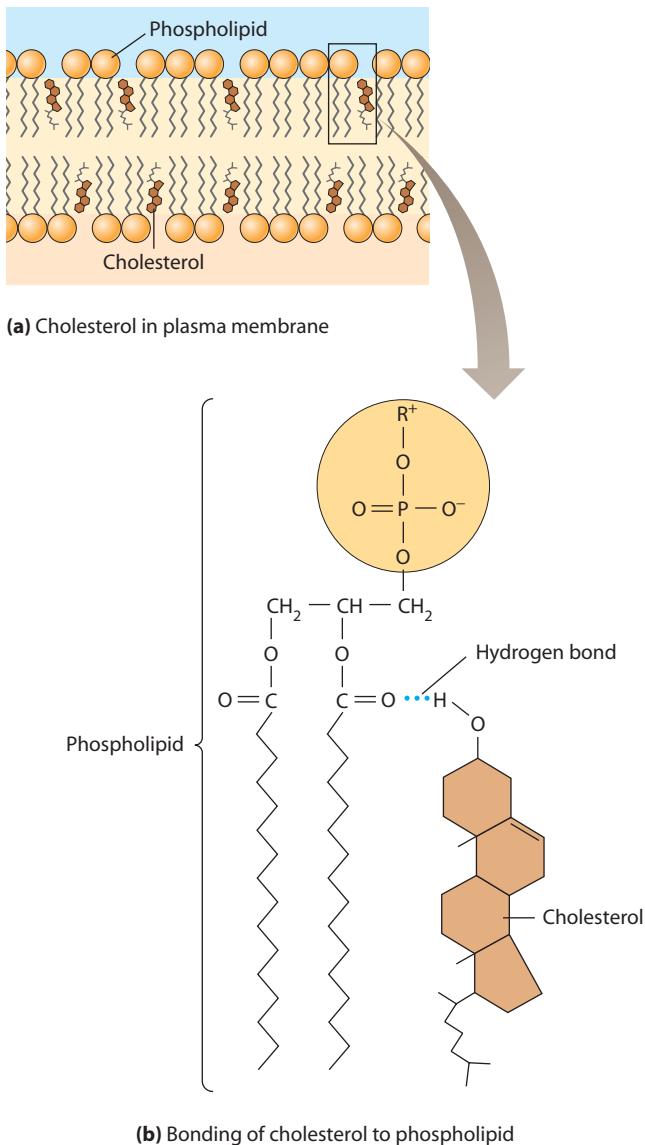

FIGURE 7-15 Orientation of Cholesterol Molecules in a Lipid Bilayer. (a) Cholesterol molecules are present in both lipid monolayers in the plasma membranes of most animal cells, but a given molecule is localized to one of the two layers. (b) Each molecule orients itself in the lipid layer so that its single hydroxyl group is close to the polar head group of a neighboring phospholipid molecule. The hydroxyl group of cholesterol forms a hydrogen bond with the oxygen of the ester bond between the glycerol backbone and a fatty acid. The nonpolar steroid rings and hydrocarbon side group of the cholesterol molecule interact with adjacent hydrocarbon chains of the membrane phospholipids.

Most Organisms Can Regulate Membrane Fluidity

Most organisms, whether prokaryotic or eukaryotic, are able to regulate membrane fluidity, primarily by changing the lipid composition of the membranes. This ability is especially important for *poikilotherms*—organisms such as bacteria, fungi, protozoa, algae, plants, invertebrates, and

“cold-blooded” animals such as snakes that cannot regulate their own temperature. Because lipid fluidity decreases as the temperature falls, membranes of these organisms would gel upon cooling if the organism had no way to compensate for decreases in environmental temperature.

You may have experienced this compensating effect even though you are a *homeotherm*, or “warm-blooded” organism: On chilly days, your fingers and toes can get so cold that the membranes of sensory nerve endings cease to function, resulting in temporary numbness. At high temperatures, on the other hand, the lipid bilayers of poikilotherms become so fluid that they no longer serve as an effective permeability barrier. For example, most cold-blooded animals are paralyzed by temperatures that are much above 45°C because nerve cell membranes become so leaky to ions that overall nervous function becomes disabled.

Fortunately, most poikilotherms can compensate for temperature changes by altering the lipid composition of their membranes, thereby regulating membrane fluidity. This capability is called **homeoviscous adaptation** because the main effect of such regulation is to keep the viscosity of the membrane approximately the same despite changes in temperature. Consider, for example, what happens when bacterial cells are transferred from a warmer to a cooler environment. In some species of the genus *Micrococcus*, a drop in temperature triggers an increase in the proportion of 16-carbon versus 18-carbon fatty acids in the plasma membrane. This helps the cell maintain membrane fluidity because the shorter fatty acid chains have less attraction for each other, and this increases the fluidity of membranes.

In this case, the desired increase in membrane fluidity is accomplished by activating an enzyme that removes two terminal carbons from 18-carbon hydrocarbon tails. In other bacterial species, adaptation to environmental temperature involves an alteration in the extent of unsaturation of membrane fatty acids rather than in their length. In the common intestinal bacterium *Escherichia coli*, for example, a decrease in environmental temperature triggers the synthesis of a *desaturase* enzyme that introduces double bonds into the hydrocarbon chains of fatty acids. As these unsaturated fatty acids are incorporated into membrane phospholipids, they decrease the transition temperature of the membrane, thereby ensuring that the membrane remains fluid at the lower temperature.

Homeoviscous adaptation also occurs in yeasts and plants. In these organisms, temperature-related changes in membrane fluidity appear to depend on the increased solubility of oxygen in the cytoplasm at lower temperatures. Oxygen is a substrate for the desaturase enzyme system involved in the generation of unsaturated fatty acids. With more oxygen available at lower temperatures, unsaturated fatty acids are synthesized at a greater rate and membrane fluidity increases, thereby offsetting the temperature effect.

This capability has great agricultural significance because plants that can adapt in this way are cold hardy (resistant to chilling) and can thus be grown in colder environments. Animals such as amphibians and reptiles also adapt to lower temperatures by increasing the proportion of unsaturated fatty acids in their membranes. Furthermore, these animals can increase the proportion of cholesterol in the membrane, thereby decreasing the interaction between hydrocarbon chains and reducing the tendency of the membrane to gel.

Although homeoviscous adaptation is generally most relevant to poikilothermic organisms, it is also important to mammals that hibernate. As an animal enters hibernation, its body temperature often drops substantially—a decrease of more than 30°C for some rodents. The animal adapts to this change by incorporating a greater proportion of unsaturated fatty acids into membrane phospholipids as its body temperature falls.

Lipid Rafts Are Localized Regions of Membrane Lipids That Are Involved in Cell Signaling

Until recently, the lipid component of a membrane was regarded as uniformly fluid and relatively homogeneous within a given monolayer. In recent years, however, the discovery of localized regions of membrane lipids that sequester proteins involved in cell signaling has generated much excitement. These regions are called either *lipid microdomains* or, more popularly, **lipid rafts**—and represent areas of lateral heterogeneity within a membrane monolayer. Lipid rafts are dynamic structures that change in composition as individual lipids and proteins move in and out of them. They were first identified in the outer monolayer of the plasma membrane of eukaryotic cells but have since been detected in the inner monolayer also.

Lipid rafts in the outer membrane monolayer of animal cells are characterized by elevated levels of cholesterol and glycosphingolipids. The glycosphingolipids have longer and more saturated fatty acid tails than those seen in most other membrane lipids. Moreover, the phospholipids present in lipid rafts are more highly saturated than those in the surrounding membrane. These properties, plus the rigidity and hydrophobic nature of cholesterol, allow tight packing of the cholesterol and the hydrocarbon tails of the glycosphingolipids and the phospholipids. As a result, lipid rafts are thicker and less fluid than the rest of the membrane, thereby distinguishing them as discrete lipid microdomains. In addition, these regions are less able to be solubilized by nonionic detergents, a characteristic that facilitates their separation from the rest of the membrane components as intact structures for subsequent analysis.

Initial models of lipid raft formation proposed that localized regions of tightly-associated cholesterol and glycosphingolipid molecules attracted particular raft-associated proteins. Some of these raft-associated proteins are lipoproteins containing a fatty acid such as palmitate

attached to a specific cysteine residue, a feature that may facilitate their targeting to lipid rafts. Recent proteomic studies of lipid raft regions have identified over 200 proteins enriched in lipid rafts. Some of these raft-associated proteins can capture and organize particular raft lipids, suggesting an active role of these proteins in lipid raft formation. In addition, lipid rafts contain actin-binding proteins, and some studies have suggested a role of the cytoskeleton in forming and organizing lipid rafts. Studies using inhibitors have shown that both depletion of cholesterol in cells and disruption of the actin cytoskeleton interfere with targeting of proteins to lipid rafts.

Much of the excitement surrounding lipid rafts relates to their role in the detection of, and responses to, extracellular chemical signals. For example, lipid rafts are involved in the transport of nutrients and ions across cell membranes, the binding of activated immune system cells to their microbial targets, and the transport of cholera toxin into intestinal cells. Many receptor proteins involved in the detection of external chemical signals are localized to the outer lipid monolayer of the plasma membrane. When a receptor binds its specific ligands, it can move into particular lipid rafts that are also located in the outer monolayer. Receptor-containing lipid rafts in the outer monolayer are thought to be coupled functionally to specific lipid rafts in the inner monolayer. Some lipid rafts contain specific *kinases*, enzymes that generate second messengers within the cell by catalyzing the phosphorylation of specific substances. In this way, signals that are detected by the receptor proteins in the outer monolayer can be transmitted to the interior of the cell by the functional links between the lipid rafts in the two membrane monolayers.

Closely related to lipid rafts in structure and perhaps in function are *caveolae* (Latin for “little caves”), which are small, flask-shaped invaginations of the plasma membrane of mammalian cells that were first observed more than 50 years ago. They contain the cholesterol-binding protein *caveolin*, which contributes to their curved morphology, and are enriched in cholesterol, sphingolipids, and lipid-anchored proteins. Proposed cellular roles for caveolae include participation in endocytosis and exocytosis, redox sensing, and regulation of airway function in the lungs. In addition, caveolae have been shown to contain proteins important in calcium signaling in heart muscle cells and have been discussed as potential targets for treatment of cardiovascular disease.

Membrane Proteins: The “Mosaic” Part of the Model

Having looked in some detail at the “fluid” aspect of the fluid mosaic model, we come now to the “mosaic” part. That may include lipid rafts and other lipid domains, but the main components of the membrane mosaic are the many membrane proteins as initially envisioned by Singer and Nicolson. We will look first at the confirming evidence that microscopists provided for the membrane as

a mosaic of proteins and then consider the major classes of membrane proteins.

The Membrane Consists of a Mosaic of Proteins: Evidence from Freeze-Fracture Microscopy

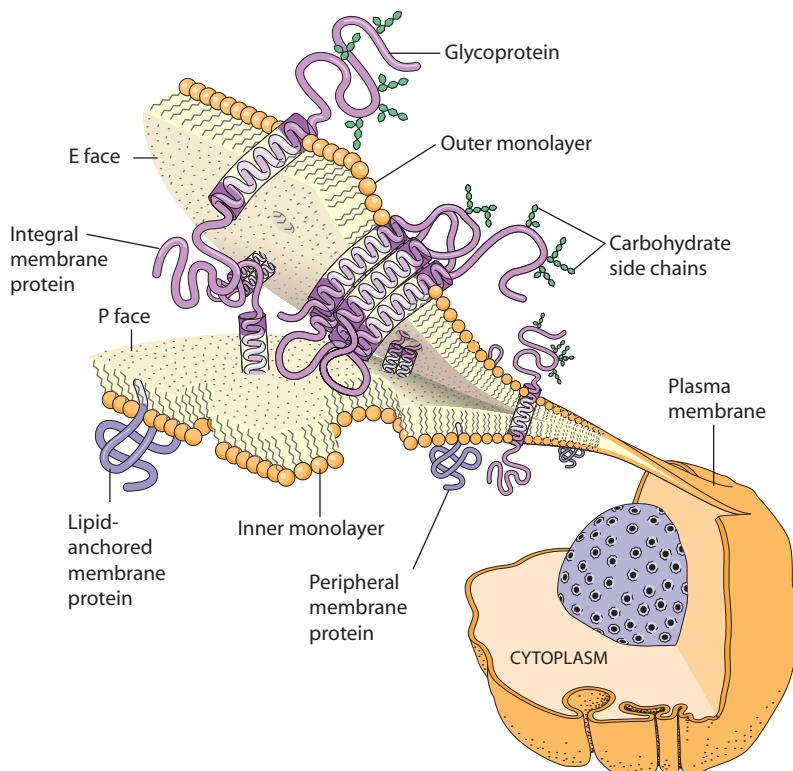

Strong support for the fluid mosaic model came from studies in which artificial bilayers and natural membranes were prepared for electron microscopy by **freeze fracturing**. In this technique, a lipid bilayer or a membrane (or a cell containing membranes) is frozen quickly and then subjected to a sharp blow from a diamond knife. Because the nonpolar interior of the bilayer is the path of least resistance through the frozen specimen, the resulting fracture often follows the plane between the two layers of membrane lipid. As a result, the bilayer is split into its inner and outer monolayers, revealing the inner surface of each (Figure 7-16a).

Electron micrographs of membranes prepared in this way provide striking evidence that proteins are actually

suspended within membranes. Whenever a fracture plane splits the membrane into its two layers, particles having the size and shape of globular proteins can be seen adhering to one or the other of the inner membrane surfaces, called the *E* (for *exoplasmic*) and *P* (for *protoplasmic*) faces (Figure 7-16b). Moreover, the abundance of such particles correlates well with the known protein content of the particular membrane under investigation. The electron micrographs in Figure 7-17 illustrate this well: The erythrocyte plasma membrane has a rather low protein/lipid ratio (1.14; see Table 7-1) and a rather low density of particles when subjected to freeze fracture (Figure 7-17a), whereas a chloroplast membrane has a higher protein/lipid ratio (2.33) and a correspondingly higher density of intramembranous particles, especially on the inner lipid layer (Figure 7-17b).

Confirmation that the particles seen in this way really *are* proteins came from work by David Deamer and Daniel Branton, who used the freeze-fracture technique to examine artificial bilayers with and without added protein. Bilayers formed from pure phospholipids showed no

(a) Separation of membrane monolayers. Notice how the fracture plane has passed through the hydrophobic interior of the membrane, revealing the inner surfaces of the two monolayers. Integral membrane proteins that remain with the outer monolayer are seen on the E (exoplasmic) face, whereas those that remain with the inner monolayer are seen on the P (protoplasmic) face.

(b) Surface view of monolayers. This sketch of a freeze-fractured membrane shows electron micrographs of the E and P faces from the plasma membrane of a mouse kidney tubule cell. Individual proteins imbedded in either face show up as small particles (TEMs).

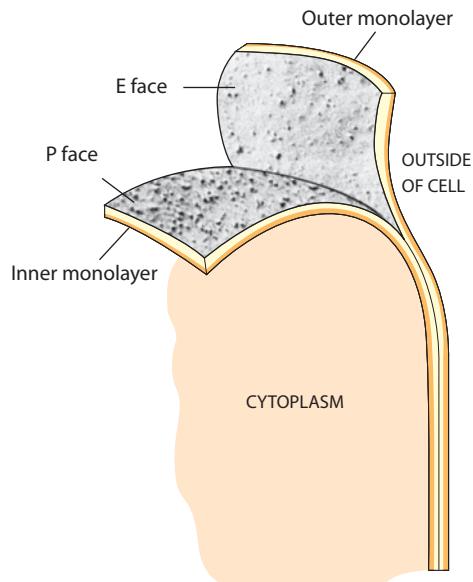

FIGURE 7-16 Freeze-Fracture Analysis of a Membrane. Sketches of a freeze-fractured membrane showing separation of the two lipid monolayers: (a) drawings of representative membrane components and (b) an electron micrograph of the surface of each monolayer.

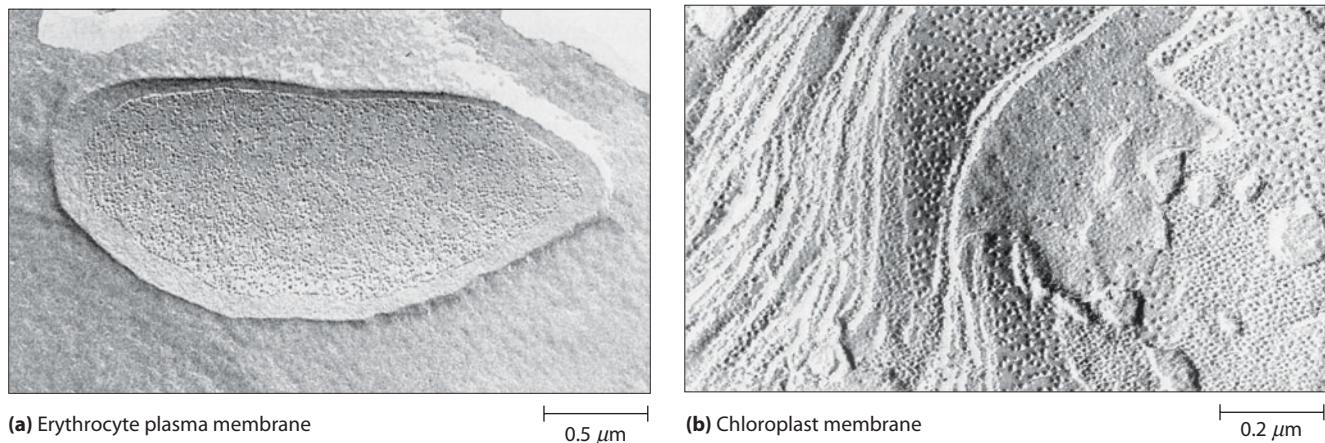

FIGURE 7-17 Membrane Proteins Visualized by Freeze-Fracture Electron Microscopy. Membrane proteins appear as discrete particles embedded within the lipid bilayer. The lower density of particles in (a) the erythrocyte membrane compared with (b) the chloroplast membrane agrees well with the protein/lipid ratios of the two membranes—1.14 and 2.33, respectively (TEMs).

evidence of particles on their interior surfaces (**Figure 7-18a**). When proteins were added to the artificial bilayers, however, particles similar to those seen in natural membranes were readily visible (Figure 7-18b).

Membranes Contain Integral, Peripheral, and Lipid-Anchored Proteins

Membrane proteins differ in their affinity for the hydrophobic interior of the membrane and therefore in the extent to which they interact with the lipid bilayer. That difference in affinity, in turn, determines how easy or difficult it is to extract a given protein from the membrane. Based on the conditions required to extract them—and thus, by extension, on the nature of their association with the lipid bilayer—membrane proteins fall into one of three categories: integral, peripheral, or lipid-anchored. We will

consider each of these in turn, referring in each case to the diagrams shown in **Figure 7-19**.

The plasma membrane of the human erythrocyte, shown in **Figure 7-20**, provides a cellular context for our discussion. This membrane has been one of the most widely studied since the time of Gorter and Grendel, due to the ready availability of red blood cells and how easily pure plasma membrane preparations can be made from them. We will refer to the erythrocyte plasma membrane at several points in the following discussion to note examples of different types of proteins and their roles within the membrane.

Integral Membrane Proteins. Most membrane proteins are amphipathic molecules possessing one or more hydrophobic regions that exhibit an affinity for the hydrophobic interior of the lipid bilayer. These proteins

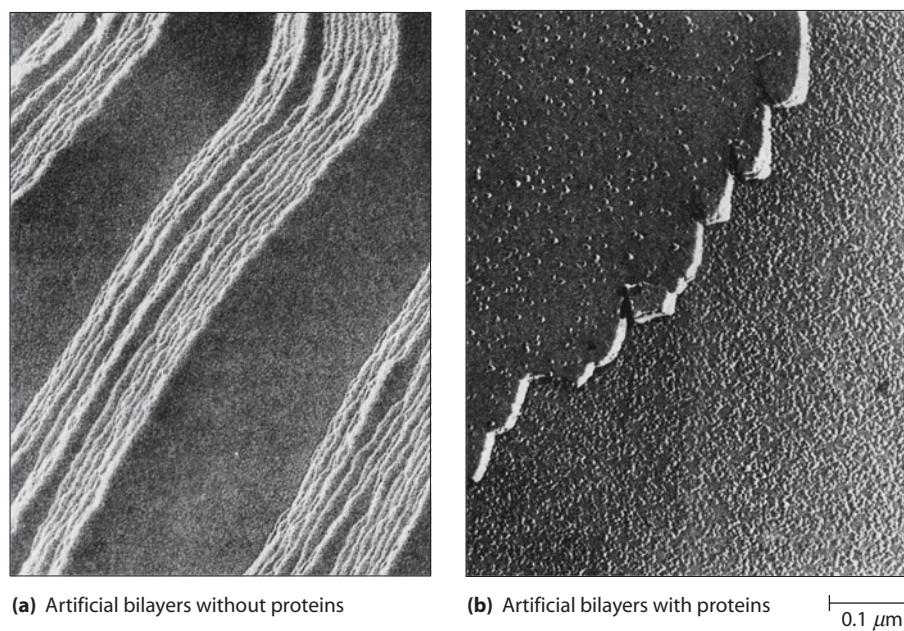

FIGURE 7-18 Freeze-Fracture Comparison of Lipid Bilayers With and Without Added Proteins. This figure compares the appearance by freeze-fracture electron microscopy of (a) artificial lipid bilayers without proteins and (b) artificial bilayers with proteins added. The white lines in the artificial membranes of part a represent individual lipid bilayers in a multilayered specimen, and the gray regions show where single bilayers have split to reveal smooth surfaces. In contrast, the artificial membrane of part b shows large numbers of globular particles in the fracture surface. These are the proteins that were added to the membrane preparation (TEMs).

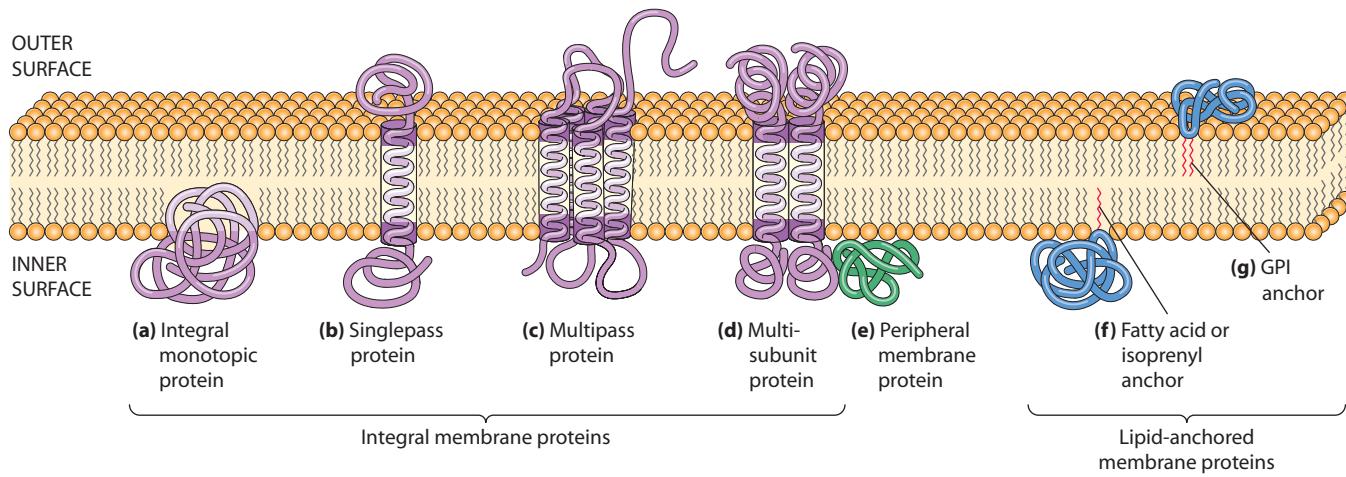

FIGURE 7-19 The Main Classes of Membrane Proteins. Membrane proteins are classified according to their mode of attachment to the membrane. Integral membrane proteins (a–d) contain one or more hydrophobic regions that are embedded within the lipid bilayer. (a) A few integral proteins appear to be embedded in the membrane on only one side of the bilayer (integral monotopic proteins). However, most integral proteins are transmembrane proteins that span the lipid bilayer either (b) once (singlepass proteins) or (c) multiple times (multipass proteins). Multipass proteins may consist of either a single polypeptide, as in part c, or (d) several associated polypeptides (multisubunit proteins). (e) Peripheral membrane proteins are too hydrophilic to penetrate into the membrane but are attached to the membrane by electrostatic and hydrogen bonds that link them to adjacent membrane proteins or to phospholipid head groups. Lipid-anchored proteins (f–g) are hydrophilic and do not penetrate into the membrane; they are covalently bound to lipid molecules that are embedded in the lipid bilayer. (f) Proteins on the inner surface of the membrane are usually anchored by either a fatty acid or an isoprenyl group. (g) On the outer membrane surface, the most common lipid anchor is glycosylphosphatidylinositol (GPI).

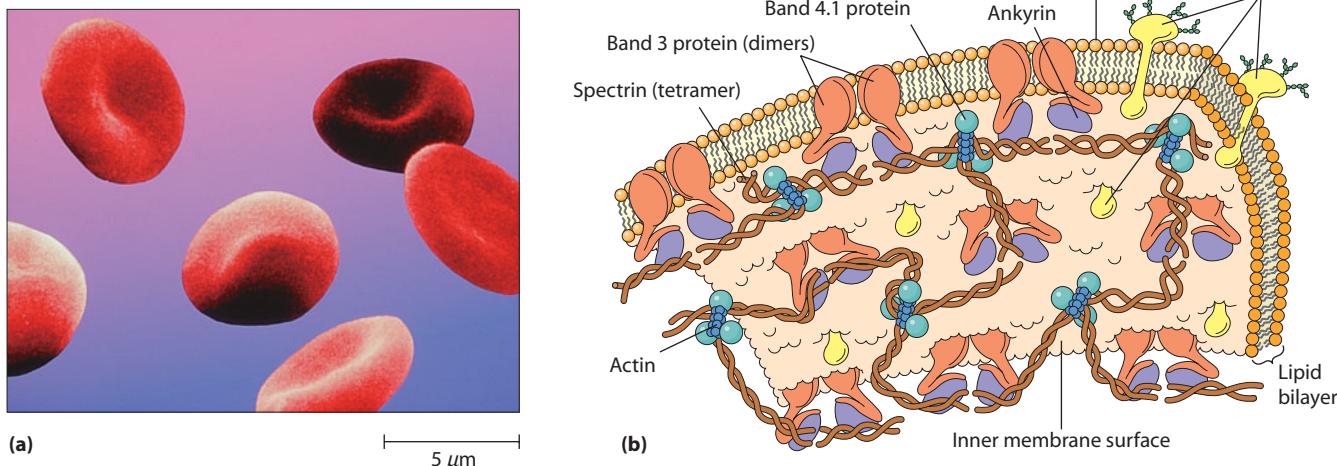

FIGURE 7-20 Structural Features of the Erythrocyte Plasma Membrane. (a) An erythrocyte is a small, disk-shaped cell with a diameter of about $7\ \mu\text{m}$. A mammalian erythrocyte contains no nucleus or other organelles, which makes it easy to obtain very pure plasma membrane preparations without contamination by organelle membranes, as often occurs with plasma membrane preparations from other cell types. (b) The erythrocyte plasma membrane as seen from inside the cell. The membrane has a relatively simple protein composition. The two major integral membrane proteins are glycophorin and an anion exchange protein known from its electrophoretic mobility as band 3. The membrane is anchored to the underlying cytoskeleton by long, slender strands of tetrameric spectrin, $(\alpha\beta)_2$, that are linked to glycophorin molecules by band 4.1 protein and to band 3 protein by ankyrin, another peripheral membrane protein. The free ends of adjacent spectrin tetramers are held together by short chains of actin and band 4.1. Not shown is another protein, band 4.2, that assists ankyrin in linking spectrin to band 3 protein. For the electrophoretic fractionation of these proteins, see Figure 7-22.

are called **integral membrane proteins** because their hydrophobic regions are embedded within the membrane interior in a way that makes these molecules difficult to remove from membranes. However, such proteins also have one or more hydrophilic regions that extend outward from the membrane into the aqueous phase on one or both sides of the membrane. Because of their affinity for the lipid bilayer, integral membrane proteins are difficult to isolate and study by standard protein purification techniques, most of which are designed for water-soluble proteins. Treatment with a detergent that disrupts the lipid bilayer is usually necessary to solubilize and extract integral membrane proteins.

A few integral membrane proteins are known to be embedded in, and therefore to protrude from, only one side of the bilayer. These are called **integral monotopic proteins** (Figure 7-19a). However, most integral membrane proteins are **transmembrane proteins**, which means that they span the membrane and have hydrophilic regions protruding from the membrane on both sides. Such proteins cross the membrane either once (*singlepass proteins*; Figure 7-19b) or several times (*multipass proteins*; Figure 7-19c). Some multipass proteins consist of a single polypeptide (Figure 7-19c), whereas others have two or more polypeptides (*multisubunit proteins*; Figure 7-19d).

Most transmembrane proteins are anchored to the lipid bilayer by one or more hydrophobic **transmembrane segments**, one for each time the protein crosses the bilayer. In most cases, the polypeptide chain appears to span the membrane in an α -helical conformation consisting of about 20–30 amino acid residues, most—sometimes even all—of which have hydrophobic R groups. In some multipass proteins, however, several transmembrane segments are arranged as a β sheet in the form of a closed β sheet—the so-called β barrel. This structure is especially prominent in a group of pore-forming transmembrane proteins called *porins* that are found in the outer membrane of many bacteria as well as chloroplasts and mitochondria. Regardless of their conformation, transmembrane segments are usually separated along the primary structure of the protein by hydrophilic sequences that protrude or loop out on the two sides of the membrane. Loop regions containing positively charged amino acid residues are more likely to be found on the cytoplasmic side of the membrane. This “positive-inside rule” helps to ensure that all molecules of a particular transmembrane protein are oriented the same way.

Singlepass membrane proteins have just one transmembrane segment, with a hydrophilic carboxyl (C-) terminus extending out of the membrane on one side and a hydrophilic amino (N-) terminus protruding on the other side. Depending on the particular protein, the C-terminus may protrude on either side of the membrane. An example of a singlepass protein is *glycophorin*, a prominent protein in the erythrocyte plasma membrane (Figure 7-20b). Glycophorin is oriented in the membrane so that its C-terminus is on the inner surface of the membrane and its N-terminus is on the outer surface (Figure 7-21a).

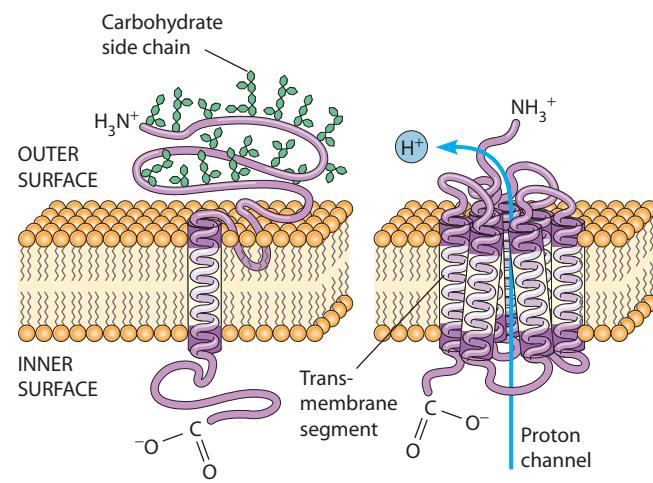

FIGURE 7-21 The Structures of Two Integral Membrane Proteins.

(a) Glycophorin is a singlepass integral membrane protein in the erythrocyte plasma membrane. Its α -helical transmembrane segment consists entirely of hydrophobic amino acids. The N-terminus protrudes on the outer surface, the C-terminus on the cytoplasmic surface. Glycophorin is a glycoprotein, with 16 carbohydrate chains attached to its outer surface. (b) Bacteriorhodopsin is a multipass integral membrane protein in the plasma membrane of *Halobacterium*. Its seven transmembrane segments, which account for about 70% of its 248 amino acids, are organized into a proton channel. The C- and N-termini of the protein have short hydrophilic segments that protrude on the inner and outer surfaces of the plasma membrane, respectively. Short hydrophilic segments also link each of the transmembrane segments.

Multipass membrane proteins have several transmembrane segments, ranging from 2 or 3 to 20 or more such segments. An example of a multipass protein in the erythrocyte plasma membrane is a dimeric transport protein called *band 3 protein* (also known as the *anion exchange protein*). Each of its two polypeptides spans the lipid bilayer at least six times, with both the C-terminus and the N-terminus on the same side of the membrane. Current models of the dimeric protein assume a total of 12 transmembrane segments.

One of the best-studied examples of a multipass protein is bacteriorhodopsin, the plasma membrane protein that serves halobacteria as a proton pump (see Figure 7-3g). Its three-dimensional structure was reported by Unwin and Henderson in 1975, based on electron microscopy. Bacteriorhodopsin turned out to have seven α -helical, membrane-spanning segments, each corresponding to a sequence of about 20 hydrophobic amino acids in the primary structure of the protein (Figure 7-21b). The seven transmembrane segments are positioned in the membrane to form a channel and thereby to facilitate the light-activated pumping of protons across the membrane, a topic we will return to in Chapter 8.

Peripheral Membrane Proteins. In contrast to integral membrane proteins, some membrane-associated proteins lack discrete hydrophobic sequences and therefore do not penetrate into the lipid bilayer. Instead, these **peripheral**

membrane proteins are bound to membrane surfaces through weak electrostatic forces and hydrogen bonding with the hydrophilic portions of integral proteins and perhaps with the polar head groups of membrane lipids (Figure 7-19e). The presence of aromatic amino acid residues, particularly the hydrophobic tryptophan side chain, is believed to play a role in anchoring proteins at the membrane-water interface. Peripheral proteins are more readily removed from membranes than integral proteins and can usually be extracted by changing the pH or ionic strength.

The main peripheral proteins of the erythrocyte plasma membrane are *spectrin*, *ankyrin*, and a protein called *band 4.1* (see Figure 7-20b). These proteins are bound to the inner surface of the plasma membrane, where they form a skeletal meshwork that supports the plasma membrane and helps maintain the shape of the erythrocyte (see Figure 7-20a).

Lipid-Anchored Membrane Proteins. When Singer and Nicolson initially proposed the fluid mosaic model, they regarded all membrane proteins as either peripheral or integral membrane proteins. However, we now recognize a third class of proteins that are neither specifically peripheral nor integral but have some of the characteristics of both. The polypeptide chains of these **lipid-anchored membrane proteins** are located on one of the surfaces of the lipid bilayer but are covalently bound to lipid molecules embedded within the bilayer (Figure 7-19, parts f and g).

Several mechanisms are employed for attaching lipid-anchored proteins to membranes. Proteins bound to the inner surface of the plasma membrane are attached by covalent linkage either to a fatty acid or to an isoprene derivative called an *isoprenyl group* (Figure 7-19f). In the case of **fatty acid-anchored membrane proteins**, the protein is synthesized in the cytosol and then covalently attached to a saturated fatty acid embedded within the membrane bilayer, usually *myristic acid* (14 carbons) or *palmitic acid* (16 carbons). **Isoprenylated membrane proteins**, on the other hand, are synthesized as soluble cytosol proteins before being modified by addition of multiple 5-carbon isoprenyl groups (see Figure 3-27f), usually in the form of a 15-carbon *farnesyl group* or 20-carbon *geranylgeranyl group*. After attachment, the farnesyl or geranylgeranyl group is inserted into the lipid bilayer of the membrane.

Many lipid-anchored proteins attached to the external surface of the plasma membrane are covalently linked to *glycosylphosphatidylinositol (GPI)*, a glycolipid found in the outer monolayer of the plasma membrane (Figure 7-19g). Lipid rafts are enriched in these **GPI-anchored membrane proteins**, which are made in the endoplasmic reticulum as singlepass transmembrane proteins that subsequently have their transmembrane segments cleaved off and replaced by GPI anchors. The proteins are then transported from the ER to the exterior of the plasma membrane. Once at the cell surface, GPI-anchored proteins can be released from the membrane by the enzyme *phospholipase C*, which is specific for phosphatidylinositol linkages.

Proteins Can Be Separated by SDS-Polyacrylamide Gel Electrophoresis

Before continuing our discussion of membrane proteins, it is useful to consider briefly how membrane proteins are isolated and studied. We will look first at the general problem of solubilizing and extracting proteins from membranes, and we will then learn about an electrophoretic technique that is very useful in the fractionation and characterization of proteins.

Isolation of Membrane Proteins. A major challenge to protein chemists has been the difficulty of isolating and studying membrane proteins, many of which are hydrophobic. Peripheral membrane proteins are in general fairly straightforward to isolate because they are loosely bound to the membrane by weak electrostatic interactions and hydrogen bonding with either the hydrophilic portions of integral membrane proteins or the polar head groups of membrane lipids. Peripheral proteins can be extracted from the membrane by changes in pH or ionic strength. Peripheral membrane proteins can also be solubilized by the use of a chelating (cation-binding) agent to remove calcium or by addition of urea, which breaks hydrogen bonds. Lipid-anchored proteins are similarly amenable to isolation, though with the requirement that the covalent bond to the lipid must first be cleaved. Once extracted from the membrane, most peripheral and lipid-anchored proteins are sufficiently hydrophilic to be purified and studied with techniques commonly used by protein chemists.

Integral membrane proteins, on the other hand, are difficult to isolate from membranes, especially in a manner that preserves their biological activity. In most cases, these proteins can be solubilized only by using detergents that disrupt hydrophobic interactions and dissolve the lipid bilayer. As we will now see, the use of strong ionic detergents such as *sodium dodecyl sulfate (SDS)* allows integral membrane proteins not just to be isolated, but to be fractionated and analyzed by the technique of electrophoresis. However, the use of such strong detergents can affect the function of the protein, and may be suitable only for analytical purposes.

SDS-Polyacrylamide Gel Electrophoresis. Cells contain thousands of different macromolecules that must be separated from one another before the properties of individual components can be investigated. One of the most common approaches for separating molecules from each other is **electrophoresis**, a group of related techniques that utilize an electrical field to separate charged molecules. How quickly any given molecule moves during electrophoresis depends upon its charge as well as its size. Electrophoresis can be carried out using various support media, such as paper, cellulose acetate, starch, polyacrylamide, or agarose (a polysaccharide obtained from seaweed). Of these media, gels made of polyacrylamide or agarose provide the best separation and are most

commonly employed for the electrophoresis of nucleic acids and proteins.

When electrophoresis is used to study membrane proteins, membrane fragments are first solubilized with the anionic detergent SDS, which disrupts most protein-protein and protein-lipid associations. The proteins denature, unfolding into stiff polypeptide rods that cannot refold because their surfaces are coated with negatively

charged detergent molecules. The solubilized, SDS-coated polypeptides are then layered on the top of a polyacrylamide gel. An electrical potential is then applied across the gel, such that the bottom of the gel is the positively charged anode (**Figure 7-22**). Because the polypeptides are coated with negatively charged SDS molecules, they migrate down the gel toward the anode. The polyacrylamide gel can be thought of as a fine meshwork that

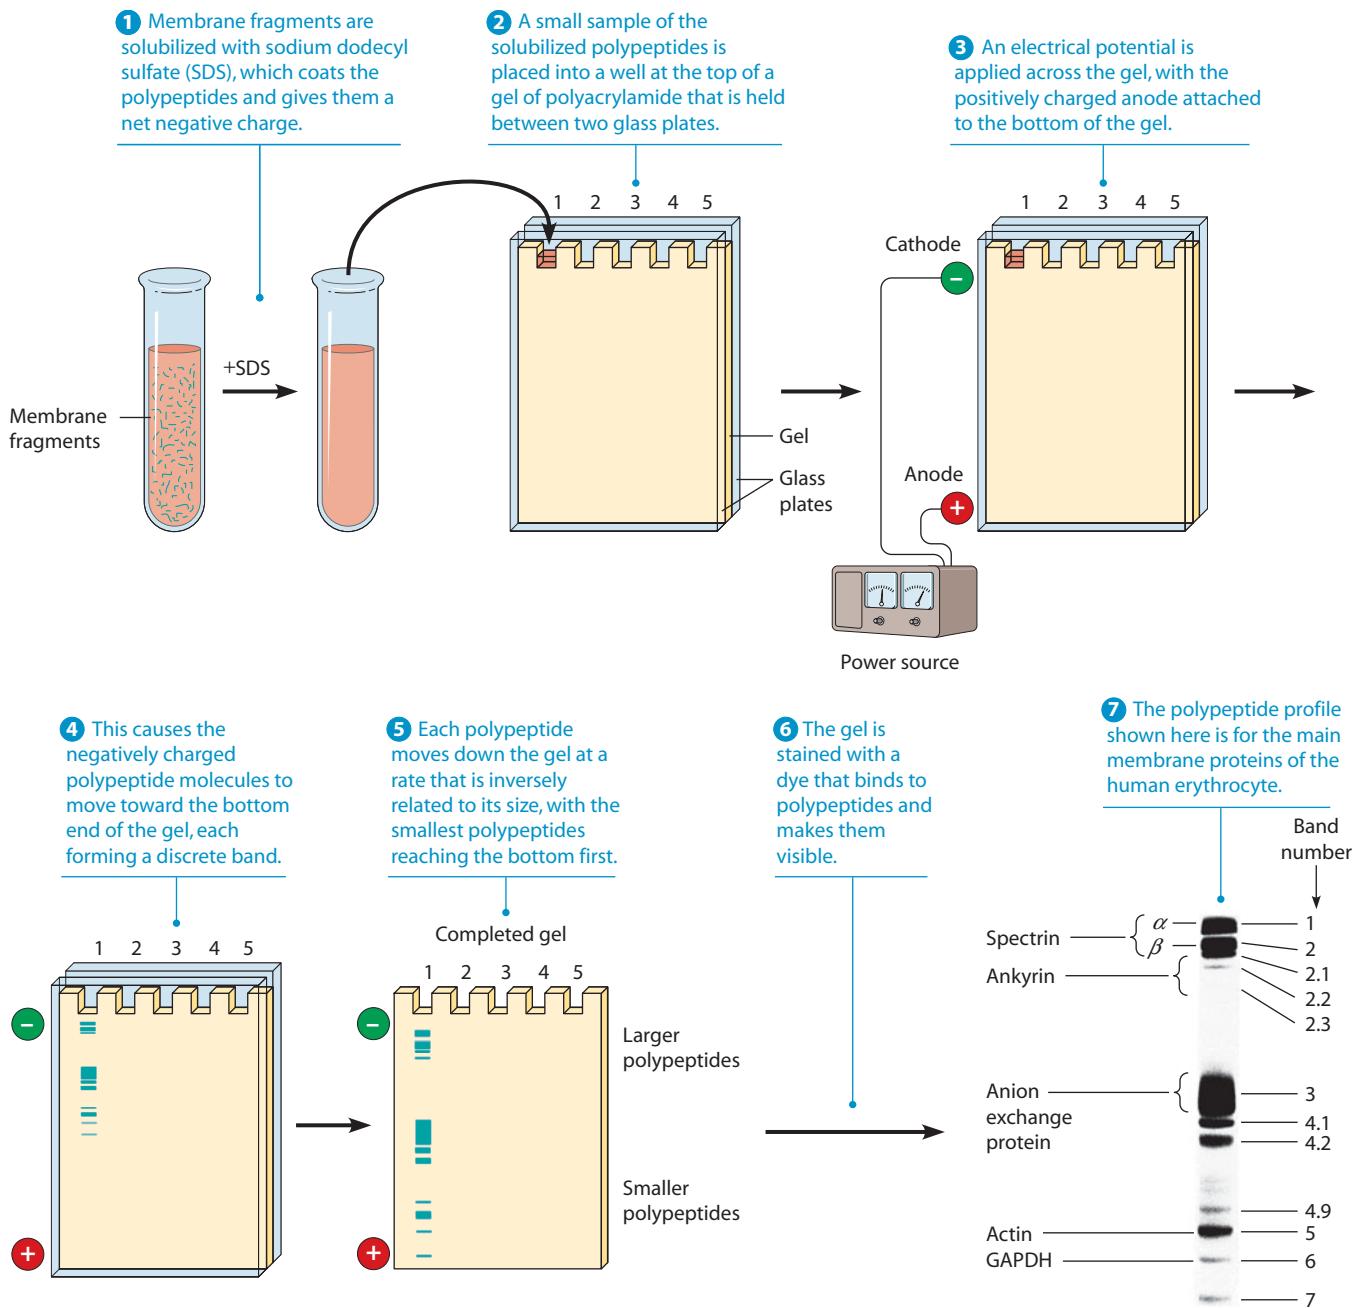

FIGURE 7-22 SDS-Polyacrylamide Gel Electrophoresis (SDS-PAGE) of Membrane Proteins. Steps **1** through **6** show the general procedure used to separate membrane proteins using SDS-PAGE. Following step **1**, the procedure is the same as is used for soluble, nonmembrane proteins. Step **7** shows the individual polypeptides separated from an erythrocyte membrane preparation. The separated bands of protein were initially identified using sequential numbers, as shown on the right. We now know the identity of some of these separated proteins, such as glyceraldehyde-3-phosphate dehydrogenase (GAPDH), shown on the left.

impedes the movement of large molecules more than that of small molecules. As a result, polypeptides move down the gel at a rate that is inversely related to the logarithm of their size.

When the smallest polypeptides approach the bottom of the gel, the process is terminated. The gel is then stained with a dye that binds to polypeptides and makes them visible. (*Coomassie brilliant blue* is commonly used for this purpose.) The particular polypeptide profile shown in Figure 7-22 is for the membrane proteins of human erythrocytes, most of which we have already encountered (see Figure 7-20b). Typically, a set of purified proteins of known molecular weights is run in one lane of the gel alongside the other samples to determine the molecular weights of the polypeptides in the samples.

A more advanced form of electrophoresis known as two-dimensional (2D) SDS-PAGE is often used to separate polypeptides based on both charge and size. Proteins are separated in a thin, nondenaturing, tubular gel so that positively charged polypeptides move to one end of the gel and negatively charged polypeptides move to the other end. Neutral polypeptides will be found in the center. The more charge an individual polypeptide has, the further it will be found from the center. Then, the entire gel is placed at the top of a denaturing SDS-PAGE gel, and proteins move out of the tubular gel and down the denaturing gel based on their molecular sizes. After staining, the individual polypeptides are seen as a set of spots scattered throughout the gel.

Following electrophoresis, individual polypeptides can be detected and identified using a procedure known as **Western blotting**. In this procedure, the polypeptides in a standard SDS-PAGE gel or a 2D SDS-PAGE gel are transferred directly to a nylon or nitrocellulose membrane that is placed flat against the gel. An electric field is used to transfer the proteins from the gel to the membrane, where they remain in the same relative positions that they occupied in the gel. By using labeled antibodies that are known to bind to specific polypeptides, researchers can identify and quantify the polypeptides from the gel. Western blotting is very useful in determining which proteins are present in or on a particular cell. This technique can be used, for example, to identify certain immune system cells or specific types of cancer cells.

Determining the Three-Dimensional Structure of Membrane Proteins Is Becoming More Feasible

Determining the three-dimensional structure of integral membrane proteins has been difficult for many years, primarily because these proteins are generally difficult to isolate and purify due to their hydrophobicity. However, they are proving increasingly amenable to study by *X-ray crystallography*, which determines the structure of proteins that can be isolated in crystalline form. For the many membrane proteins for which no crystal structure is available, an alternative approach called *hydropathic*

analysis can be used, provided that the protein or its gene can at least be isolated and sequenced. We will look briefly at each of these techniques.

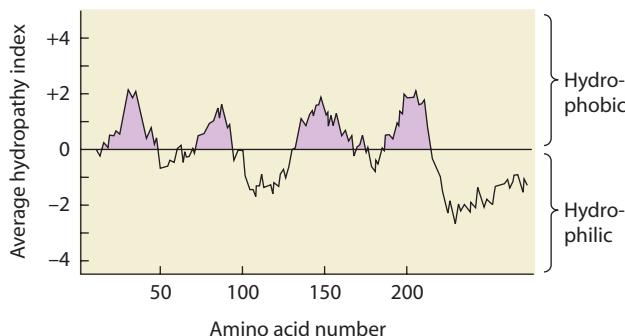

X-Ray Crystallography. X-ray crystallography is widely used to determine the three-dimensional structure of proteins. A description of this technique is included in the Appendix (see page A-27). The difficulty of isolating integral membrane proteins in crystalline form virtually excluded these proteins from crystallographic analysis for many years. The first success was reported by Hartmut Michel, Johann Deisenhofer, and Robert Huber, who crystallized the photosynthetic reaction center from the purple bacterium, *Rhodopseudomonas viridis*, and determined its molecular structure by X-ray crystallography. Based on their detailed three-dimensional structure of the protein, these investigators also provided the first detailed look at how pigment molecules are arranged to capture light energy, a topic we will return to in Chapter 11 (see Figure 11B-1 on p. 302). In recognition of this work, Michel, Deisenhofer, and Huber shared the Nobel Prize for Chemistry in 1988.

Despite this breakthrough, the application of X-ray crystallography to the study of integral membrane proteins progressed very slowly until the late 1990s, particularly at the level of resolution required to identify transmembrane helices. More recently, however, there has been a veritable explosion of X-ray crystallographic data for integral membrane proteins. According to the data assembled by Stephen White and his colleagues at the University of California, Irvine, there were only 18 proteins whose three-dimensional structures had been determined by 1997. Since then, approximately 200 proteins have been added to the list. Initially, most of these proteins were from bacterial sources, reflecting the relative ease with which membrane proteins are able to be isolated from microorganisms. Increasingly, however, membrane proteins from eukaryotic sources are proving amenable to X-ray crystallographic analysis as well.

Hydropathy Analysis. For the many integral membrane proteins that have not yet yielded to X-ray crystallography, the likely number and locations of transmembrane segments can often be inferred, provided that the protein or its gene can at least be isolated and sequenced. Once the amino acid sequence of a membrane protein is known, the number and positions of transmembrane segments can be inferred from a **hydropathy** (or **hydrophobicity**) plot, as shown in **Figure 7-23**. Such a plot is constructed by using a computer program to identify clusters of hydrophobic amino acids. The amino acid sequence of the protein is scanned through a series of “windows,” each representing a region of about 10 amino acids, with each successive window one amino acid further along in the sequence.

Based on the known hydrophobicity values for the various amino acids, a **hydropathy index** is calculated for each successive window by averaging the hydrophobicity values of the amino acids in the window. (By convention, hydrophobic amino acids have positive hydropathy values

(a) Hydropathy plot of connexin. The hydropathy index on the vertical axis is a numerical measure of the relative hydrophobicity of successive segments of the polypeptide chain based on its amino acid sequence.

(b) Transmembrane structure of connexin. Connexin has four distinct hydrophobic regions, which correspond to the four α -helical segments that span the plasma membrane.

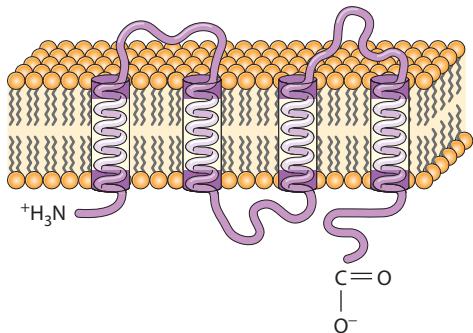

FIGURE 7-23 Hydropathy Analysis of an Integral Membrane Protein. A hydropathy plot is a means of representing hydrophobic regions (positive values) and hydrophilic regions (negative values) along the length of a protein. This example uses hydropathy data to analyze the plasma membrane protein *connexin*.

and hydrophilic residues have negative values.) The hydropathy index is then plotted against the positions of the windows along the sequence of the protein. The resulting hydropathy plot predicts how many membrane-spanning regions are present in the protein, based on the number of positive peaks. The hydropathy plot shown in Figure 7-23a is for a plasma membrane protein called *connexin*. The plot shows four positive peaks and therefore predicts that *connexin* has four stretches of hydrophobic amino acids and hence four transmembrane segments, as shown in Figure 7-23b.

Molecular Biology Has Contributed Greatly to Our Understanding of Membrane Proteins

Membrane proteins have not yielded as well as other proteins to biochemical techniques, mainly because of the problems involved in isolating and purifying hydrophobic proteins in physiologically active form. Procedures such as

SDS-PAGE and hydropathy analysis have certainly been useful, as have labeling techniques involving radioisotopes or fluorescent antibodies, which we will discuss later in the chapter. Within the past three decades, however, the study of membrane proteins has been revolutionized by the techniques of molecular biology, especially DNA sequencing and recombinant DNA technology. DNA sequencing makes it possible to deduce the amino acid sequence of a protein without the need to isolate the protein in pure form for amino acid sequencing.

In addition, sequence comparisons between proteins often reveal evolutionary and functional relationships that might not otherwise have been appreciated. DNA pieces can also be used as probes to identify and isolate sequences that encode related proteins. Moreover, the DNA sequence for a particular protein can be altered at specific nucleotide positions to determine the effects of changing specific amino acids on the activity of the mutant protein it codes for. **Box 7A** describes these exciting developments in more detail.

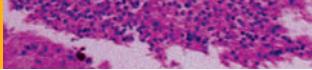

Membrane Proteins Have a Variety of Functions

What functions do membrane proteins perform? Most of what we summarized about membrane function at the beginning of the chapter is relevant here because the functions of a membrane are really just those of its chemical components, especially its proteins.

Some of the proteins in membranes are *enzymes*, which accounts for the localization of specific functions to specific membranes. As we will see in coming chapters, each of the organelles in a eukaryotic cell is in fact characterized by its own distinctive set of membrane-bound enzymes. We encountered an example earlier when we noted the association of glucose-6-phosphatase with the ER. Another example is glyceraldehyde-3-phosphate dehydrogenase (GAPDH), an enzyme involved in the catabolism of blood glucose. GAPDH is a peripheral plasma membrane protein in erythrocytes and other cell types (see Figure 7-22, step 7). Closely related to enzymes in their function are *electron transport proteins* such as the cytochromes and iron-sulfur proteins that are involved in oxidative processes in mitochondria, chloroplasts, and the plasma membranes of prokaryotic cells.

Other membrane proteins function in solute transport across membranes. These include *transport proteins*, which facilitate the movement of nutrients such as sugars and amino acids across membranes, and *channel proteins*, which provide hydrophilic passageways through otherwise hydrophobic membranes. Also in this category are *transport ATPases*, which use the energy of ATP to pump ions across membranes.

Numerous membrane proteins are *receptors* involved in recognizing and mediating the effects of specific chemical signals that impinge on the surface of the cell. Hormones, neurotransmitters, and growth-promoting substances are examples of chemical signals that interact with specific

Revolutionizing the Study of Membrane Proteins: The Impact of Molecular Biology

Because membrane proteins mediate a remarkable variety of cellular functions, cell biologists are very interested in these proteins. The study of membrane proteins has begun to yield definitive insights and answers as biochemical techniques commonly used to isolate and analyze cellular proteins have been applied to membrane proteins. This chapter describes several such applications, including SDS-polyacrylamide gel electrophoresis, hydropathy analysis, and procedures for labeling membrane proteins with radioactivity or fluorescent antibodies. Two other biochemical approaches that can be used to study membrane proteins are affinity labeling and membrane reconstitution.

Affinity labeling utilizes radioactive molecules that bind to specific proteins because of known functions of the proteins. For example, cytochalasin B is known to be a potent inhibitor of glucose transport. Membranes that have been exposed to radioactive cytochalasin B are therefore likely to contain radioactivity bound specifically to protein molecules involved in glucose transport.

Membrane reconstitution involves the formation of artificial membranes from specific purified components. In this approach, proteins are extracted from membranes with detergent solutions and separated individually. The purified proteins are then mixed together with phospholipids to form liquid-filled membrane vesicles called *liposomes* that can be “loaded” with particular molecules. These reconstituted vesicles can then be tested for their ability to carry out specific membrane protein functions, such as nutrient transport or cell-to-cell communication.

Despite some success with these approaches, membrane biologists are often stymied in their attempts to isolate, purify, and study membrane proteins. Biochemical techniques that work well with soluble proteins are not often useful with hydrophobic proteins. However, the study of membrane proteins has been revolutionized by the techniques of molecular biology, especially *DNA sequencing* and *recombinant DNA technology*. We will consider these techniques in detail in Chapters 18 and 20, but we need not wait until then to appreciate the enormous impact of molecular biology on the study of membranes and membrane proteins. **Figure 7A-1** summarizes several approaches that have proven especially powerful for both membrane and nonmembrane proteins.

Vital to these approaches is the isolation (cloning) of a gene or gene fragment that encodes all or part of a specific protein (Figure 7A-1, top). A top priority is to determine the nucleotide sequence of the cloned gene **1**. *DNA sequencing* is one of the triumphs of molecular biology. Determining the nucleotide sequence of a DNA molecule is now far easier than determining the amino acid sequence of the protein it encodes. Moreover, most of the sequencing procedure is carried out quickly and automatically by DNA sequencing machines. Once the DNA for a particular protein has been sequenced, the predicted *amino acid* sequence of the protein can be deduced by using the genetic code (see Figure 21-6) **2**. The predicted amino acid sequence can then be studied using *hydropathy analysis* (see Figure 7-23) to identify likely transmembrane segments of the protein **3**.

Knowing the amino acid sequence of the protein also allows the investigator to prepare synthetic peptides that correspond to

specific segments of the protein **4**. Antibodies made against these peptides can then be radioactively labeled and used to determine which regions of the protein are exposed on one side of the membrane or the other. This information, combined with the hydropathy data, often provides compelling evidence for the likely structure of the protein and its orientation within the membrane—and possibly for its mode of action as well. For example, the structure of the CFTR protein that is defective in people with cystic fibrosis was determined in this way (see Box 8B, pages 206–207).

Another powerful technique, **site-specific mutagenesis**, is used to examine the effect of changing specific amino acids in a protein **5**. The DNA sequence encoding the protein is altered by changing the nucleotides corresponding to a particular amino acid. The mutant DNA is then introduced into living cells, which then synthesize a mutant protein having the altered amino acid. Then, the functional properties of this mutant protein can be studied to determine whether the amino acid is required for proper protein function.

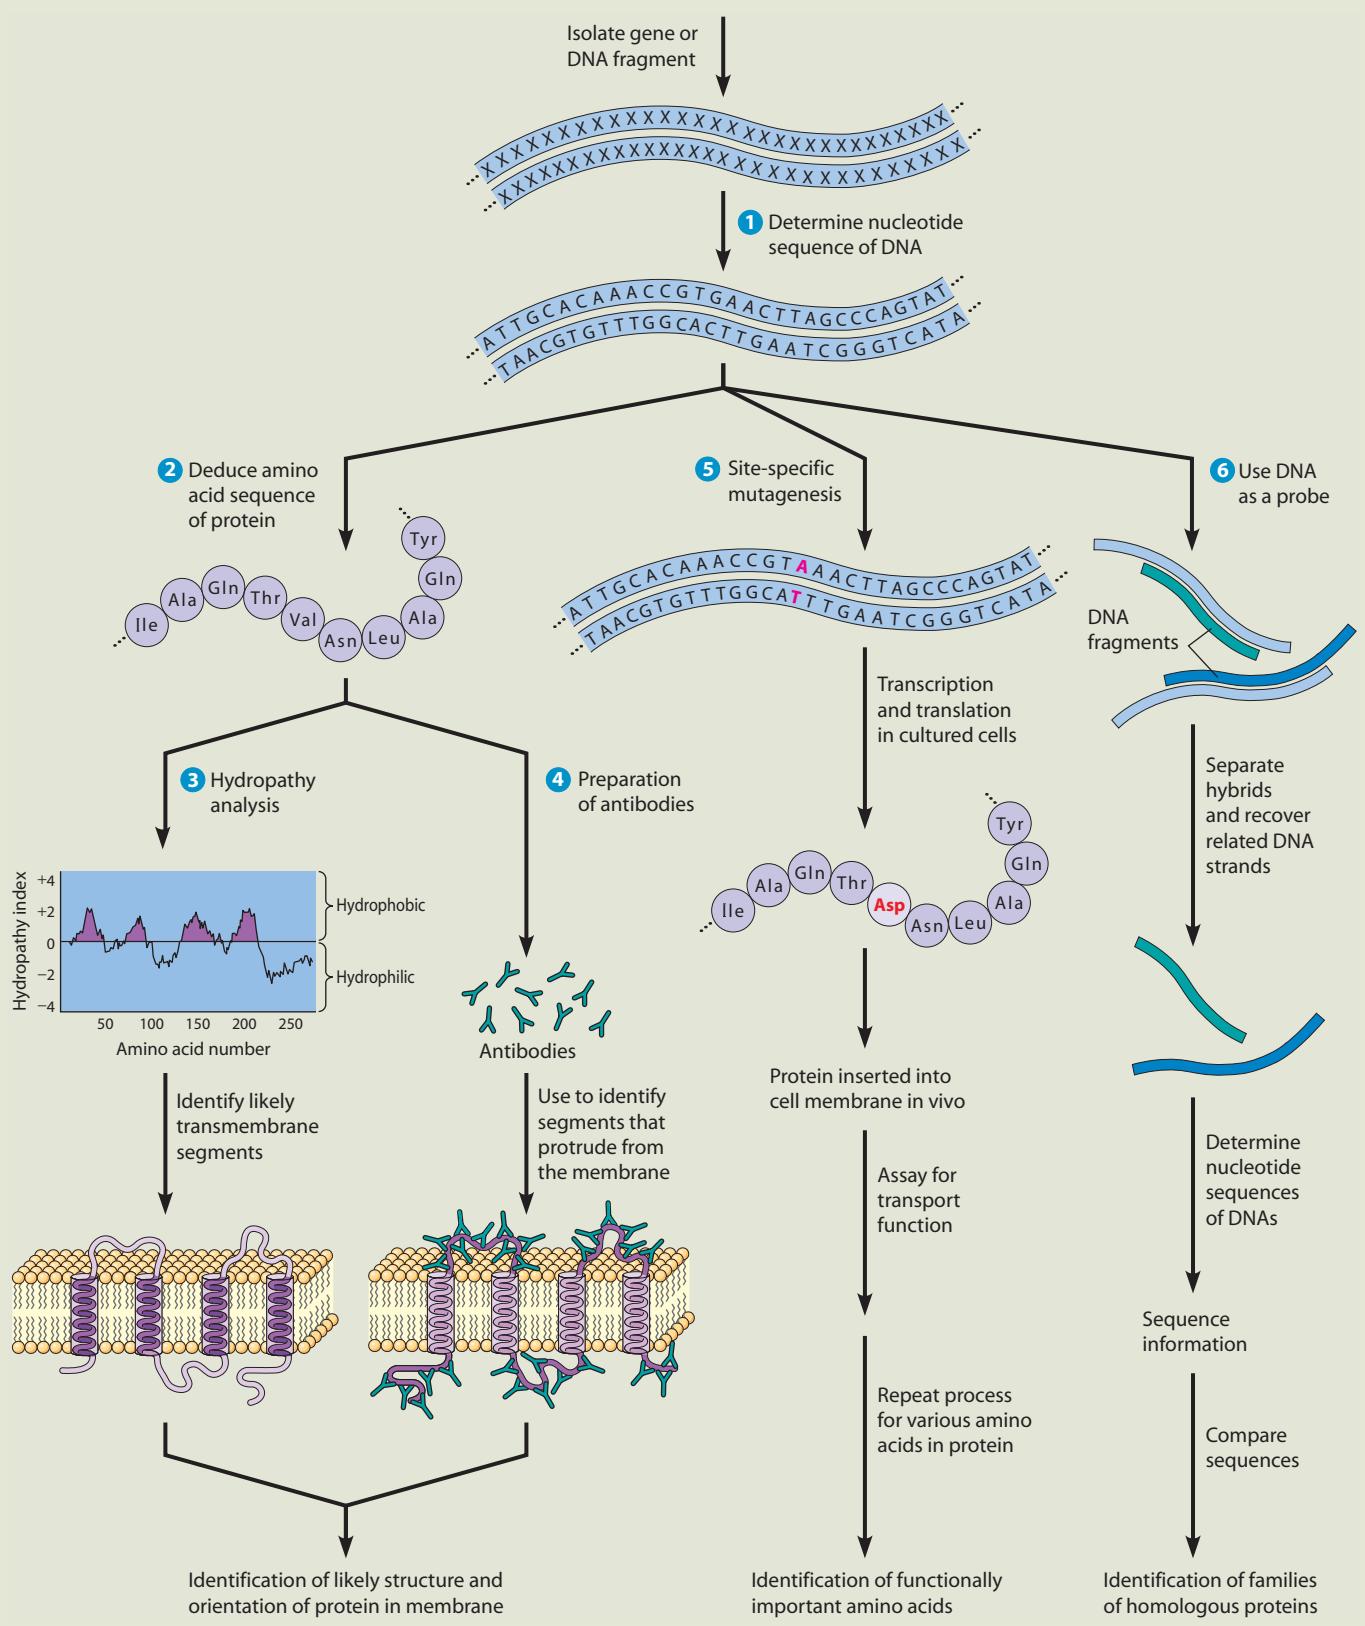

A gene or gene segment can be used as a *DNA probe* to isolate similar DNA sequences **6**. DNA identified in this way is likely to encode proteins similar to the protein that the probe DNA codes for. Such proteins are likely to be related to each other both in evolutionary origin and in their mechanisms of action.

Thanks to the advent of techniques for sequencing whole genomes (discussed in Chapter 18), we can now search whole genomes for nucleotide sequences similar to those already known to encode specific proteins. In this way, various *families*, or groups, of related proteins can be identified. The use of computerized databases, such as GenBank at the National Institutes of Health, has been extremely valuable in suggesting roles for proteins based entirely on their gene sequences.

From studies based on these and other techniques, we now know that cells in the human body need more than 30 families of membrane proteins to facilitate the transport of the great variety of solutes that must be moved across membranes. Each member of such a family may be present in a variety of *isoforms* that differ in such properties as time of expression during development, tissue distribution, or location within the cell. Perhaps it is not so surprising, then, to learn that the genes known to encode transport proteins represent about 10% of the human genome!

Most of these molecular approaches are indirect in the sense that they allow scientists to deduce properties and functions of proteins rather than proving them directly. Still, these techniques are powerful tools that have already significantly expanded our understanding of membrane proteins. And certainly in the future, these and newer techniques of molecular biology, such as proteomics, will continue to revolutionize the study of membranes and their proteins.

FIGURE 7A-1 Application of Molecular Biology Techniques to the Study of Membrane Proteins. These techniques are invaluable for studying membrane proteins, which are often very difficult to isolate.

protein receptors on the plasma membrane of target cells. In most cases, the binding of a hormone or other signal molecule to the appropriate receptor on the membrane surface triggers some sort of intracellular response, which in turn elicits the desired effect. Membrane proteins are also involved with intercellular communication. Examples include the proteins that form structures called *connexons* at *gap junctions* between animal cells and those that make up the *plasmodesmata* between plant cells.

Other cellular functions in which membrane proteins play key roles include uptake and secretion of various substances by endocytosis and exocytosis; targeting, sorting, and modification of proteins within the endoplasmic reticulum and the Golgi complex; and the detection of light, whether by the human eye, a bacterial cell, or a plant leaf. Membrane proteins are also vital components of various structures, including the links between the plasma membrane and the extracellular matrix located outside of the cell, the pores found in the outer membranes of mitochondria and chloroplasts, and the pores of the nuclear envelope. All these topics are discussed in later chapters. Other membrane proteins are involved in *autophagy* (“self eating”), a process we will learn about in more detail in Chapter 12. During autophagy, cells digest their own organelles or structures that become damaged or are no longer needed. In this way, the molecular components of these structures can be recycled and reused in newly synthesized structures.

A final group of membrane-associated proteins are those with structural roles in stabilizing and shaping the cell membrane. Examples include spectrin, ankyrin, and band 4.1 protein, the erythrocyte peripheral membrane proteins that we encountered earlier (see Figure 7-20b). Long, thin tetramers of α and β spectrin, $(\alpha\beta)_2$, are linked to glycophorin molecules by band 4.1 protein and short actin filaments and to band 3 proteins by ankyrin and another protein, called band 4.2. (Appropriately enough, *ankyrin* is derived from the Greek word for “anchor.”) In this way, spectrin and its associated proteins form a cytoskeletal network that underlies and supports the plasma membrane. This spectrin-based network gives the red blood cell its distinctive biconcave shape (see Figure 7-20a) and enables the cell to withstand the stress on its membrane as it is forced through narrow capillaries in the circulatory system. Proteins that are structurally homologous to spectrin and spectrin-associated proteins are found just beneath the plasma membrane in many other cell types also, indicating that a cytoskeletal meshwork of peripheral membrane proteins underlies the plasma membrane of many different kinds of cells.

The function of a membrane protein is usually reflected in how the protein is associated with the lipid bilayer. For example, a protein that functions on only one side of a membrane is likely to be a peripheral protein or a lipid-anchored protein. Membrane-bound enzymes that catalyze reactions on only one side of a membrane, such as the ER enzyme glucose-6-phosphatase are in this category. In contrast, the tasks of transporting solutes or transmitting signals across a membrane clearly require transmembrane

proteins. In Chapter 8 we will examine the role of transmembrane proteins in transport of materials across membranes. In Chapter 14 we will see how transmembrane receptors bind signaling molecules (such as hormones) on the outside of the plasma membrane and then generate signals inside the cell.

Membrane Proteins Are Oriented Asymmetrically Across the Lipid Bilayer

Earlier in the chapter, we noted that most membrane lipids are distributed asymmetrically between the two monolayers of the lipid bilayer. Most membrane proteins also exhibit an asymmetric orientation with respect to the bilayer. For example, peripheral proteins, lipid-anchored proteins, and integral monotopic proteins are by definition associated with one or the other of the membrane surfaces (see Figure 7-19). Once in place, these proteins cannot move across the membrane from one surface to the other. Integral membrane proteins that span the membrane are embedded in both monolayers, but they are asymmetrically oriented. In other words, the regions of the protein molecule that are exposed on one side of the membrane are structurally and chemically different from the regions of the protein exposed on the other side of the membrane. Moreover, all of the molecules of a given protein are oriented the same way in the membrane.

To determine how proteins are oriented in a membrane, radioactive labeling procedures have been devised that distinguish between proteins exposed on the inner and outer surfaces of membrane vesicles. One such approach makes use of the enzyme *lactoperoxidase* (LP), which catalyzes the covalent binding of iodine to proteins. When the reaction is carried out in the presence of ^{125}I , a radioactive isotope of iodine, LP labels the proteins. Because LP is too large to pass through membranes, only proteins exposed on the outer surface of intact membrane vesicles are labeled (**Figure 7-24a**).

To label only those proteins that are exposed on the inner membrane surface, vesicles are first exposed to a hypotonic (low ionic strength) solution to make them more permeable to large molecules. Under these conditions, LP can enter the vesicles. When the vesicles are then transferred to an isotonic solution that contains ^{125}I but no external LP, the ^{125}I , being a small molecule, can diffuse into the vesicle where the LP is trapped. Thus, the enzyme labels the proteins exposed on the inner surface of the vesicle membrane (Figure 7-24b, c). In this way, it is possible to determine whether a given membrane protein is exposed on the inner membrane surface only, on the outer surface only, or on both surfaces.

In a similar approach, the enzyme *galactose oxidase* (GO) can be used to label carbohydrate side chains that are attached to membrane proteins or lipids. Vesicles are first treated with GO to oxidize galactose residues in carbohydrate side chains. The vesicles are then exposed to tritiated borohydride ($^3\text{H}-\text{BH}_4$), which reduces the galactose groups, introducing labeled hydrogen atoms in the

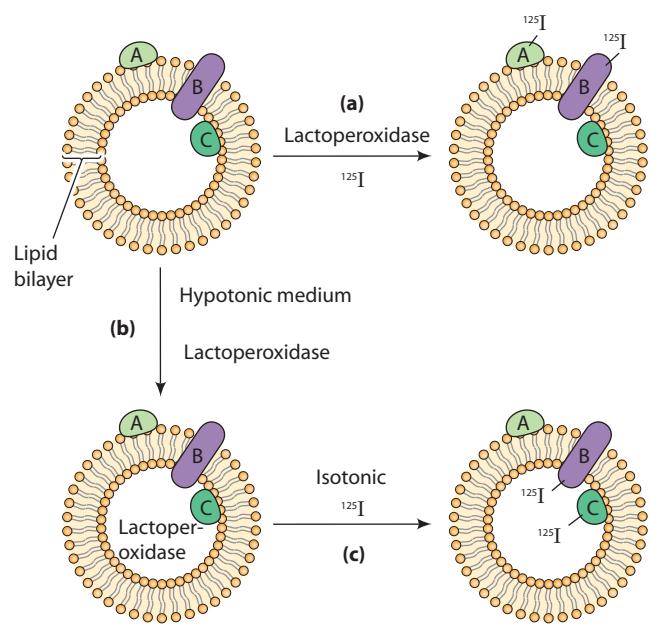

FIGURE 7-24 A Method for Labeling Proteins Exposed on One or Both Surfaces of a Membrane Vesicle. (a) When lactoperoxidase (LP) and ^{125}I are present in the solution outside a membrane vesicle, LP catalyzes the labeling of membrane proteins exposed on the outer membrane surface (i.e., proteins A and B). If membrane vesicles are (b) first incubated in a hypotonic medium to make them permeable to LP and (c) then transferred to an isotonic solution containing ^{125}I but no external LP, proteins exposed on the inner membrane surface (i.e., proteins B and C) become labeled.

process. In both of these approaches, the labeled proteins are typically separated on an SDS-PAGE gel that is then dried and exposed to X-ray film to reveal the locations of the labeled polypeptides.

The orientation of a protein within a membrane can also be determined using antibodies that are designed to recognize specific parts of the protein. Intact cells (or organelles) are exposed to these antibodies and are then tested to determine whether antibodies have bound to the membrane. If so, it can be concluded that the antibody-binding site, or *epitope*, must be on the outer membrane surface.

Many Membrane Proteins Are Glycosylated

In addition to lipids and proteins, most membranes contain small but significant amounts of carbohydrates, except for chloroplast, mitochondrial, and bacterial membranes. The plasma membrane of the human erythrocyte, for example, contains about 49% protein, 43% lipid, and 8% carbohydrate by weight. The glycolipids that we encountered earlier account for a small portion of membrane carbohydrate, but most of the carbohydrate in membranes is found as part of **glycoproteins**—membrane proteins with carbohydrate chains covalently linked to amino acid side chains.

The addition of a carbohydrate side chain to a protein is called **glycosylation**. This process occurs in the ER and Golgi compartments of the cell soon after synthesis. As Figure 7-25 shows, glycosylation involves linkage of the carbohydrate either to the nitrogen atom of an amino group

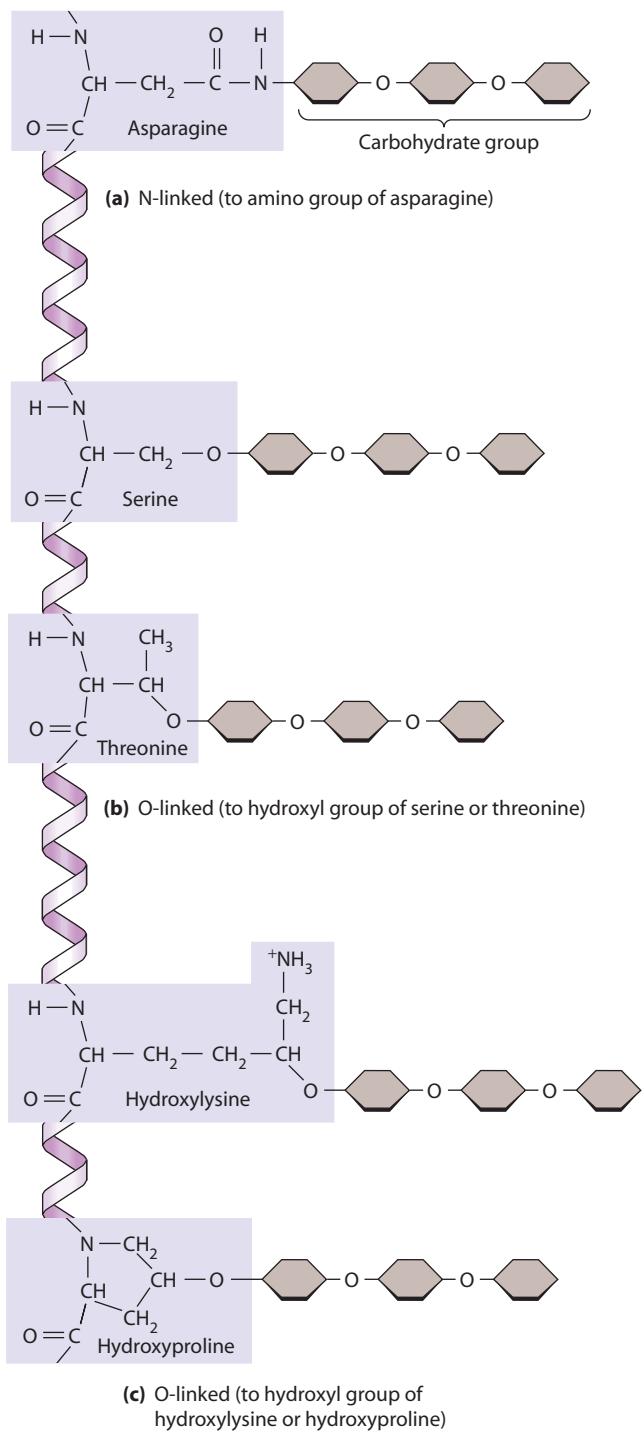

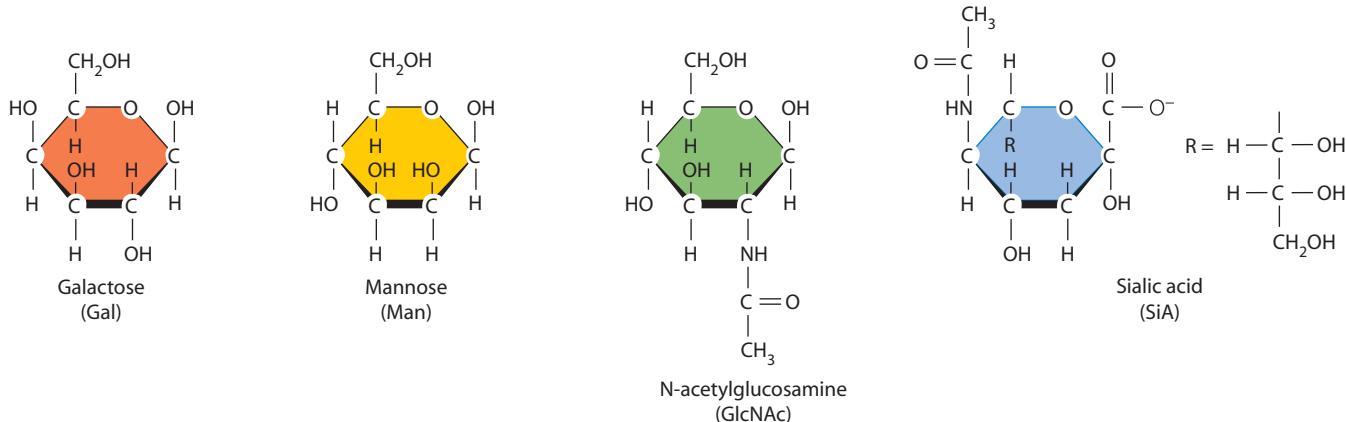

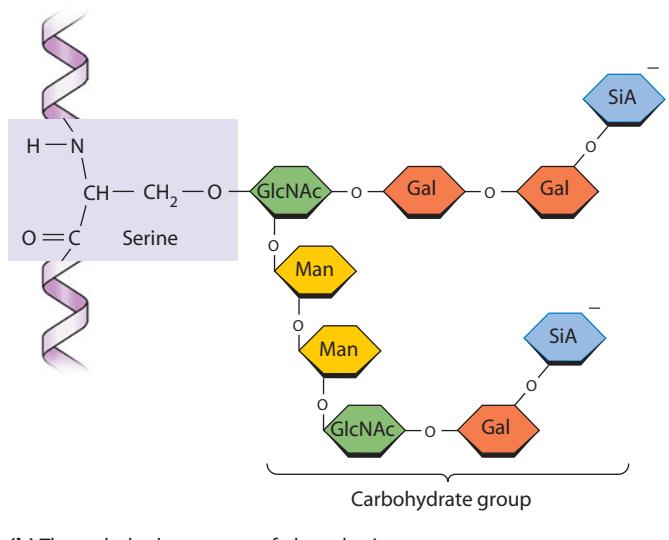

FIGURE 7-25 N-Linked and O-Linked Glycosylation of Membrane Proteins. Carbohydrate groups are linked to specific amino acid residues in membrane proteins in two different ways. (a) N-linked carbohydrates are attached to the amino group of asparagine side chains. (b) O-linked carbohydrates are attached to the hydroxyl group of serine or threonine side chains. (c) In some cases, O-linked carbohydrates are attached to the hydroxyl group of the modified amino acids hydroxylysine and hydroxyproline.

(*N*-linked glycosylation) or to the oxygen atom of a hydroxyl group (*O*-linked glycosylation). N-linked carbohydrates are attached to the amino group on the side chain of asparagine (Figure 7-25a), whereas O-linked carbohydrates are usually bound to the hydroxyl groups of either serine or threonine

(a) Common sugars found in glycoproteins

(b) The carbohydrate group of glycophorin

(Figure 7-25b). In some cases, O-linked carbohydrates are attached to the hydroxyl group of hydroxylysine or hydroxyproline, which are derivatives of the amino acids lysine and proline, respectively (Figure 7-25c).

The carbohydrate chains attached to glycoproteins can be either straight or branched and range in length from 2 to about 60 sugar units. The most common sugars used in constructing these chains are *galactose*, *mannose*, *N-acetylglucosamine*, and *sialic acid* (Figure 7-26a). Figure 7-26b shows the carbohydrate chain found in the erythrocyte plasma membrane protein, glycophorin. This integral membrane protein has 16 such carbohydrate chains attached to the portion of the molecule (the N-terminus) that extends outward from the erythrocyte membrane. Of these 16 chains, 1 is N-linked and 15 are O-linked. Notice that both branches of the carbohydrate chain terminate in a negatively charged sialic acid. Because of these anionic groups on their surfaces, erythrocytes repel each other, thereby reducing blood viscosity.

Glycoproteins are most prominent in plasma membranes, where they play an important role in cell-cell recognition. Consistent with this role, glycoproteins are always positioned so that the carbohydrate groups

FIGURE 7-26 Examples of Carbohydrates Found in Glycoproteins. (a) The four most common carbohydrates in glycoproteins are galactose (Gal), mannose (Man), *N*-acetylglucosamine (GlcNAc), and sialic acid (SiA). (b) For example, 15 of the 16 carbohydrate chains of glycophorin are linked to the amino acid serine in the hydrophilic portion of the protein on the outer surface of the erythrocyte plasma membrane. Each of these carbohydrate chains consists of three units of Gal and two units each of GlcNAc, Man, and SiA. The two terminal sialic acid groups are negatively charged.

protrude on the external surface of the cell membrane. This arrangement, which contributes to membrane asymmetry, has been shown experimentally using *lectins*, plant proteins that bind specific sugar groups very tightly. For example, *wheat germ agglutinin*, a lectin found in wheat embryos, binds very specifically to oligosaccharides that terminate in *N*-acetylglucosamine, whereas *concanavalin A*, a lectin from jack beans, recognizes mannose groups in internal positions. Investigators visualize these lectins by linking them to *ferritin*, an iron-containing protein that shows up as an electron-dense spot when viewed with an electron microscope. When such ferritin-linked lectins are used as probes to localize the oligosaccharide chains of membrane glycoproteins, binding is always specifically to the outer surface of the plasma membrane.

In many animal cells, the carbohydrate groups of plasma membrane glycoproteins and glycolipids protrude from the cell surface and form a surface coat called the **glycocalyx** (meaning “sugar coat”). Figure 7-27 shows the prominent glycocalyx of an intestinal epithelial cell. The carbohydrate groups on the cell surface are important components of the recognition sites of membrane receptors such as those involved in binding extracellular signal

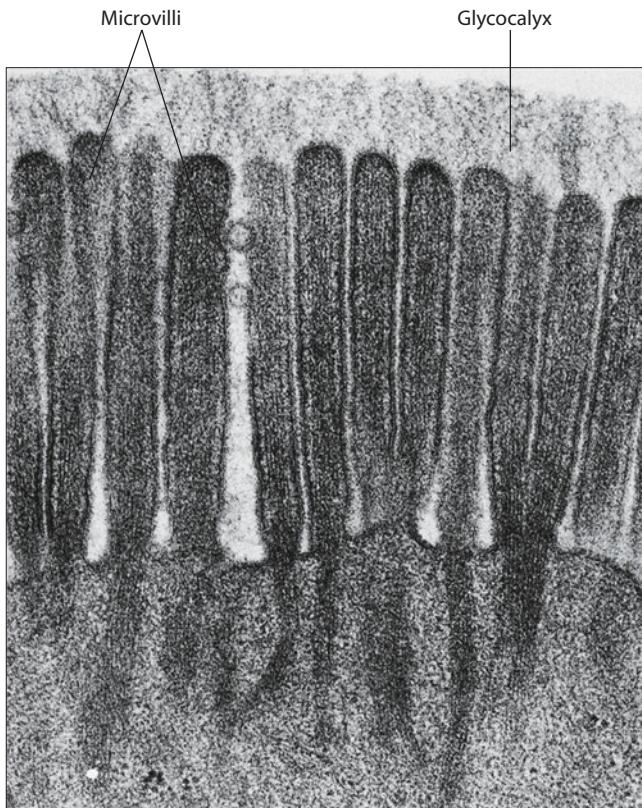

FIGURE 7-27 The Glycocalyx of an Intestinal Epithelial Cell. This electron micrograph of a cat intestinal epithelial cell shows the microvilli (fingerlike projections that are involved in absorption) and the glycocalyx on the cell surface. The glycocalyx on this cell is about 150 nm thick and consists primarily of oligosaccharide chains about 1.2–1.5 nm in diameter (TEM).

molecules, in antibody-antigen reactions, and in intercellular adhesion to form tissues. In some pathogenic bacteria, such as *Streptococcus pneumoniae*, the presence of a glycocalyx can hide the antigenic surface proteins that would

normally stimulate the immune response. This allows these bacteria to escape detection and subsequent destruction by immune system cells and thus enables them to adhere to target cells and cause disease in the host organism.

Membrane Proteins Vary in Their Mobility

Earlier in the chapter, we noted that lipid molecules can diffuse laterally within the plane of a membrane (see Figure 7-11). Now we can ask the same question about membrane proteins: Are they also free to move within the membrane? In fact, membrane proteins are much more variable than lipids in their mobility. Some proteins appear to move freely within the lipid bilayer. Others are constrained, often because they are anchored to protein complexes located adjacent to one side of the membrane or the other.

Experimental Evidence for Protein Mobility. Particularly convincing evidence for the mobility of at least some membrane proteins has come from *cell fusion experiments* such as those summarized in **Figure 7-28**. In these studies, David Frye and Michael Edidin took advantage of two powerful techniques, one that enabled them to fuse cells from two different species and another that made it possible for them to label specific proteins on the surfaces of cells with antibodies containing fluorescent dye molecules. *Antibodies* are immune system proteins that recognize and bind to specific molecular *antigens* such as cell surface proteins.

Frye and Edidin prepared two **fluorescent antibodies**, each one having a differently-colored dye linked to it, so that the human and mouse proteins could be distinguished. The anti-mouse antibodies were linked to a green fluorescent dye called *fluorescein*, whereas the anti-human antibodies were linked to a red fluorescent dye, *rhodamine*.

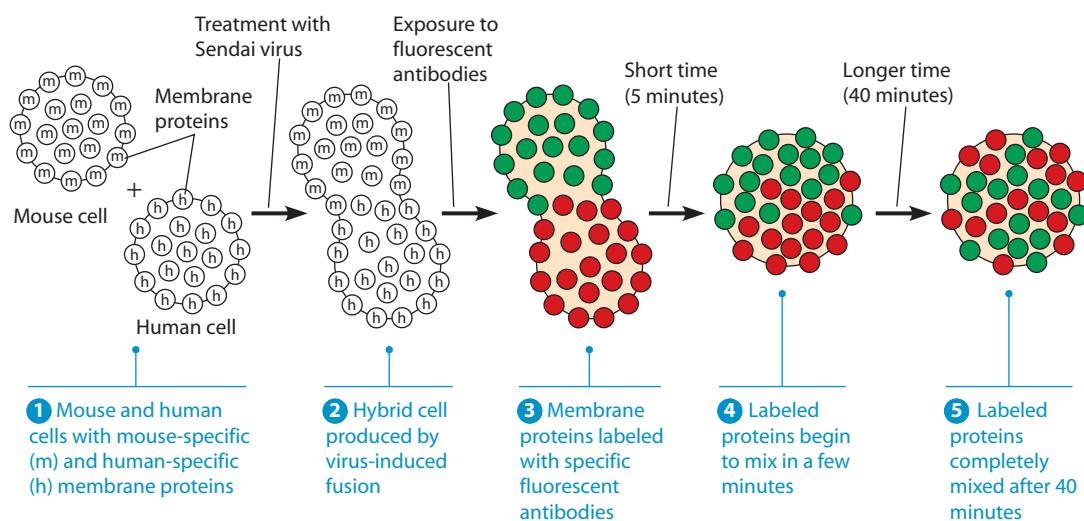

FIGURE 7-28 Demonstration of the Mobility of Membrane Proteins by Cell Fusion. The mobility of membrane proteins can be shown experimentally by the mixing of membrane proteins that occurs when cells from two different species (mouse and human) are fused and the membrane proteins are labeled with specific fluorescent antibodies.

Thus, under a fluorescence microscope, the mouse cells appeared green and the human cells appeared red due to each antibody recognizing and binding to its specific protein antigens on the surface of the cells (Figure 7-28).

Frye and Edidin fused mouse and human cells using Sendai virus, exposed them to the red and green fluorescent antibodies, and observed the fused cells by fluorescence microscopy. At first, the green fluorescent membrane proteins from the mouse cell were localized on one-half of the hybrid cell surface, and the red fluorescent membrane proteins derived from the human cell were restricted to the other half (see Figure 7-28). In a few minutes, however, the proteins from the two parent cells began to intermix. After 40 minutes, the separate regions of green and red fluorescence were completely intermingled.

If the fluidity of the membrane was depressed by lowering the temperature below the transition temperature of the lipid bilayer, this intermixing could be prevented. Frye and Edidin therefore concluded that the intermingling of the fluorescent proteins had been caused by lateral diffusion of the human and mouse proteins through the fluid lipid bilayer of the plasma membrane. Compared to most membrane lipids, however, membrane proteins diffuse through the lipid bilayer much more slowly due to their larger size.

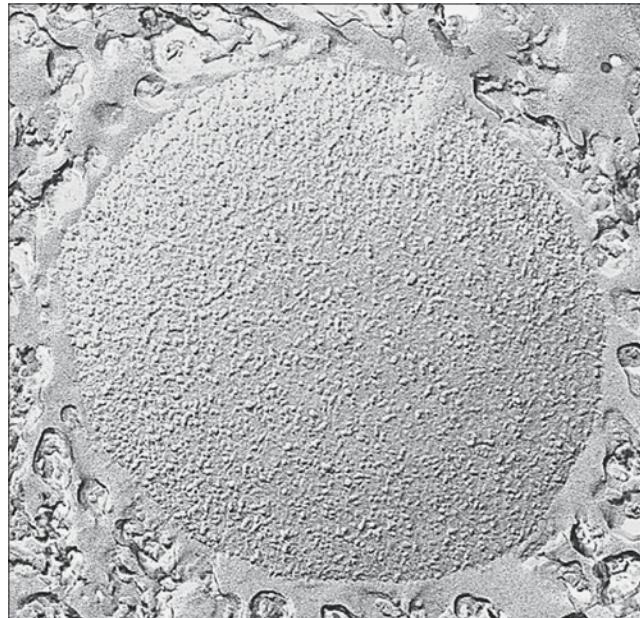

If proteins are completely free to diffuse within the plane of the membrane, then they should eventually become randomly distributed. Support for the idea that at least some membrane proteins behave in this way has emerged from freeze-fracture microscopy, which directly

visualizes proteins embedded within the lipid bilayer. When plasma membranes are examined in freeze-fracture micrographs, their embedded protein particles often tend to be randomly distributed. Such evidence for protein mobility is not restricted to the plasma membrane. It has also been found, for example, that the protein particles of the inner mitochondrial membranes are randomly arranged (**Figure 7-29a**). If isolated mitochondrial membrane vesicles are exposed to an electrical potential, the protein particles, which bear a net negative charge, all move to one end of the vesicle (Figure 7-29b). Removing the electrical potential causes the particles to become randomly distributed again, indicating that these proteins are free to move within the lipid bilayer.

Experimental Evidence for Restricted Mobility.

Although many types of membrane proteins have been shown to diffuse through the lipid bilayer, their rates of movement vary. A widely used approach for quantifying the rates at which membrane proteins diffuse is fluorescence photobleaching recovery, a technique discussed earlier in the context of lipid mobility (see Figure 7-11). The rate at which unbleached molecules from adjacent parts of the membrane move back into the bleached area can be used to calculate the diffusion rates of various kinds of fluorescent lipid or protein molecules.

Membrane proteins are much more variable in their diffusion rates than lipids are. A few membrane proteins diffuse almost as rapidly as lipids, but most diffuse more

(a)

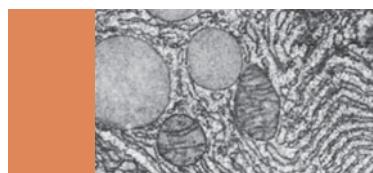

(b)

FIGURE 7-29 Evidence for the Mobility of Membrane Proteins. (a) Freeze-fracture micrograph showing the random distribution of protein particles in vesicles prepared from the inner mitochondrial membrane. (b) Exposure of the vesicles to an electrical field causes the membrane particles to migrate to one end of the vesicle (upper right of micrograph). If membrane proteins were not mobile, this movement of proteins to one side of the vesicle would not happen.

slowly than would be expected if they were completely free to move within the lipid bilayer. Moreover, the diffusion of many membrane proteins is restricted to a limited area of the membrane, indicating that at least some membranes consist of a series of separate *membrane domains* that differ in their protein compositions and hence in their functions. For example, the cells lining your small intestine have membrane proteins that transport solutes such as sugars and amino acids out of the intestine and into the body. These transport proteins are restricted to the side of the cell where the corresponding type of transport is required.

Mechanisms for Restricting Protein Mobility. Several different mechanisms account for restricted protein mobility and hence for cell polarization. In some cases, membrane

proteins aggregate within the membrane, forming large complexes that move only sluggishly, if at all. In other cases, membrane proteins form structures that become barriers to the diffusion of other membrane proteins, thereby effectively creating specific membrane domains. The *tight junctions* to be discussed in Chapter 17 are one example. The most common restraint on the mobility of membrane proteins, however, is imposed by the binding, or *anchoring*, of such proteins to structures located adjacent to one side of the membrane or the other. For example, many proteins of the plasma membrane are anchored either to elements of the cytoskeleton on the inner surface of the membrane or to extracellular structures such as the extracellular matrix of animal cells. We will encounter both of these anchoring mechanisms in Chapter 17.

SUMMARY OF KEY POINTS

The Functions of Membranes

- Cells have a variety of membranes that define the boundaries of the cell and its internal compartments. All biological membranes have the same general structure: a fluid phospholipid bilayer containing a mosaic of embedded proteins.
- While the lipid component of membranes provides a permeability barrier, specific proteins in the membrane regulate transport of materials into and out of cells and organelles.
- Membranes serve as sites for specific proteins and thus can have specific functions. They can detect and transduce external signals, mediate contact and adhesion between neighboring cells, or participate in cell-to-cell communication. They also help to produce external structures such as the cell wall or extracellular matrix.

Models of Membrane Structure: An Experimental Perspective

- Our current understanding of membrane structure represents the culmination of more than a century of studies, beginning with the recognition that lipids are an important membrane component.
- Once proteins were recognized as important components, Davson and Danielli proposed their “sandwich” model—a lipid bilayer surrounded on both sides by layers of proteins. As membranes and membrane proteins were examined in more detail, however, this model was eventually discredited.
- In place of the sandwich model, Singer and Nicolson’s fluid mosaic model emerged and is now the universally accepted description of membrane structure. According to this model, proteins with varying affinities for the hydrophobic membrane interior float in and on a fluid lipid bilayer.

- We now know that lipids and proteins are not distributed randomly in the membrane but are often found in micro-domains known as lipid rafts that are involved in cell signaling and other interactions.

Membrane Lipids: The “Fluid” Part of the Model

- Prominent lipids in most membranes include numerous types of phospholipids and glycolipids. The proportion of each lipid type can vary considerably depending on the particular membrane or monolayer.
- In eukaryotic cells, sterols are also important membrane components, including cholesterol in animal cells and phytosterols in plant cells. Sterols are not found in the membranes of most prokaryotes, but some bacterial species contain similar compounds called hopanoids.
- Proper fluidity of a membrane is critical to its function. Cells often can vary the fluidity of membranes by changing the length and degree of saturation of the fatty acid chains of the membrane lipids or by the addition of cholesterol or other sterols.
- Long-chain fatty acids pack together well and decrease fluidity. Unsaturated fatty acids contain *cis* double bonds that interfere with packing and increase fluidity.
- Most membrane phospholipids and proteins are free to move within the plane of the membrane unless they are specifically anchored to structures on the inner or outer membrane surface. Transverse diffusion, or “flip-flop,” between monolayers is not generally possible, except for phospholipids when catalyzed by enzymes called phospholipid translocators, or flippases.
- As a result, most membranes are characterized by an asymmetric distribution of lipids between the two monolayers and

an asymmetric orientation of proteins within the membranes so that the two sides of the membrane are structurally and functionally dissimilar.

Membrane Proteins: The “Mosaic” Part of the Model

- Proteins are major components of all cellular membranes. Membrane proteins are classified as integral, peripheral, or lipid anchored, based on how they are associated with the lipid bilayer.
- Integral membrane proteins have one or more short segments of predominantly hydrophobic amino acids that anchor the protein to the membrane. Most of these transmembrane segments are α -helical sequences of about 20–30 predominantly hydrophobic amino acids.
- Peripheral membrane proteins are hydrophilic and remain on the membrane surface. They are typically attached to the polar head groups of phospholipids by ionic and hydrogen bonding.

- Lipid-anchored proteins are also hydrophilic in nature but are covalently linked to the membrane by any of several lipid anchors that are embedded in the lipid bilayer.
- Membrane proteins function as enzymes, electron carriers, transport molecules, and receptor sites for chemical signals such as neurotransmitters and hormones. Membrane proteins also stabilize and shape the membrane and mediate intercellular communication and cell-cell adhesion.
- Many proteins in the plasma membrane are glycoproteins, with carbohydrate side chains that protrude from the membrane on the external side, where they play important roles as recognition markers on the cell surface.
- Thanks to current advances in SDS-PAGE, molecular biology X-ray crystallography, affinity labeling, and the use of specific antibodies, we are learning much about the structure and function of membrane proteins that were difficult to study in the recent past.

MAKING CONNECTIONS

By now, you should have an appreciation for the molecular basis of membrane structure and the experimental evidence that led to our current understanding of membrane structure. You are also now familiar with many of the types of lipids and proteins that make up these membranes and how they contribute to the functions of specific membranes. In the next chapter, you can apply your knowledge of membrane structure and function as we investigate in detail the mechanisms by which cells can transport molecules across membranes. In Chapters 10 and 11, you will see how the transport of H^+ ions across membranes to create an electrochemical charge gradient is critical for ATP synthesis, both for aerobic respiration in the mitochondrion and for photosynthesis in the chloroplast. We will then study how lipids and proteins are targeted to and inserted into particular membranes in cells in Chapter 12 and how they are processed and sorted to their final destinations, whether it may be into a partic-

ular organelle, to the plasma membrane, or out of the cell as a secreted product. We will rely heavily on our understanding of membranes as we investigate electrical and chemical signaling in Chapters 13 and 14, as you learn about ion channels crucial for nerve impulse transmission, receptor proteins involved in hormonal signaling, and cellular responses to growth factors and other signaling molecules. As we proceed through studies of cell motility, the cytoskeleton, and cell-cell recognition and adhesion in the next few chapters, you will rely extensively on what you have learned about membranes in this chapter. And as we finish our studies in this textbook with detailed looks at the cell nucleus, cell division, and cancer cells, you can better appreciate the important roles of membranes. You will see how defects in cell signaling and adhesion can lead to cancer, and you will learn how we can use our knowledge of membrane proteins to identify and perhaps destroy specific types of cancer cells.

PROBLEM SET

More challenging problems are marked with a •.

7-1 Functions of Membranes. For each of the following statements, specify which one of the five general membrane functions (permeability barrier, localization of function, regulation of transport, detection of signals, or intercellular communication) the statement illustrates.

- (a) When cells are disrupted and fractionated into subcellular components, the enzyme cytochrome P-450 is recovered with the endoplasmic reticulum fraction.
- (b) On their outer surface tissue, cells of multicellular organisms carry specific glycoproteins that are responsible for cell-cell adhesion.

- (c) The interior of a membrane consists primarily of the hydrophobic portions of phospholipids and amphipathic proteins.
- (d) Photosystems I and II are embedded in the thylakoid membrane of the chloroplast.
- (e) All of the acid phosphatase in a mammalian cell is found within the lysosomes.
- (f) The membrane of a plant root cell has an ion pump that exchanges phosphate inward for bicarbonate outward.
- (g) The inner mitochondrial membrane contains an ATP-ADP carrier protein that couples outward ATP movement to inward ADP movement.

- (h) Insulin does not enter a target cell but instead binds to a specific membrane receptor on the external surface of the membrane, thereby activating the enzyme adenylyl cyclase on the inner membrane surface.
- (i) Adjacent plant cells frequently exchange cytoplasmic components through membrane-lined channels called plasmodesmata.

7-2 Elucidation of Membrane Structure. Each of the following observations played an important role in enhancing our understanding of membrane structure. Explain the significance of each, and indicate in what decade of the timeline shown in Figure 7-3 the observation was most likely made.

- (a) When a membrane is observed in the electron microscope, both of the thin, electron-dense lines are about 2 nm thick, but the two lines are often distinctly different from each other in appearance.
- (b) Ethylurea penetrates much more readily into a membrane than does urea, and diethylurea penetrates still more readily.
- (c) The addition of phospholipase to living cells causes rapid digestion of the lipid bilayers of the membranes, which suggests that the enzyme has access to the membrane phospholipids.
- (d) When artificial lipid bilayers are subjected to freeze-fracture analysis, no particles are seen on either face.
- (e) The electrical resistivity of artificial lipid bilayers is several orders of magnitude greater than that of real membranes.
- (f) Some membrane proteins can be readily extracted with 1 M NaCl, whereas others require the use of an organic solvent or a detergent.
- (g) When halobacteria are grown in the absence of oxygen, they produce a purple pigment that is embedded in their plasma membranes and has the ability to pump protons outward when illuminated. If the purple membranes are isolated and viewed by freeze-fracture electron microscopy, they are found to contain patches of crystalline particles.

7-3 Wrong Again. For each of the following false statements, change the statement to make it true and explain your reasoning.

- (a) Because membranes have a hydrophobic interior, polar and charged molecules cannot pass through membranes.
- (b) Proteins typically transmit signals from the outside of the cell to the cytoplasm by flip-flopping from the outer membrane monolayer to the inner monolayer.
- (c) O-linked and N-linked glycoproteins are formed when sugar chains are attached to the oxygen and nitrogen atoms of the peptide bonds in proteins.
- (d) The three-dimensional structure of a protein cannot be determined unless the protein can be isolated from cells in pure form.
- (e) You would expect membrane lipids from tropical plants such as palm and coconut to have short-chain fatty acids with multiple C=C double bonds.

7-4 Gorter and Grendel Revisited. Gorter and Grendel's classic conclusion that the plasma membrane of the human erythrocyte consists of a lipid bilayer was based on the following observations: (i) the lipids that they extracted with acetone from 4.74×10^9 erythrocytes formed a monolayer 0.89 m^2 in area when spread

out on a water surface; and (ii) the surface area of one erythrocyte was about $100 \mu\text{m}^2$, according to their measurements.

- (a) Show from these data how they came to the conclusion that the erythrocyte membrane is a bilayer.
- (b) We now know that the surface area of a human erythrocyte is about $145 \mu\text{m}^2$. Explain how Gorter and Grendel could have come to the right conclusion when one of their measurements was only about two-thirds of the correct value.

7-5 Martian Membranes. Imagine a new type of cell was discovered on Mars in an organism growing in benzene, a non-polar liquid. The cell had a lipid bilayer made of phospholipids, but its structure was very different from that of our cell membranes.

- (a) Draw what might be a possible structure for this new type of membrane. What might be characteristic features of the phospholipid head groups?
- (b) What properties would you expect to find in membrane proteins embedded in this membrane?
- (c) How might you isolate and visualize these unusual membranes?

7-6 That's About the Size of It. From chemistry, we know that each methylene ($-\text{CH}_2-$) group in a straight-chain hydrocarbon advances the chain length by about 0.13 nm. And from studies of protein structure, we know that one turn of an α helix includes 3.6 amino acid residues and extends the long axis of the helix by about 0.56 nm. Use this information to answer the following:

- (a) How long is a single molecule of palmitate (16 carbon atoms) in its fully extended form? What about molecules of laurate (12C) and arachidate (20C)?
- (b) How does the thickness of the hydrophobic interior of a typical membrane compare with the length of two palmitate molecules laid end to end? What about two molecules of laurate or arachidate?
- (c) Approximately how many amino acids must a helical transmembrane segment of an integral membrane protein have if the segment is to span the lipid bilayer defined by two palmitate molecules laid end to end?
- (d) The protein bacteriorhodopsin has 248 amino acids and seven transmembrane segments. Approximately what portion of the amino acids are part of the transmembrane segments? Assuming that most of the remaining amino acids are present in the hydrophilic loops linking the transmembrane segments together, approximately how many amino acids are present in each of these loops, on the average?

7-7 Temperature and Membrane Composition. Which of the following responses are *not* likely to be seen when a bacterial culture growing at 37°C is transferred to a culture room maintained at 25°C ? Explain your reasoning.

- (a) Initial decrease in membrane fluidity
- (b) Gradual replacement of shorter-chain fatty acids by longer-chain fatty acids in the membrane phospholipids
- (c) Gradual replacement of stearate by oleate in the membrane phospholipids
- (d) Enhanced rate of synthesis of unsaturated fatty acids
- (e) Incorporation of more cholesterol into the membrane

7-8 Membrane Fluidity and Temperature. The effects of temperature and lipid composition on membrane fluidity are often studied by using artificial membranes containing only one or a few kinds of lipids and no proteins. Assume that you and your lab partner have made the following artificial membranes:

Membrane 1: Made entirely from phosphatidylcholine with saturated 16-carbon fatty acids.

Membrane 2: Same as membrane 1, except that each of the 16-carbon fatty acids has a single *cis* double bond.

Membrane 3: Same as membrane 1, except that each of the saturated fatty acids has only 14 carbon atoms.

After determining the transition temperatures of samples representing each of the membranes, you discover that your lab partner failed to record which membranes the samples correspond to. The three values you determined are -36°C , 23°C , and 41°C . Assign each of these transition temperatures to the correct artificial membrane, and explain your reasoning.

7-9 The Little Bacterium That Can't. *Acholeplasma laidlawii* is a small bacterium that cannot synthesize its own fatty acids and must therefore construct its plasma membrane from whatever fatty acids are available in the environment. As a result, the *Acholeplasma* membrane takes on the physical characteristics of the fatty acids available at the time.

- (a) If you give *Acholeplasma* cells access to a mixture of saturated and unsaturated fatty acids, they will thrive at room temperature. Can you explain why?
- (b) If you transfer the bacteria of part a to a medium containing only saturated fatty acids but make no other changes in culture conditions, they will stop growing shortly after the change in medium. Explain why.
- (c) What is one way you could get the bacteria of part b growing again without changing the medium? Explain your reasoning.
- (d) If you were to maintain the *Acholeplasma* culture of part b under the conditions described there for an extended period of time, what do you predict will happen to the bacterial cells? Explain your reasoning.
- (e) What result would you predict if you were to transfer the bacteria of part a to a medium containing only unsaturated fatty acids without making any other changes in the culture conditions? Explain your reasoning.

• 7-10 Hydropathy: The Plot Thickens. A hydropathy plot can be used to predict the structure of a membrane protein based on its amino acid sequence and the hydrophobicity values of the amino acids. Hydrophobicity is measured as the standard free energy change, $\Delta G'$, for the transfer of a given amino acid residue from a hydrophobic solvent into water, in kilojoules/mole (kJ/mol). The hydropathy index is calculated by averaging the hydrophobicity values for a series of short segments of the polypeptide, with each segment displaced one amino acid further from the N-terminus. The hydropathy index of each successive segment is then plotted as a function of the location of that segment in the amino acid sequence, and the plot is examined for regions of high hydropathy index.

- (a) Why do scientists try to predict the structure of a membrane protein by this indirect means when the technique of X-ray crystallography would reveal the structure directly?
- (b) Given the way it is defined, would you expect the hydrophobicity index of a hydrophobic residue such as valine or

isoleucine to be positive or negative? What about a hydrophilic residue such as aspartic acid or arginine?

- (c) Listed below are four amino acids and four hydrophobicity values. Match the hydrophobicity values with the correct amino acids, and explain your reasoning.

Amino acids: alanine; arginine; isoleucine; serine
Hydrophobicity (in kJ/mol): +3.1; +1.0; -1.1; -7.5

- (d) Shown in **Figure 7-30** is a hydropathy plot for a specific integral membrane protein. Draw a horizontal bar over each transmembrane segment as identified by the plot. How long is the average transmembrane segment? How well does that value compare with the number you calculated in Problem 7-6c? How many transmembrane segments do you think the protein has? Can you guess which protein this might be?

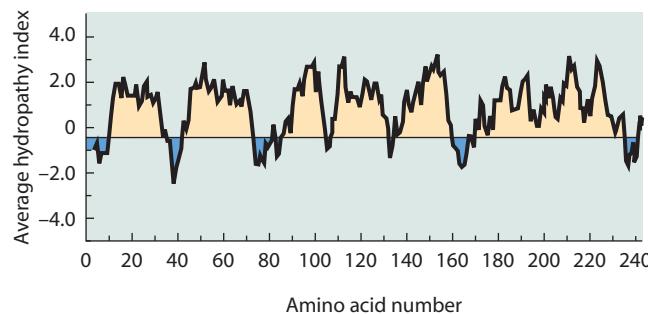

FIGURE 7-30 Hydropathy Plot for an Integral Membrane Protein. See Problem 7-10d.

• 7-11 Inside or Outside? From Figure 7-24, we know that exposed regions of membrane proteins can be labeled with ^{125}I by the lactoperoxidase (LP) reaction. Similarly, carbohydrate side chains of membrane glycoproteins can be labeled with ^{3}H by oxidation of galactose groups with galactose oxidase (GO) followed by reduction with tritiated borohydride ($^{3}\text{H}-\text{BH}_4$). Noting that both LP and GO are too large to penetrate into the interior of an intact cell, explain each of the following observations made with intact erythrocytes.

- (a) When intact cells are incubated with LP in the presence of ^{125}I and the membrane proteins are then extracted and analyzed on SDS-polyacrylamide gels, several of the bands on the gel are found to be radioactive.
- (b) When intact cells are incubated with GO and then reduced with $^{3}\text{H}-\text{BH}_4$, several of the bands on the gel are found to be radioactive.
- (c) All of the proteins of the plasma membrane that are known to contain carbohydrates are labeled by the GO/ $^{3}\text{H}-\text{BH}_4$ method.
- (d) None of the proteins of the erythrocyte plasma membrane that are known to be devoid of carbohydrate is labeled by the LP/ ^{125}I method.
- (e) If the erythrocytes are ruptured before the labeling procedure, the LP procedure labels virtually all of the major membrane proteins.

• 7-12 Inside-Out Membranes. It is technically possible to prepare sealed vesicles from erythrocyte membranes in which the original orientation of the membrane is inverted. Such vesicles have what was originally the cytoplasmic side of the membrane facing outward.

- (a) What results would you expect if such inside-out vesicles were subjected to the GO/ ^3H —BH₄ procedure described in Problem 7-11?
- (b) What results would you expect if such inside-out vesicles were subjected to the LP/ ^{125}I procedure of Problem 7-11?
- (c) What conclusion would you draw if some of the proteins that become labeled by the LP/ ^{125}I method of part b were

among those that had been labeled when intact cells were treated in the same way in Problem 7-11a?

- (d) Knowing that it is possible to prepare inside-out vesicles from erythrocyte plasma membranes, can you think of a way to label a transmembrane protein with ^3H on one side of the membrane and with ^{125}I on the other side?

Transport Across Membranes: Overcoming the Permeability Barrier

In Chapter 7, we focused on the structure and chemistry of membranes. We noted that its hydrophobic interior makes a membrane an effective barrier to the passage of most molecules and ions, thereby keeping some substances inside the cell and others out. Within eukaryotic cells, membranes also delineate organelles by retaining the appropriate molecules and ions needed for specific functions.

However, it is not enough to think of membranes simply as permeability barriers. Crucial to the proper functioning of a cell or organelle is the ability to overcome the permeability barriers for specific molecules and ions so that they can be moved into and out of the cell or organelle selectively. In other words, membranes are not simply barriers to the indiscriminate movement of substances into and out of cells and organelles. They are also selectively permeable, allowing the controlled passage of specific molecules and ions from one side of the membrane to the other. In this chapter we will look at the ways substances are moved selectively across membranes, and we will consider the significance of such transport processes to the life of the cell.

Cells and Transport Processes

An essential feature of every cell and subcellular compartment is its ability to accumulate a variety of substances at concentrations that are often strikingly different from those in the surrounding environment. Some of these substances are macromolecules—such as DNA, RNA, and proteins—that are moved into and out of cells and organelles by mechanisms we will consider in later chapters. Specifically, Chapter 12 includes a discussion of *endocytosis* and *exocytosis*, bulk transfer processes whereby substances are moved into and out of cells enclosed within membrane-bounded vesicles. Mechanisms for the secretion of proteins from cells and for the import of proteins into organelles are discussed in Chapter 22.

As important as these topics are, most of the substances that move across membranes are not macromolecules but dissolved gases, ions, and small organic molecules—*solute*s, in other words. Some of the more common ions transported across membranes are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), chloride (Cl^-), and hydrogen (H^+) ions. Most of the small organic molecules are *metabolites*—substrates, intermediates, and products in the various metabolic pathways that take place within cells or specific organelles. Sugars, amino acids, and nucleotides are some common examples. Such solutes are almost always present at higher concentrations on the inside of the cell or organelle than on the outside. Very few cellular reactions or processes could occur at reasonable rates if they had to depend on the low concentrations at which essential substrates are present in the cell's surroundings. In some cases, such as electrical signaling in nerve and muscle tissue, the controlled movement of ions across the membrane is central to the function of the cell. Also, many prescribed medications have intracellular targets and therefore must be able to cross membranes to enter the cell.

A central aspect of cell function, then, is **transport**—the ability to move ions and organic molecules across membranes selectively. The importance of membrane transport is evidenced by the fact that about 20% of the genes that have been identified in the bacterium *Escherichia coli* are involved in some aspect of transport. **Figure 8-1** summarizes a few of the many transport processes that occur within eukaryotic cells.

Solutes Cross Membranes by Simple Diffusion, Facilitated Diffusion, and Active Transport

Three fundamentally different mechanisms are involved in the movement of solutes across membranes, as shown in **Table 8-1**. A few types of molecules move across membranes by *simple diffusion*—direct, unaided movement of

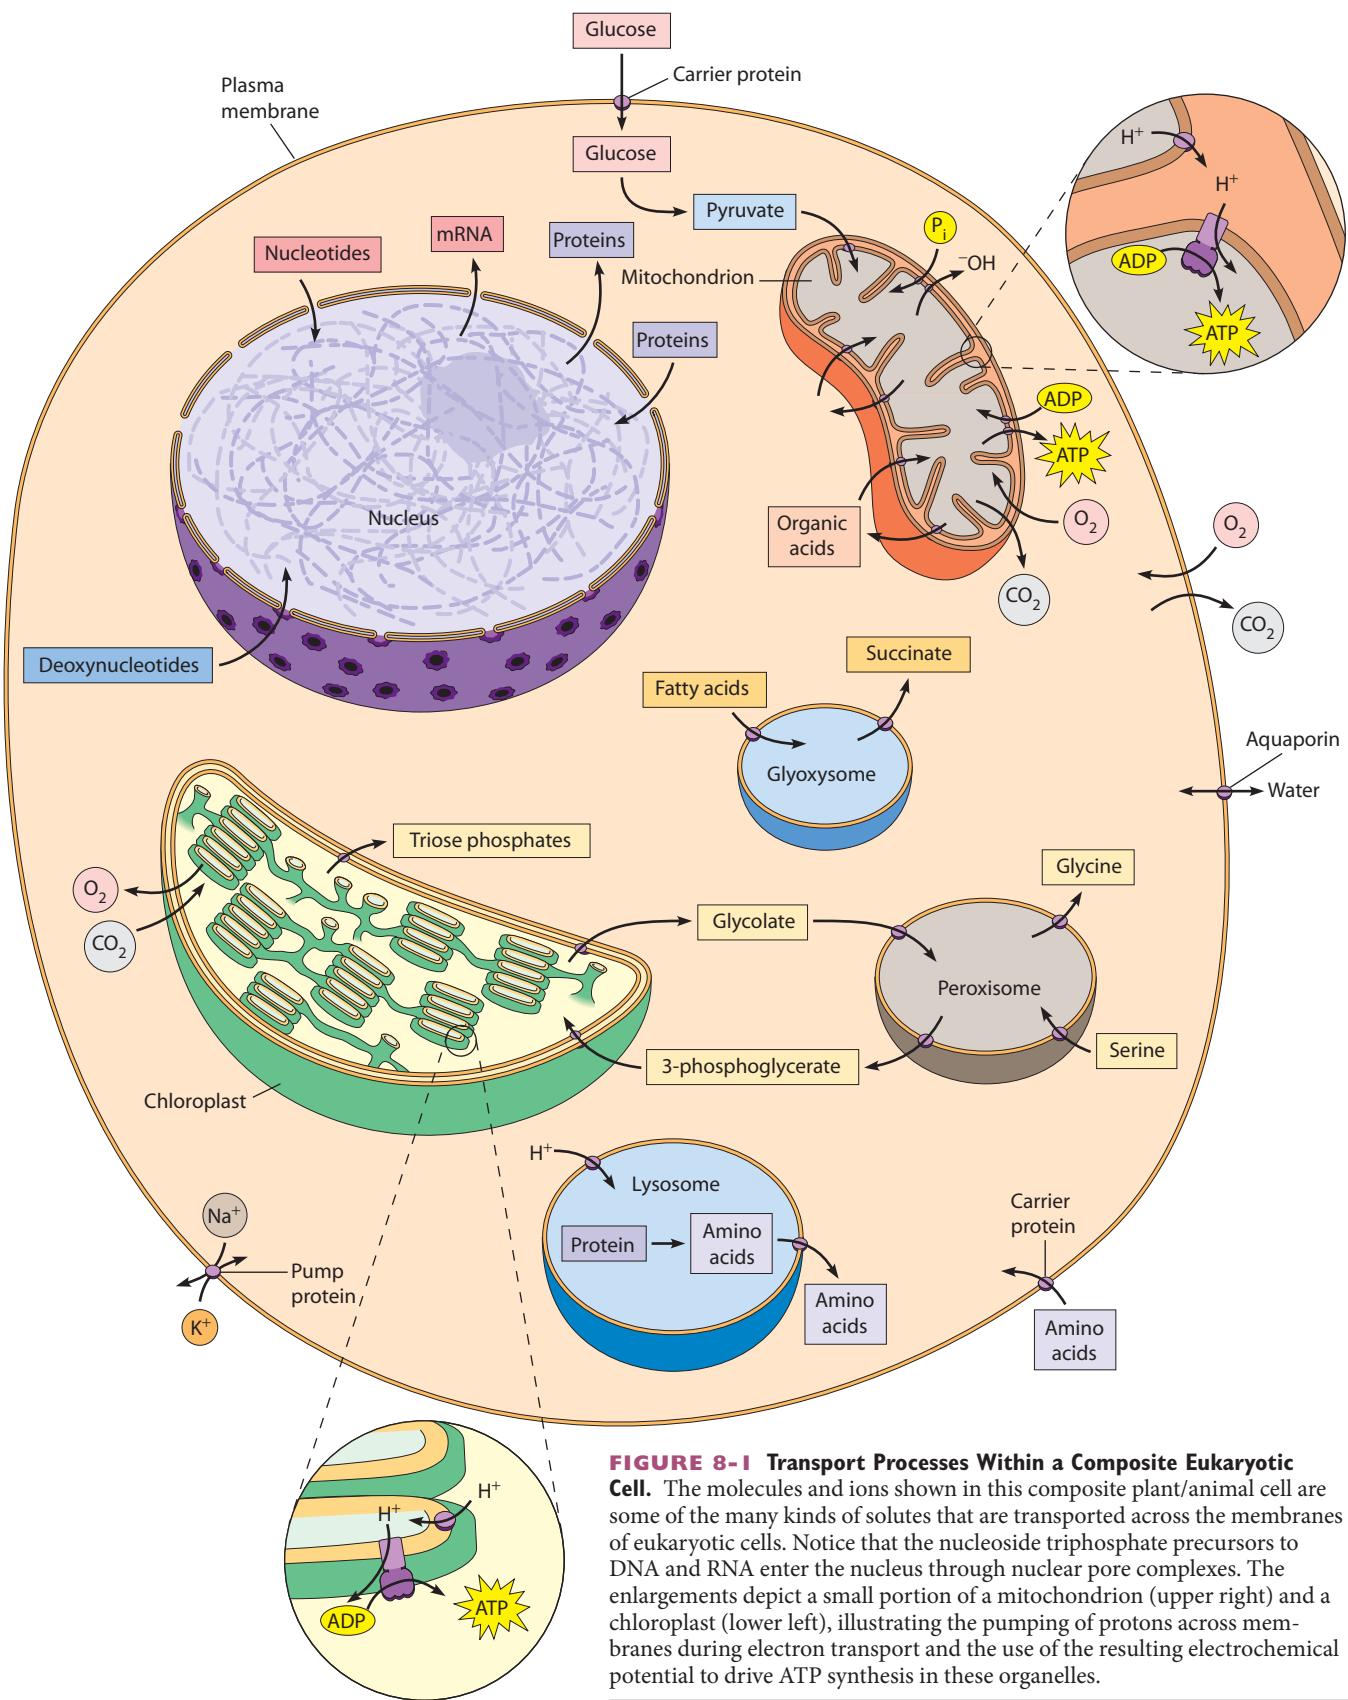

FIGURE 8-1 Transport Processes Within a Composite Eukaryotic Cell. The molecules and ions shown in this composite plant/animal cell are some of the many kinds of solutes that are transported across the membranes of eukaryotic cells. Notice that the nucleoside triphosphate precursors to DNA and RNA enter the nucleus through nuclear pore complexes. The enlargements depict a small portion of a mitochondrion (upper right) and a chloroplast (lower left), illustrating the pumping of protons across membranes during electron transport and the use of the resulting electrochemical potential to drive ATP synthesis in these organelles.

Table 8-1

Comparison of Simple Diffusion, Facilitated Diffusion, and Active Transport

Properties	Simple Diffusion	Facilitated Diffusion	Active Transport
Solutes transported			
	Small polar (H ₂ O, glycerol)	Small polar (H ₂ O, glycerol)	
	Small nonpolar (O ₂ , CO ₂)	Large polar (glucose)	Large polar (glucose)
	Large nonpolar (oils, steroids)	Ions (Na ⁺ , K ⁺ , Ca ²⁺)	Ions (Na ⁺ , K ⁺ , Ca ²⁺)
Thermodynamic properties			
Direction relative to electrochemical gradient	Down	Down	Up
Metabolic energy required	No	No	Yes
Intrinsic directionality	No	No	Yes
Kinetic properties			
Membrane protein required	No	Yes	Yes
Saturation kinetics	No	Yes	Yes
Competitive inhibition	No	Yes	Yes

solute molecules into and through the lipid bilayer in the direction dictated by the difference in the concentrations of the solute on the two sides of the membrane.

For most solutes, however, movement across biological membranes at a significant rate is possible only because of the presence of *transport proteins*—integral membrane proteins that recognize substances with great specificity and speed their movement across the membrane. In some cases, transport proteins move solutes down their free energy gradient (a gradient of concentration, charge, or both) in the direction of thermodynamic equilibrium. This process is known as *facilitated diffusion* of solutes (sometimes called *passive transport*) and requires no input of energy.

In other cases, transport proteins mediate the *active transport* of solutes, moving them against their respective free energy gradients in an energy-requiring process. Active transport must be driven by an energy-yielding process such as the hydrolysis of ATP or the simultaneous transport of another solute, usually an ion such as H⁺ or Na⁺, down its free energy gradient. As we discuss each of these three transport processes in turn, it will be useful to refer back to Table 8-1.

The Movement of a Solute Across a Membrane Is Determined by Its Concentration Gradient or Its Electrochemical Potential

The movement of a molecule that has no net charge is determined by the **concentration gradient** of that molecule across the membrane. Simple or facilitated diffusion of a molecule involves exergonic movement “down” the concentration gradient (negative ΔG), whereas active transport involves endergonic movement “up” the concentration gradient (positive ΔG) and requires some driving force.

The movement of an ion, on the other hand, is determined by its **electrochemical potential**, which is the sum, or combined effect, of its concentration gradient and the charge gradient across the membrane. Facilitated diffusion of an ion involves exergonic movement in the direction dictated by its electrochemical potential. In contrast, active transport of an ion involves endergonic movement against the electrochemical potential for that ion.

The active transport of ions across a membrane creates the charge gradient, or **membrane potential** (V_m), across the membrane that is present in most cells. Most cells have a negative V_m , which by convention means they have an excess of negatively charged solutes inside the cell. For example, a resting nerve cell has a V_m of approximately -60 mV . This charge difference favors the inward movement of cations such as Na⁺ and the outward movement of anions such as Cl⁻. It also opposes the outward movement of cations and the inward movement of anions. In Chapter 13, we will discuss in detail the role of cellular membrane potential in neuron function.

In all organisms, active transport of ions across the plasma membrane results in asymmetric distributions of ions inside and outside of cells, creating an electrochemical gradient for many ions. For example, in human skeletal muscle, the concentrations of Na⁺ and Cl⁻ are over 10-fold higher outside the cell than inside, while the concentration of K⁺ is approximately 40-fold higher inside the cell.

The Erythrocyte Plasma Membrane Provides Examples of Transport Mechanisms

In our discussion of membrane transport processes, we will use as examples the transport proteins of the erythrocyte. These are some of the most extensively studied and

best understood of all cellular transport proteins. Vital to the erythrocyte's role in providing oxygen to body tissues is the movement across its plasma membrane of O₂, CO₂, and bicarbonate ion (HCO₃⁻), as well as glucose, which serves as the cell's main energy source. Also important is the membrane potential maintained across the plasma membrane by the active transport of potassium ions inward and sodium ions outward. In addition, special pores, or *channels*, allow water and ions to enter and leave the cell rapidly in response to cellular needs. These transport activities are summarized in **Figure 8-2** and will be used as examples in the following discussion.

Simple Diffusion: Unassisted Movement Down the Gradient

The most straightforward way for a solute to get from one side of a membrane to the other is **simple diffusion**, which is the unassisted net movement of a solute from a region where its concentration is higher to a region where its concentration is lower (Figure 8-2a). Because membranes have a hydrophobic interior, simple diffusion is typically a means of transport only for gases, nonpolar molecules, or small polar molecules such as water, glycerol, or ethanol.

Oxygen is a gas that traverses the hydrophobic lipid bilayer readily and therefore moves across membranes by simple diffusion. This behavior enables erythrocytes in the circulatory system to take up oxygen in the lungs and release it in body tissues. In the capillaries of body tissues, where oxygen concentration is low, oxygen is released from hemoglobin and diffuses passively from the cytoplasm of the erythrocyte into the blood plasma and from there into the cells lining the capillaries (Figure 8-3a).

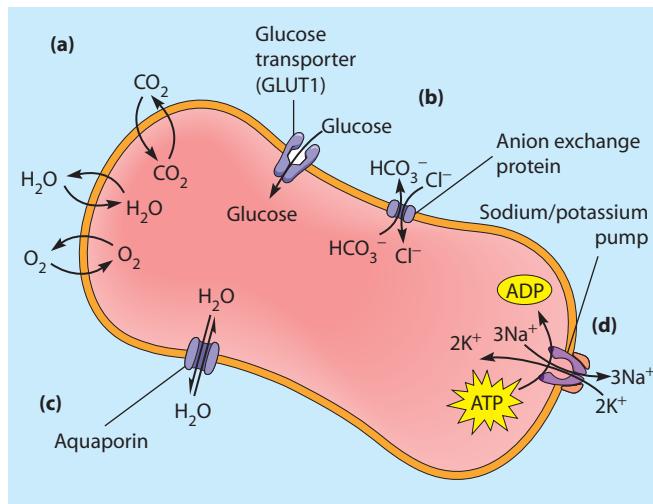

In the capillaries of the lungs, the opposite occurs: Oxygen diffuses from the inhaled air in the lungs, where its concentration is higher, into the cytoplasm of the erythrocytes, where its concentration is lower (Figure 8-3b). Carbon dioxide is also able to cross membranes by simple diffusion. However, most CO₂ is actually transported in the form of bicarbonate ion (HCO₃⁻), as we will see later in the chapter. Not surprisingly, carbon dioxide and oxygen move across the erythrocyte membrane in opposite directions. Carbon dioxide diffuses inward in body tissues and outward in the lungs.

Diffusion Always Moves Solutes Toward Equilibrium

No matter how a population of molecules is distributed initially, diffusion always tends to create a random solution in which the concentration is the same everywhere. To illustrate this point, consider the apparatus shown in **Figure 8-4a**, consisting of two chambers separated by a membrane that is freely permeable to molecules of S, an uncharged solute represented by the black dots. Initially, the concentration of S is higher in chamber A than in chamber B. Other conditions being equal, random

(a) Simple diffusion. Oxygen, carbon dioxide, and water diffuse directly across the plasma membrane in response to their relative concentrations inside and outside the cell.

(b) Facilitated diffusion mediated by carrier proteins. The movement of glucose across the plasma membrane is facilitated by a specific glucose transporter called GLUT1. An anion exchange protein facilitates the reciprocal transport of chloride (Cl⁻) and bicarbonate (HCO₃⁻).

(c) Facilitated diffusion mediated by channel proteins. Aquaporin channel proteins can facilitate the rapid inward or outward movement of water molecules.

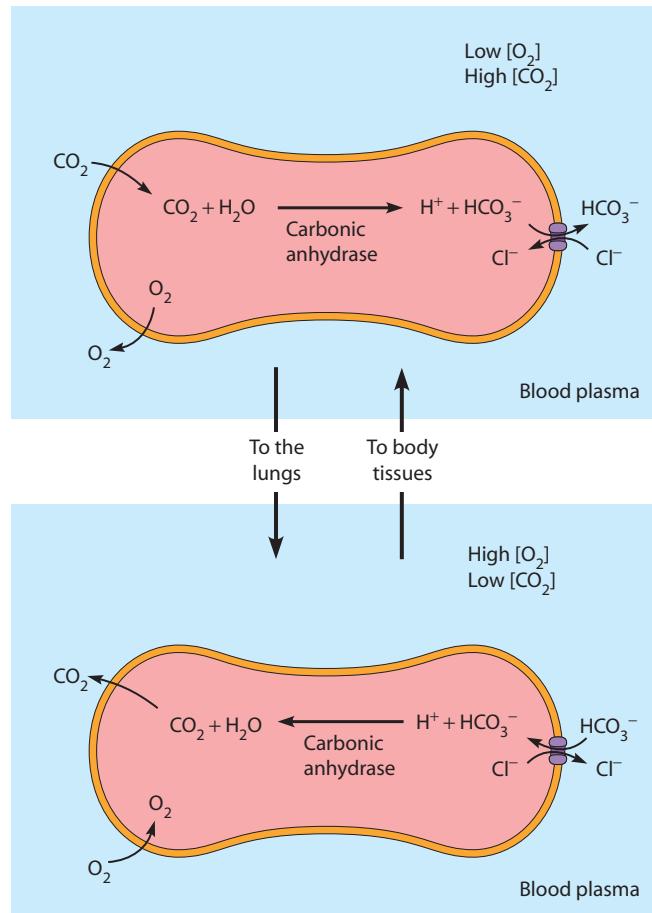

(d) Active transport. Driven by the hydrolysis of ATP, the Na⁺/K⁺ pump moves three sodium ions outward for every two potassium ions moved inward, establishing an electrochemical potential across the plasma membrane for both ions.

FIGURE 8-2 Important Transport Processes of the Erythrocyte. Depicted here are several types of transport processes that are vital to erythrocyte function.

movements of solute molecules back and forth through the membrane will lead to a net movement of solute S from chamber A to chamber B. When the concentration of S is equal on both sides of the membrane, the system is at equilibrium. Random back-and-forth movement of individual molecules continues, but no further net change in concentration occurs. Thus, *diffusion is always movement toward equilibrium* and is therefore a spontaneous process.

Another way to express this is to say that diffusion always tends toward minimum free energy. As we learned in Chapter 5, chemical reactions and physical processes always proceed in the direction of decreasing free energy, in accordance with the second law of thermodynamics. Diffusion through membranes is no exception: Free energy is minimized as molecules move down their

(a) In the capillaries of body tissues (low $[O_2]$ and high $[CO_2]$ relative to the erythrocytes), O_2 is released by hemoglobin within the erythrocytes and diffuses outward to meet tissue needs. CO_2 diffuses inward and is converted to bicarbonate by carbonic anhydrase in the cytosol. Bicarbonate ions are transported outward by the anion exchange protein, accompanied by the inward movement of chloride ions to maintain charge balance. Carbon dioxide therefore returns to the lungs as bicarbonate ions.

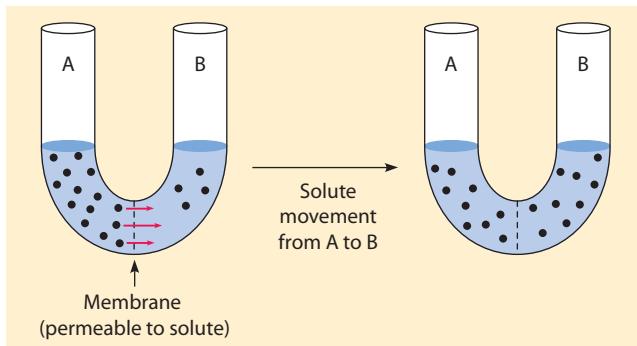

(b) In the capillaries of the lungs (high $[O_2]$ and low $[CO_2]$ relative to the erythrocytes), O_2 diffuses inward and binds to hemoglobin. Bicarbonate moves inward from the blood plasma, accompanied by an outward movement of chloride ions. Incoming bicarbonate is converted into CO_2 , which diffuses out of the erythrocytes and into the cells lining the capillaries of the lungs. The CO_2 is now ready to be expelled from the body.

FIGURE 8-3 Directions of Oxygen, Carbon Dioxide, and Bicarbonate Transport in Erythrocytes. The directions in which O_2 , CO_2 , and HCO_3^- move across the plasma membrane of the erythrocyte depend on the location of the erythrocyte in the body.

concentration gradient. The driving force for diffusion is entropy, the randomization of molecules as concentrations equalize on both sides of the membrane (like the jumping beans in Box 5A, page 116). We will apply this principle later in the chapter when we calculate ΔG , the free energy change that accompanies the transport of molecules and ions across membranes. Strictly speaking,

(a) Simple diffusion takes place when the membrane separating chambers A and B is permeable to molecules of dissolved solute, represented by the black dots. Net movement of solute molecules across the membrane is from chamber A to B (high to low solute concentration). Equilibrium is reached when the solute concentration is the same in both chambers.

(b) Osmosis occurs when the membrane between the two chambers is not permeable to the dissolved solute, represented by the black triangles. Because solute cannot cross the membrane, water diffuses from chamber B where the solute concentration is lower (more water) to chamber A where the solute concentration is higher (less water). At equilibrium, the solute concentration will be equal on both sides of the membrane.

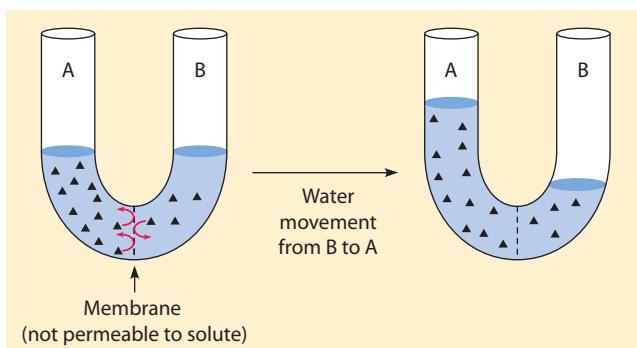

FIGURE 8-4 Comparison of Simple Diffusion and Osmosis. In both examples shown, there is initially more solute in chamber A than in chamber B. The membrane in example (a) is permeable to the solute and the membrane in example (b), like a typical cell membrane, is not.

therefore, *diffusion always proceeds from regions of higher to lower free energy*. At thermodynamic equilibrium, no further net movement occurs because the free energy of the system is at a minimum.

Osmosis Is the Diffusion of Water Across a Selectively Permeable Membrane

Several properties of water cause it to behave in a special way. First of all, water molecules are not charged, so they are not affected by the membrane potential. Moreover, the concentration of water is not appreciably different on

opposite sides of a membrane. What, then, determines the direction in which water molecules diffuse? When a solute is dissolved in water, the solute molecules disrupt the ordered three-dimensional interactions that normally occur between individual molecules of water, thereby increasing the entropy and decreasing the free energy of the solution. Water, like other substances, tends to diffuse from areas where its free energy is higher to areas where its free energy is lower. Thus, water tends to move from regions of lower solute concentration (higher free energy) to regions of higher solute concentration (lower free energy).

This principle is illustrated by Figure 8-4b. Solutions of differing solute concentrations are placed in chambers A and B, as in Figure 8-4a, but with the two chambers now separated by a *selectively permeable membrane* that is permeable to water but *not* to the dissolved solute. Under these conditions, water moves, or diffuses, across the membrane from chamber B to chamber A. Such movement of water in response to differences in solute concentration is called **osmosis**. Osmotic movement of water across a membrane is always from the side with the higher free energy (that is, with the lower solute concentration) to the side with the lower free energy (that is, with the higher solute concentration). For most cells, this means that water will tend to move inward because the concentration of solutes is almost always higher inside a cell than outside. If not controlled, the inward movement of water would cause cells to swell and perhaps to burst. For further discussion of osmotic water movement and how organisms from different kingdoms control water content and movement, see **Box 8A**.

Simple Diffusion Is Limited to Small, Nonpolar Molecules

To investigate the factors influencing the diffusion of solutes through membranes, scientists frequently use membrane models. An important advance in developing such models was provided in 1961 by Alec Bangham and his colleagues, who found that when lipids are extracted from cell membranes and dispersed in water, they form *liposomes*. Liposomes are small vesicles about $0.1\text{ }\mu\text{m}$ in diameter, each consisting of a closed, spherical, lipid bilayer that is devoid of membrane proteins. Bangham showed that it is possible to trap solutes such as potassium ions in the liposomes as they form and then measure the rate at which the solute escapes by diffusion across the liposome bilayer.

The results were remarkable. Ions such as potassium and sodium were trapped in the vesicles for days, whereas small uncharged molecules such as oxygen exchanged so rapidly that the rates could hardly be measured. The inescapable conclusion was that the lipid bilayer represents the primary permeability barrier of a membrane. Small uncharged molecules can pass through the barrier by simple diffusion, whereas sodium and potassium ions can barely pass at all. Based on subsequent experiments by

many investigators using a variety of lipid bilayer systems and thousands of different solutes, we can predict with considerable confidence how readily a solute will diffuse across a lipid bilayer. The three main factors affecting diffusion of solutes are *size*, *polarity*, and *charge*. We will consider each of these factors in turn.

Solute Size. Generally speaking, lipid bilayers are more permeable to smaller molecules than to larger molecules. The smallest molecules relevant to cell function are water, oxygen, and carbon dioxide. Membranes are quite permeable to these molecules, which require no specialized transport processes for moving into and out of cells, although we will see later that there is a specialized transporter in some cells allowing rapid transport of water molecules across certain membranes. But, in the absence of a transporter, even such small molecules do not move across membranes freely. Water molecules, for example, diffuse across a bilayer 10,000 times more slowly than they move when allowed to diffuse freely in the absence of a membrane.

Still, water diffuses across membranes at rates much higher than would be expected for such a polar molecule. The reason for this behavior is not well understood. One proposal is that membranes contain tiny pores that allow the passage of water molecules but are too small for any other polar substance. An alternative suggestion is that in the continual movements of membrane lipids, transient “holes” are created in the lipid monolayers that allow water molecules to move first through one monolayer and then through the other. There is little experimental evidence to support either of these hypotheses, however, and simple diffusion of water across membranes remains an enigma.

In addition to water, small polar molecules with a molecular weight (MW) of up to about 100—such as ethanol ($\text{CH}_3\text{CH}_2\text{OH}$; MW = 46) and glycerol ($\text{C}_3\text{H}_8\text{O}_3$; MW = 92)—are able to diffuse across membranes. However, larger polar molecules such as glucose ($\text{C}_6\text{H}_{12}\text{O}_6$; MW = 180) cannot. Cells therefore need specialized proteins in their plasma membranes to facilitate the entry of glucose and most other polar solutes.

Solute Polarity. There is a correlation between the lipid solubility of a molecule and its membrane permeability. In general, lipid bilayers are more permeable to nonpolar molecules and less permeable to polar molecules. This is because nonpolar molecules dissolve more readily in the hydrophobic phase of the lipid bilayer and can therefore cross the membrane much more rapidly than can polar molecules of similar size. For example, the steroid hormones estrogen and testosterone are largely nonpolar and therefore can diffuse across membranes despite having molecular weights of 370 and 288, respectively.

A simple measure of the polarity (or nonpolarity) of a solute is its *partition coefficient*, which is the ratio of its solubility in an organic solvent (such as vegetable oil or octanol)

Osmosis: The Diffusion of Water Across a Selectively Permeable Membrane

Most of the discussion in this chapter focuses on the transport of solutes—ions and small molecules that are dissolved in the aqueous environment of cells, their organelles, and their surroundings. That emphasis is quite appropriate because most of the traffic across membranes involves ions such as K^+ , Na^+ , and H^+ , and hydrophilic molecules such as sugars, amino acids, and a variety of metabolic intermediates. But to understand solute transport fully, we also need to understand the forces that act on water, thereby determining its movement within and between cells.

Because most solutes cannot cross cell membranes, water tends to move across membranes in response to differences in solute concentrations on the two sides of the membrane. Specifically, water tends to diffuse from the side of the membrane with the lower solute concentration to the side with the higher solute concentration. This diffusion of water, called osmosis, is readily observed when a selectively permeable membrane separates two compartments, one of them containing a solute that cannot cross the membrane (see Figure 8-4b). Water will move across the membrane to equalize the concentration of solutes on both sides of the membrane.

Osmotic movement of water into and out of a cell is related to the relative **osmolarity**, or solute concentration, of the extracellular solution. A solution with a higher solute concentration than that inside a cell is called a *hypertonic solution*, whereas a solution with a solute concentration lower than that inside a cell is referred to as a *hypotonic solution*. Hypertonic solutions cause water molecules to diffuse out of the cell, dehydrating it. In contrast, hypotonic solutions cause water to diffuse into the cell, increasing the internal pressure. A solution with the same solute concentration as the cell is called an *isotonic solution*, and there will be no net movement of water in either direction.

Osmosis accounts for a well-known observation: Cells tend to shrink or swell as the solute concentration of the extracellular medium changes. Consider, for example, the scenario of **Figure 8A-1**. An animal cell that starts out in an isotonic solution will shrink and shrivel if it is transferred to a hypertonic solution. On the other hand, the cell will swell if placed in a hypotonic solution. And it will actually lyse—or burst—if placed in a very hypotonic solution, such as pure water containing no solutes.

Osmolarity: A Common Problem with Different Solutions

The osmotic movements of water shown in Figure 8A-1 occur because of differences in the osmolarity of the cytoplasm and the extracellular solution. Usually, the solute concentration is greater inside a cell than outside. This is due both to the high concentrations of ions and small organic molecules required for normal cellular functions and to the large numbers of macromolecules dissolved in the cytosol. In addition, most of these molecules are charged, and the counterions that balance these charges contribute significantly to the intracellular osmolarity. Thus, most cells are hypertonic compared with their surroundings, so water will move inward across the plasma membrane, causing the cells to swell.

How do cells cope with the problem of high osmolarity and the resulting influx of water due to osmosis? Cells of plants, algae, fungi, and many bacteria have rigid cell walls that keep the cells

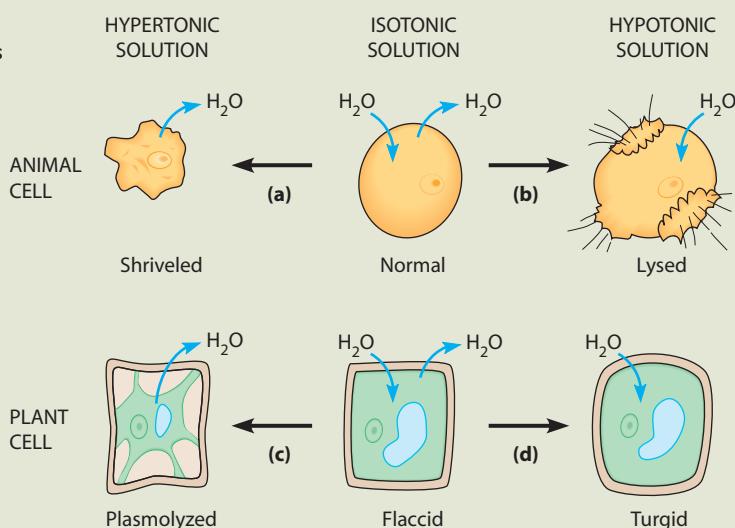

FIGURE 8A-1 Responses of Animal and Plant Cells to Changes in Osmolarity. (a) If an animal cell (or other cell not surrounded by a cell wall) is transferred from an isotonic solution to a hypertonic solution, water leaves the cell and the cell shrivels. (b) If the cell is transferred to a hypotonic solution, water enters the cell and the cell swells, sometimes to the point that it bursts. (c) Plant cells (or other cells with rigid cell walls) also shrivel (plasmolyze) in a hypertonic solution, but (d) they will only become turgid—and will not burst—in a hypotonic solution.

VIDEOS www.thecellplace.com Plasmolysis of plant cells

from swelling and bursting in a hypotonic solution (Figure 8A-1d). Instead, the cells become very firm from the **turgor pressure** that builds up due to the inward movement of water. The resulting turgidity accounts for the firmness, or *turgor*, of fully hydrated plant tissue. Without this turgidity, the tissue will wilt.

In a hypertonic solution, on the other hand, the outward movement of water causes the plasma membrane to pull away from the cell wall by a process called **plasmolysis** (Figure 8A-1c). The wilting of a plant or a plant part during water deprivation is due to the plasmolysis of its cells. You can demonstrate plasmolysis readily by dropping a piece of celery into a solution with a high concentration of salt or sugar. Plasmolysis can be a practical problem when plants are grown under conditions of high salinity, as is sometimes the case in locations near an ocean.

Cells without cell walls solve the osmolarity problem by continuously and actively pumping out inorganic ions, thereby reducing the intracellular osmolarity and thus minimizing the difference in solute concentration between the cell and its surroundings. Animal cells continuously remove sodium ions. This is, in fact, one important purpose of the Na^+/K^+ pump. Animal cells swell and sometimes even lyse when treated with *ouabain*, an inhibitor of the Na^+/K^+ pump. When medications are given intravenously in a hospital, they are typically dissolved in *phosphate-buffered saline*, which has the same osmolarity as the blood, avoiding potential problems of cell lysis or dehydration.

to its solubility in water. In general, the more nonpolar—or hydrophobic—a substance is, the higher its partition coefficient and the more readily and rapidly it can move across (or dissolve in) a membrane. For example, the partition coefficients of the various amino acids were used in Chapter 7 to calculate the hydrophyt index of a protein. Amino acids with nonpolar side chains (see Figure 3-2), such as tryptophan, leucine, and valine, have high partition coefficients and are likely to be found in transmembrane regions of a membrane protein, in contrast to those with those with polar side chains and low partition coefficients (serine and threonine).

Solute Charge. The relative impermeability of polar substances in general and of ions in particular is due to their strong association with water molecules, forming a *shell of hydration*. For such solutes to move into the membrane, the water molecules must be stripped off, and an input of energy is required to eliminate the bonding between the ions and the water molecules. Therefore, the association of ions with water molecules to form shells of hydration dramatically restricts ion transport across membranes.

The impermeability of membranes to ions is important to cell activity because in order to function, every cell must maintain an electrochemical potential across its plasma membrane. In most cases this potential is a gradient either of sodium ions (animal cells) or protons (most other cells). On the other hand, membranes must also allow ions to cross the barrier in a controlled manner. As we will see later in the chapter, the proteins that facilitate ion transport serve as hydrophilic channels that provide a low-energy pathway for movement of the ions across the membrane.

The Rate of Simple Diffusion Is Directly Proportional to the Concentration Gradient

So far, we have focused on qualitative aspects of simple diffusion. We can be more quantitative by considering the thermodynamic and kinetic properties of the process (see Table 8-1). Thermodynamically, simple diffusion is always an exergonic process, requiring no input of energy. Individual molecules simply diffuse randomly in both directions, but net flux will always be in the direction of minimum free energy—which in the case of uncharged molecules means down the concentration gradient.

Kinetically, a key feature of simple diffusion is that the net rate of transport for a specific substance is directly proportional to the concentration difference for that substance across the membrane over a broad concentration range. For the diffusion of solute S from the outside to the inside of a cell, the expression for the rate, or velocity, of inward diffusion through the membrane, v_{inward} , is

$$v_{\text{inward}} = P\Delta[S] \quad (8-1)$$

where v_{inward} is the rate of inward diffusion (in moles/second·cm² of membrane surface), and $\Delta[S]$ is the concentration gradient of the solute across the membrane

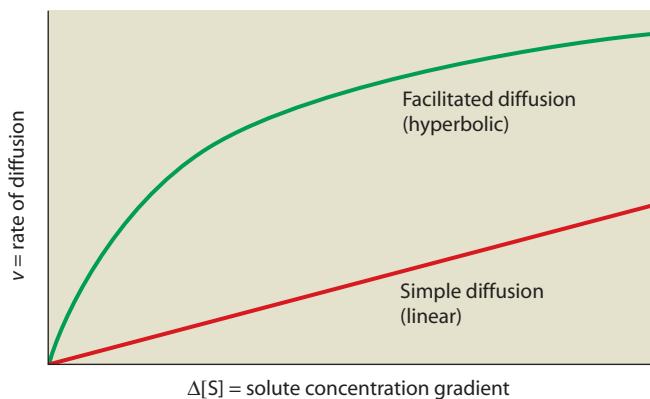

FIGURE 8-5 Comparison of the Kinetics of Simple Diffusion and Facilitated Diffusion.

For simple diffusion across a membrane, the relationship between v , the rate of diffusion, and $\Delta[S]$, the solute concentration gradient, is linear over a broad concentration range (red line). For facilitated diffusion, the relationship is linear when the concentration gradient is small, but exhibits saturation kinetics and is therefore hyperbolic (green line), eventually reaching a maximum value at very high $\Delta[S]$.

($\Delta[S] = [S]_{\text{outside}} - [S]_{\text{inside}}$). P is the permeability coefficient, an experimentally determined parameter that depends on the thickness and viscosity of the membrane; the size, shape, and polarity of S; and the equilibrium distribution of S in the membrane and aqueous phases. As either the permeability or the concentration gradient increases, the rate of inward transport increases.

As Equation 8-1 indicates, simple diffusion is characterized by a linear relationship between the inward flux of the solute across the membrane and the concentration gradient of the solute, with no evidence of saturation at high concentrations. This relationship is seen as the red line in Figure 8-5. Simple diffusion differs in this respect from facilitated diffusion, which is subject to saturation and generally follows Michaelis-Menten kinetics, as we will see shortly. Simple diffusion can therefore be distinguished from facilitated diffusion by its kinetic properties, as indicated in Table 8-1.

We can summarize simple diffusion by noting that it is relevant only to molecules such as ethanol and O₂ that are small enough and/or nonpolar enough to cross membranes without the aid of transport proteins. Simple diffusion proceeds exergonically in the direction dictated by the concentration gradient, with a linear, nonsaturating relationship between the diffusion rate and the concentration gradient.

Facilitated Diffusion: Protein-Mediated Movement Down the Gradient

Most substances in cells are too large or too polar to cross membranes at reasonable rates by simple diffusion, even if the process is exergonic. Such solutes can move into and out of cells and organelles at appreciable rates only with the

assistance of **transport proteins** that mediate the movement of solute molecules across the membrane. If such a process is exergonic, it is called **facilitated diffusion** because the solute still diffuses in the direction dictated by the concentration gradient (for uncharged molecules) or by the electrochemical gradient (for ions), with no input of energy needed. The role of the transport protein is simply to provide a path through the hydrophobic lipid bilayer, facilitating the “downhill” diffusion of a polar or charged solute across an otherwise impermeable barrier.

As an example of facilitated diffusion, consider the movement of glucose across the plasma membrane of a cell in your body. The concentration of glucose is typically higher in the blood than in the cell, so the inward transport of glucose is exergonic—that is, it does not require the input of energy. However, glucose is too large and too polar to diffuse across the membrane unaided. A transport protein is required to facilitate its inward movement.

Carrier Proteins and Channel Proteins Facilitate Diffusion by Different Mechanisms

Transport proteins involved in facilitated diffusion of small molecules and ions are integral membrane proteins that contain several, or even many, transmembrane segments and therefore traverse the membrane multiple times. Functionally, these proteins fall into two main classes that transport solutes in quite different ways. **Carrier proteins** (also called *transporters* or *permeases*) bind one or more solute molecules on one side of the membrane and then undergo a conformational change that transfers the solute to the other side of the membrane. In so doing, a carrier protein binds the solute molecules in such a way as to shield the polar or charged groups of the solute from the nonpolar interior of the membrane.

Channel proteins, on the other hand, form hydrophilic channels through the membrane that allow the passage of solutes without a major change in the conformation of the protein. Some of these channels are relatively large and non-specific, such as the *pores* found in the outer membranes of bacteria, mitochondria, and chloroplasts. Pores are formed by transmembrane proteins called *porins* and allow selected hydrophilic solutes with molecular weights up to about 600 to diffuse across the membrane. However, most channels are small and highly selective. Most of these smaller channels are involved in the transport of ions rather than molecules and are therefore referred to as *ion channels*. The movement of solutes through ion channels is much more rapid than transport by carrier proteins, presumably because complex conformational changes are not necessary.

Carrier Proteins Alternate Between Two Conformational States

An important topic of contemporary membrane research concerns the mechanisms whereby transport proteins facilitate the movement of solutes across membranes. For carrier proteins, the most likely explanation is the **alternating**

conformation model, in which the carrier protein is an allosteric protein that alternates between two conformational states. In one state the solute-binding site of the protein is open or accessible on one side of the membrane. Following solute binding, the protein changes to an alternate conformation in which the solute-binding site is on the other side of the membrane, triggering its release. We will encounter an example of this mechanism shortly when we discuss the facilitated diffusion of glucose into erythrocytes.

Carrier Proteins Are Analogous to Enzymes in Their Specificity and Kinetics

As we noted earlier, carrier proteins are sometimes called *permeases*. This term is apt because the suffix *-ase* suggests a similarity between carrier proteins and enzymes. Like an enzyme-catalyzed reaction, facilitated diffusion involves an initial binding of the “substrate” (the solute to be transported) to a specific site on a protein surface (the solute’s binding site on the carrier protein) and the eventual release of the “product” (the transported solute), with an “enzyme-substrate” complex (solute bound to carrier protein) as an intermediate. Like enzymes, carrier proteins can be regulated by external factors that bind and modulate their activity.

Specificity of Carrier Proteins. Another property that carrier proteins share with enzymes is *specificity*. Like enzymes, transport proteins are highly specific, often for a single compound or a small group of closely related compounds and sometimes even for a specific stereoisomer. A good example is the carrier protein that facilitates the diffusion of glucose into erythrocytes (see Figure 8-2b). This protein recognizes only glucose and a few closely related monosaccharides, such as galactose and mannose. Moreover, the protein is *stereospecific*: it accepts the D- but not the L-isomer of these sugars. This specificity is presumably a result of the precise stereochemical fit between the solute and its binding site on the carrier protein.

Thus, the properties of carrier proteins explain the characteristic features of facilitated diffusion: movement of polar molecules and ions down a concentration gradient, specificity for the particular substrate transported, the ability to be saturated at high levels of substrate, and sensitivity to specific inhibitors of transport.

Kinetics of Carrier Protein Function. As you might expect from the analogy with enzymes, carrier proteins become saturated as the concentration of the transportable solute is raised. This is because the number of transport proteins is limited, and each transport protein functions at some finite maximum velocity. As a result, carrier-facilitated transport, like enzyme catalysis, exhibits *saturation kinetics*. This type of transport has an upper limiting velocity V_{\max} and a constant K_m corresponding to the concentration of transportable solute needed to achieve one-half of the maximum rate of transport. This

means that the initial rate of solute transport, v , can be described mathematically by the same equation we used to describe enzyme kinetics (Equation 6-7, page 139):

$$v = \frac{V_{\max}[S]}{K_m + [S]} \quad (8-2)$$

where $[S]$ is the initial concentration of solute on one side of the membrane (e.g., on the outside of the membrane if the initial rate of inward transport is to be determined). A plot of transport rate versus initial solute concentration is therefore hyperbolic for facilitated diffusion instead of linear as for simple diffusion (see Figure 8-5, green line). This difference in saturation kinetics is an important means of distinguishing between simple and facilitated diffusion (see Table 8-1).

A further similarity between enzymes and carrier proteins is that proteins are often subject to *competitive inhibition* by molecules or ions that are structurally related to the intended “substrate.” For example, the transport of glucose by a glucose carrier protein is competitively inhibited by the other monosaccharides that the protein also accepts—that is, the rate of glucose transport is reduced in the presence of other transportable sugars.

Carrier Proteins Transport Either One or Two Solutes

Although carrier proteins are similar in their kinetics and their presumed mechanism of action involving alternate conformations, they may differ in significant ways. The most important differences concern the number of solutes transported and the direction they move. When a carrier protein transports a single solute across the membrane, the process is called **uniport** (Figure 8-6a). The glucose carrier protein we will discuss shortly is a *uniporter*. When two solutes are transported simultaneously and their transport is coupled such that transport of either stops if the other is absent, the process is called **coupled transport** (Figure 8-6b). Coupled transport is referred to as **symport** (or *cotransport*) if the two solutes are moved in the same direction or as **antiport** (or *countertransport*) if the two solutes are moved in opposite directions across the membrane. The transport proteins that mediate these processes are called **symporters** and **antiporters**, respectively. As we will see later, these same terms apply whether the mode of transport is facilitated diffusion or active transport.

The Erythrocyte Glucose Transporter and Anion Exchange Protein Are Examples of Carrier Proteins

Now that we have described the general properties of carrier proteins, let us briefly consider two specific examples: the uniport carrier for glucose and the antiport anion carrier for Cl^- and HCO_3^- . Both of these transporters are present in the cell membrane of erythrocytes.

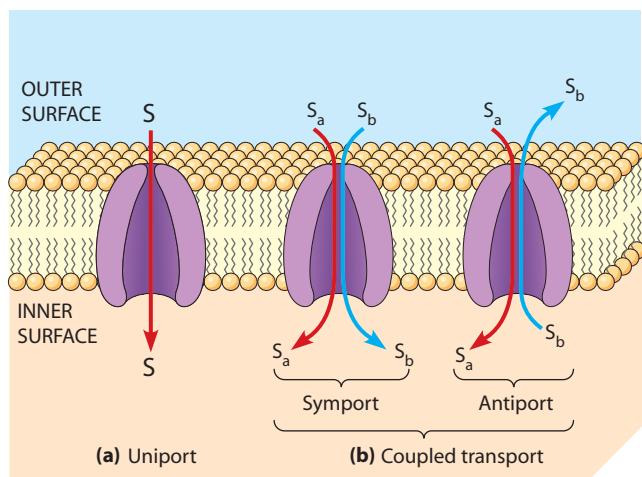

FIGURE 8-6 Comparison of Uniport, Symport, and Antiport Transport by Carrier Proteins. (a) In uniport, a membrane transport protein moves a single solute across a membrane. (b) Coupled transport involves the simultaneous transport of two solutes, S_a and S_b . Coupled transport may be either symport (both solutes moved in the same direction) or antiport (the two solutes moved in opposite directions). Note that transporters are not simply open channels, as depicted in this simplified illustration, but alternate between two conformations as solutes are transported.

The Glucose Transporter: A Uniport Carrier. As we noted earlier, the movement of glucose into an erythrocyte is an example of facilitated diffusion mediated by a uniport carrier protein (see Figure 8-2b). The concentration of glucose in blood plasma is usually in the range of 65–90 mg/100 mL, or about 3.6–5.0 mM. The erythrocyte (or almost any other cell in contact with the blood, for that matter) is capable of glucose uptake by facilitated diffusion because of its low intracellular glucose concentration and the presence in its plasma membrane of a glucose carrier protein, or **glucose transporter (GLUT)**. The GLUT of erythrocytes is called GLUT1 to distinguish it from related GLUTs in other mammalian tissues. GLUT1 allows glucose to enter the cell about 50,000 times faster than it would enter by free diffusion through a lipid bilayer.

GLUT1-mediated uptake of glucose displays all the classic features of facilitated diffusion: It is specific for glucose (and a few related sugars, such as galactose and mannose), it proceeds down a concentration gradient without energy input, it exhibits saturation kinetics, and it is susceptible to competitive inhibition by related monosaccharides. GLUT1 is an integral membrane protein with 12 hydrophobic transmembrane segments. These are presumably folded and assembled in the membrane to form a cavity lined with hydrophilic side chains that form hydrogen bonds with glucose molecules as they move through the membrane.

GLUT1 is thought to transport glucose by an alternating conformation mechanism, as illustrated in Figure 8-7. The two conformational states are called T_1 , which has the binding site for glucose open to the outside of the

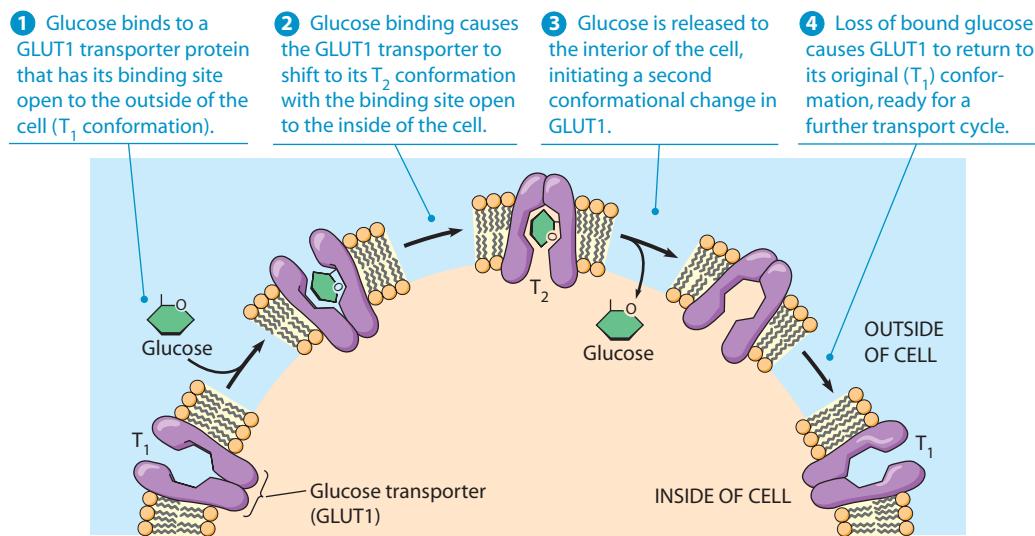

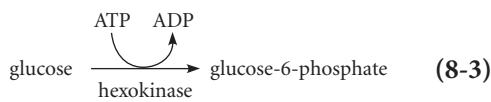

FIGURE 8-7 The Alternating Conformation Model for Facilitated Diffusion of Glucose by the Glucose Transporter GLUT1 in the Erythrocyte Membrane. The inward transport of glucose by GLUT1 is shown here in four steps, arranged at the periphery of a cell.

 **ACTIVITIES** www.thecellplace.com Facilitated diffusion

cell, and T_2 , with the binding site open to the interior of the cell. The process begins when a molecule of D-glucose collides with and binds to a GLUT1 molecule that is in its T_1 conformation ①. With glucose bound, GLUT1 now shifts to its T_2 conformation ②. The conformational change allows the release of the glucose molecule to the interior of the cell ③, after which the GLUT1 molecule returns to its original conformation, with the binding site again facing outward ④.

The example shown in Figure 8-7 is for inward transport, but the process is readily reversible because carrier proteins function equally well in either direction. A carrier protein is really just a gate in an otherwise impenetrable wall, and, like most gates, it facilitates traffic in either direction. Individual solute molecules may be transported either inward or outward, depending on the relative concentrations of the solute on the two sides of the membrane. If the concentration is higher outside, net flow will be inward. If the higher concentration occurs inside, net flow will be outward.

The low intracellular glucose concentration that makes facilitated diffusion possible for most animal cells exists because incoming glucose is quickly phosphorylated to glucose-6-phosphate by the enzyme hexokinase, with ATP as the phosphate donor and energy source:

This hexokinase reaction is the first step in glucose metabolism, which we will discuss in Chapter 9. The low K_m of hexokinase for glucose (1.5 mM) and the highly exergonic nature of the reaction ($\Delta G' = -4.0 \text{ kcal/mol}$) ensure that the concentration of glucose within the cell is kept

low, maintaining the concentration gradient across the cell membrane. For many mammalian cells, the intracellular glucose concentration ranges from 0.5 to 1.0 mM, which is about 15–20% of the glucose level in the blood plasma outside the cell.

The phosphorylation of glucose also has the effect of locking glucose in the cell, because the plasma membrane of the erythrocyte does not have a transport protein for glucose-6-phosphate. (GLUT1, like most sugar transporters, does not recognize the phosphorylated form of the sugar.) Phosphorylation is in fact a general strategy for retaining molecules within the cell because most cells do not have plasma membrane proteins capable of transporting phosphorylated compounds.

The GLUT1 of erythrocytes is just one of several glucose transporters in mammals. In humans there are 14 different GLUT proteins, each encoded by a separate gene. Each transporter has distinct physical and kinetic characteristics appropriate for its function in the particular cell type where it is found. For example, GLUT3 and GLUT4 are found in cerebral neurons and skeletal muscle, respectively, where they import glucose for energy. On the other hand, GLUT2 is the glucose transporter in liver cells, which break down glycogen to produce glucose for the blood. GLUT2 has properties that facilitate glucose transport *out* of liver cells to maintain blood glucose at a constant level.

The Erythrocyte Anion Exchange Protein: An Antiport Carrier. Another well-studied example of facilitated diffusion is the **anion exchange protein** of the erythrocyte plasma membrane (see Figure 8-2b). This antiport protein, also called the *chloride-bicarbonate exchanger*, facilitates the reciprocal exchange of chloride (Cl^-) and bicarbonate

(HCO_3^-) ions in opposite directions across the plasma membrane. The coupling of chloride and bicarbonate transport is obligatory, and transport will stop if either anion is absent. Moreover, the anion exchange protein is very selective. It exchanges bicarbonate for chloride in a strict 1:1 ratio, and it accepts no other anions.

The anion exchange protein is thought to function by alternating between two conformational states in what is termed a “ping-pong” mechanism. In one conformation, the anion exchange protein binds chloride on one side of the membrane. Chloride binding causes a change in conformation such that chloride is released on the other side of the membrane, where the protein binds bicarbonate. This causes a second conformational change, releasing bicarbonate on the other side of the membrane, where the protein again binds chloride. Repeated cycles of binding and release transport the two ions in opposite directions.

Either anion can bind to the protein on either side of the membrane, so the direction of transport depends upon the relative concentrations of the ions on opposite sides of the membrane. In cells with a high bicarbonate concentration, bicarbonate leaves the cell and chloride enters. In cells with a low bicarbonate concentration, the reciprocal process occurs—bicarbonate enters the cell and chloride leaves.

The anion exchange protein plays a central role in the process by which waste CO_2 produced in metabolically active tissues is delivered to the lungs to be expelled. In these tissues, CO_2 diffuses into erythrocytes, where the cytosolic enzyme *carbonic anhydrase* converts it to bicarbonate ions (see Figure 8-3). As the concentration of bicarbonate in the erythrocyte rises, it moves out of the cell. To prevent a net charge imbalance, the outward movement of each negatively charged bicarbonate ion is accompanied by the uptake of one negatively charged chloride ion.

In the lungs, this entire process is reversed: Chloride ions are transported out of erythrocytes accompanied by the uptake of bicarbonate ions, which are then converted back to CO_2 by carbonic anhydrase. The net result is the movement of CO_2 (in the form of bicarbonate ions) from tissues to the lungs, where the CO_2 is exhaled from the body. In addition, the import of bicarbonate into erythrocytes in the lungs increases the cellular pH, which enhances oxygen binding to hemoglobin in the lungs. When the erythrocytes reach the tissues and bicarbonate is exported, the cellular pH drops and oxygen binding decreases, allowing more rapid release to the tissues.

Channel Proteins Facilitate Diffusion by Forming Hydrophilic Transmembrane Channels

While some transport proteins facilitate diffusion by functioning as carrier proteins that alternate between different conformational states, others do so by forming hydrophilic *transmembrane channels* that allow specific solutes to move across the membrane directly. We will consider three kinds

of transmembrane protein channels: *ion channels*, *porins*, and *aquaporins*.

Ion Channels: Transmembrane Proteins That Allow Rapid Passage of Specific Ions. Despite their apparently simple design—a tiny pore lined with hydrophilic atoms—**ion channels** are remarkably selective. Most allow passage of only one kind of ion, so separate channels are needed for transporting such ions as Na^+ , K^+ , Ca^{2+} , and Cl^- . This selectivity is remarkable given the small differences in size and charge among some of these ions. Selectivity results both from ion-specific binding sites involving specific amino acid side chains and polypeptide backbone atoms inside the channel and from a constricted center of the channel that serves as a size filter. The rate of transport is equally remarkable: In some cases, a single channel can conduct almost a million ions of a specific type per second!

Most ion channels are *gated*, which means that the pore opens and closes in response to some stimulus. In animal cells, three kinds of stimuli control the opening and closing of gated channels: *Voltage-gated channels* open and close in response to changes in the membrane potential; *ligand-gated channels* are triggered by the binding of specific substances to the channel protein; and *mechanosensitive channels* respond to mechanical forces that act on the membrane. We will discuss gated channels in detail in Chapter 13.

Regulation of ion movement across membranes plays an important role in many types of cellular communication. Muscle contraction and many cellular responses require regulation of Ca^{2+} levels via calcium-specific ion channels. Also, the transmission of electrical signals by nerve cells depends critically on rapid, controlled changes in the movement of Na^+ and K^+ ions through their respective channels. These changes are so rapid that they are measured in milliseconds. In addition to such short-term regulation, most ion channels are subject to longer-term regulation, usually in response to external stimuli such as hormones.

Ion channels are also necessary for maintaining the proper salt balance in the cells and airways lining our lungs. In lung epithelial cells, a specific chloride ion channel known as the *cystic fibrosis transmembrane conductance regulator* (CFTR) protein helps to maintain the proper Cl^- concentration in these airways. Defects in CFTR lead to excessive buildup of mucus in the lungs, causing a life-threatening condition known as cystic fibrosis, a topic we will discuss in detail in **Box 8B**.

Porins: Transmembrane Proteins That Allow Rapid Passage of Various Solutes. Compared with ion channels, the pores found in the outer membranes of mitochondria, chloroplasts, and many bacteria are somewhat larger and much less specific. These pores are formed by multipass transmembrane proteins called **porins**. However, the

Membrane Transport, Cystic Fibrosis, and the Prospects for Gene Therapy

Transport proteins located in the plasma membrane play critical roles in speeding up and controlling the movement of molecules and ions into and out of cells. To remain healthy, our bodies depend on the proper functioning of many such membrane proteins. If any of these proteins is defective, the movement of a particular ion or molecule across cell membranes is likely to be impaired, and disease may result.

An example that has attracted the attention of researchers and doctors alike is **cystic fibrosis (CF)**, a fatal disease caused by genetic defects in a transport protein in the plasma membrane. The parts of the body that are most noticeably affected are the lungs, pancreas, and sweat glands. Complications in the lungs are the most severe medical problems because they are difficult to treat and can become life-threatening. The airways of a CF patient are often obstructed with abnormally thick mucus and are vulnerable to chronic bacterial infections, especially by *Pseudomonas aeruginosa*.

Using the tools of molecular and cellular biology, researchers have achieved a detailed understanding of this disease. During the 1980s, cells from CF patients were shown to be defective in the secretion of chloride ions (Cl^-). The cells that line unaffected lungs secrete chloride ions in response to a substance called cyclic AMP, whereas cells from CF patients do not. (Cyclic AMP is a form of AMP that is involved in a variety of regulatory roles in cells; for its structure, see Figure 14-6.) Experiments with tissue from CF patients suggested that this difference might be due to a defect in a membrane protein that normally serves as a channel for the movement of chloride ions across the membrane.

Many symptoms of CF can be explained by faulty Cl^- secretion. In the lungs of a healthy, unaffected person (Figure 8B-1a), chloride ions are secreted from the cells lining the airways and enter the lumen, the space inside the airway passage. The movement of Cl^- out of the cell and into the lumen provides the driving force for the concurrent movement of sodium ions into the lumen in order to maintain charge balance. Osmotic pressure causes water to follow the sodium and chloride ions, resulting in the secretion of a dilute salt solution. The water that moves into the lumen in this way provides vital hydration to the mucous lining of the air passages. In the cells of a person with CF, Cl^- ions cannot exit into the lumen, so sodium ions and water do not move outward either (Figure 8B-1b). As a result, the mucus is insufficiently hydrated and becomes very thick, a condition that favors bacterial growth.

An exciting breakthrough in CF research came in 1989 when investigators in the laboratories of Francis Collins at the University of Michigan and of Lap-Chee Tsui and John Riordan at the University of Toronto isolated the gene that is defective in CF patients. The gene encodes a protein called the **cystic fibrosis transmembrane conductance regulator (CFTR)**. The

sequence of nucleotide bases in the gene was determined by using methods that are described in Chapter 18 (see Figure 18-14). Knowing the base sequence of the gene, scientists were able to predict the amino acid sequence and the structure of the CFTR protein. As shown in Figure 8B-1c, the protein has two sets of *transmembrane domains* that anchor the protein in the plasma membrane and provide an anion-selective pore. It also has two *nucleotide-binding domains* that serve as binding sites for ATP, which provides the energy to drive transport of chloride ions across the membrane. In addition, the protein has a large *cytoplasmic regulatory domain*, which has several serine hydroxyl groups that can be reversibly phosphorylated. The CFTR protein has since been shown to function as a chloride channel in cells, and channel function is known to be affected when the phosphorylation sites in the regulatory domain are changed due to a mutation in the *CFTR* gene.

By sequencing the *CFTR* genes from CF patients, investigators have identified more than 600 mutations in the gene. The most common of these mutations causes the deletion of a single amino acid in the first nucleotide-binding domain ($\Delta\text{Phe-509}$). The question of how this mutation causes CF remained unanswered until researchers examined the location of the CFTR protein in cells with and without the mutation. Normal CFTR was found in the cell membrane, as predicted. In contrast, mutant CFTR was not detected in the plasma membrane.

Currently, the most likely explanation is that normal CFTR is synthesized on the rough endoplasmic reticulum (ER), moves through the Golgi complex, and is eventually inserted in the plasma membrane by a route that is explained in Chapter 12. Mutant CFTR, on the other hand, is apparently trapped in the ER, perhaps because it is folded improperly. It is therefore recognized as a defective protein and degraded. Consequently, CFTR is not present in the plasma membrane of CF cells, chloride ion secretion cannot take place, and disease results.

Armed with information about the gene and the protein associated with CF, researchers are now trying to develop new treatments or perhaps even a cure for the disease. One such approach is *gene therapy*, in which a normal copy of a gene is introduced into affected cells of the body. Investigators would like to direct normal copies of the *CFTR* gene into the cells that line the airways of CF patients. These cells should then be able to synthesize a correct CFTR protein that, unlike mutant CFTR, would be located in the plasma membrane. The CFTR proteins would then allow proper Cl^- secretion and correct the disease.

Two kinds of practical problems must be overcome if gene therapy is to work: The *CFTR* gene must be delivered efficiently to the affected tissue, and its expression must be regulated to achieve and maintain normal production of the CFTR protein. In most clinical studies to date, the normal *CFTR* gene has been introduced

transmembrane segments of porin molecules cross the membrane not as α helices but as a closed cylindrical β sheet called a β barrel (Figure 8-8). The β barrel has a water-filled pore at its center. Polar side chains (not shown) line the inside of the pore, whereas the outside of the barrel

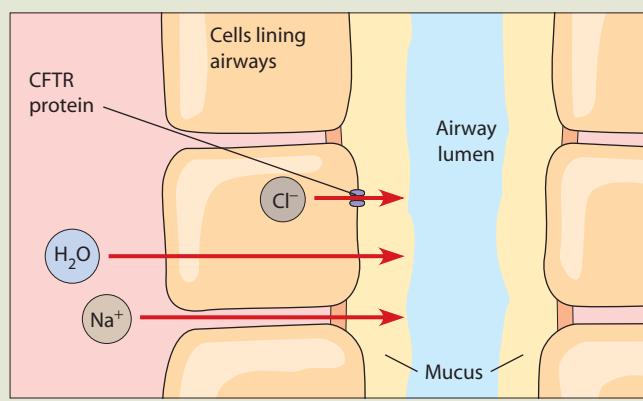

consists mainly of nonpolar side chains that interact with the hydrophobic interior of the membrane. The pore allows passage of various hydrophilic solutes. The upper size limit for the solute molecules is determined by the pore size of the particular porin—only solutes smaller than

into CF patients by one of two means: Either the *CFTR* is incorporated into the DNA of a virus called *adenovirus* or it is mixed with fat droplets called *liposomes*. The viral or liposomal preparation is sprayed as an aerosol into the nose or lungs of CF patients, who are then monitored for the correction of the chloride transport abnormality. Another strategy involves treating patients with a highly compacted DNA molecule containing the normal *CFTR* gene. This DNA is readily taken up into cells, and this procedure eliminates concerns regarding variability and possible side effects due to the use of a modified viral vector.

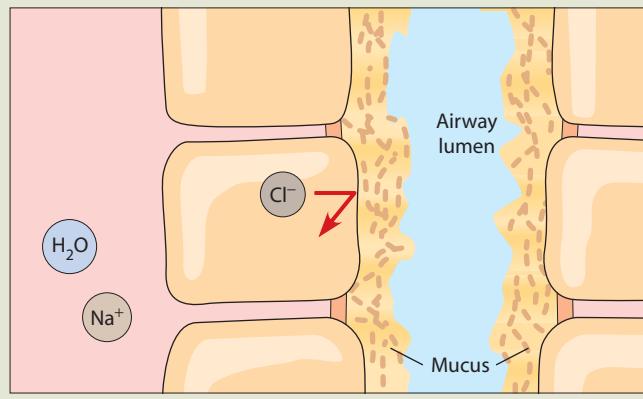

In initial experiments with CF mutant mice, several groups of British investigators showed that the chloride ion channel defect could be corrected by spraying the respiratory tract with liposomes containing the normal human *CFTR* gene. The same approach is now being used in clinical trials with human patients. In one such study, a “gene spray” of the *CFTR* gene mixed with

liposomes was administered nasally. Gene delivery and expression was demonstrated in most of the patients, but expression was short-lived and the ion channel defect was only partially corrected.

More recently, Eric Alton and his colleagues in London reported a well-controlled experiment in which they administered liposomes with or without the *CFTR* gene in the form of an aerosol to the lungs and the nose. A short-term improvement in chloride transport was seen in the patients who received the *CFTR* gene but not in the patients who received the placebo (liposome-only) treatment. The researchers also reported reduced bacterial adherence to respiratory epithelial cells in the *CFTR*-treated patients, an observation that may have significant clinical relevance. Overall, however, progress has been slow in coming, though researchers and clinicians alike remain hopeful that gene therapy will eventually become a realistic therapeutic option for treating cystic fibrosis.

Deletion of a single amino acid in the first nucleotide-binding domain of the CFTR protein blocks its transport function, resulting in cystic fibrosis.

about 600 d can pass through the *E. coli* porin shown in the figure. Mutations in certain bacterial porins can lead to antibiotic resistance in these bacteria by effectively blocking entry of the antibiotics that would normally be used to fight an infection.

Aquaporins: Transmembrane Channels That Allow Rapid Passage of Water. Whereas water can diffuse slowly across cell membranes in the absence of a protein transporter, movement of water across membranes in some tissues is much more rapid than can be accounted

for by diffusion alone. In fact, the existence of water channels in cell membranes was postulated as early as the mid-to late 1800s. Despite a century of experiments suggesting their existence, water channels remained elusive, and their very existence was sometimes in doubt.

It was not until 1992 that Peter Agre and colleagues at Johns Hopkins University finally isolated the long-sought-after water channel protein, which they named **aquaporin (AQP)**. They found that this particular erythrocyte protein, when introduced into membranes of relatively water-impermeable frog egg cells, would cause the cells to explode when placed in pure water due to the rapid influx of water. Control eggs without the protein placed in the pure water were unchanged. In 2003, Agre shared the Nobel Prize in chemistry with Roderick MacKinnon, who determined the first three-dimensional structure of an ion channel.

Aquaporins facilitate the rapid movement of water molecules into or out of cells in specific tissues that require this capability. For example, the proximal tubules of your kidneys reabsorb water as part of urine formation, and cells in this tissue have a high density of AQPs in their plasma membrane, allowing the kidney to filter more than 100 L of water per day. Aquaporins are also abundant in erythrocytes, which must be able to expand or shrink rapidly in response to sudden changes in osmotic pressure as they move through the kidney or other arterial passages. Erythrocytes have approximately 200,000 aquaporin molecules per cell.

In plants, AQPs are a prominent feature of root cell plasma membranes and the vacuolar membrane, reflecting the rapid movement of water that is required to develop turgor pressure, as discussed in Box 8A. Interestingly,

prokaryotes appear not to contain aquaporins, possibly because their small size—and hence their large surface area/volume ratio—makes facilitated transport of water unnecessary.

All aquaporins described to date are tetrameric integral membrane proteins that have four identical monomers, with each monomer containing six helical transmembrane segments. The four monomers associate side by side in the membrane with their 24 transmembrane segments oriented to form four central channels lined with hydrophilic side chains (Figure 8-8c). The space in the center of the tetramer is blocked by a lipid molecule. The diameter of each of the four water channels is about 0.3 nm, just large enough for water molecules to pass through one at a time in single file. Even with this constraint, water molecules flow through an aquaporin channel at the rate of several billion per second.

Active Transport: Protein-Mediated Movement Up the Gradient

Facilitated diffusion is an important mechanism for speeding up the movement of substances across cellular membranes. But it accounts for the transport of molecules only *toward* equilibrium, which means *down* a concentration or electrochemical gradient. What happens when a substance needs to be transported *against* a gradient, as when a nutrient or other substance is accumulated in a cell or organelle? Such situations require **active transport**, a process that differs from facilitated diffusion in one crucial aspect: Active transport makes it possible to move solutes *away* from thermodynamic equilibrium (that is, *up* a concentration gradient or *against* an electrochemical

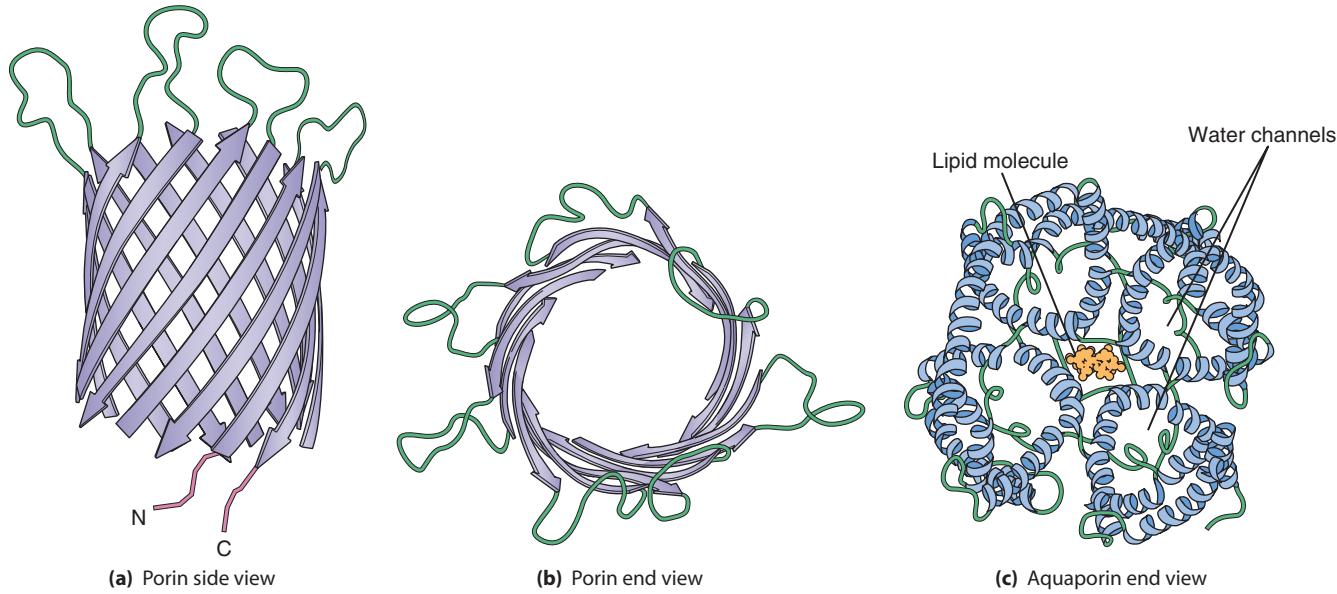

FIGURE 8-8 Porin and Aquaporin Channel Proteins. (a) Side view and (b) end view of an *E. coli* porin protein showing the 14-stranded transmembrane β -barrel. (c) End view through a human aquaporin, showing the six α helices in each of the four identical monomers. Two of the four water channels in the tetramer are labeled.

potential). Therefore, it always requires an input of energy. In other words, active transport couples a thermodynamically unfavorable process (movement up a concentration gradient) to an exergonic process (usually ATP hydrolysis). As a result, membrane proteins involved in active transport must provide mechanisms not only for moving desired solute molecules across the membrane but also for coupling such movements to energy-yielding reactions.

Active transport performs three major functions in cells and organelles. First, it makes possible the uptake of essential nutrients from the environment or surrounding fluid, even when their concentrations in the cell are already higher. Second, it allows various substances, such as secretory products and waste materials, to be removed from the cell or organelle, even when the concentration outside is greater than the concentration inside. Third, it enables the cell to maintain constant, nonequilibrium intracellular concentrations of specific inorganic ions, notably K^+ , Na^+ , Ca^{2+} , and H^+ .

This ability to create an internal cellular environment whose solute concentrations are far removed from equilibrium is a crucial feature of active transport. In contrast to simple or facilitated diffusion, which create conditions that are the same on opposite sides of a membrane, active transport is a means of establishing differences in solute concentration and/or electrical potential across membranes. The end result is a nonequilibrium steady state, without which life as we know it would be impossible. Many membrane proteins involved in active transport are called *pumps* to emphasize that an input of energy is required to move materials against their concentration or electrochemical gradients.

An important distinction between active transport and simple or facilitated diffusion concerns the direction of transport. Simple and facilitated diffusion are both *nondirectional* with respect to the membrane. For both types of diffusion, solutes can move in either direction, depending entirely on the prevailing concentration or electrochemical gradient. Active transport, on the other hand, usually has intrinsic *directionality*. An active transport system that moves a solute across a membrane in one direction will not usually move that solute in the other direction. Active transport is therefore said to be a *unidirectional* process.

The Coupling of Active Transport to an Energy Source May Be Direct or Indirect

Active transport mechanisms can be divided into two related categories that differ primarily in the source of energy and whether or not two solutes are transported simultaneously. Depending on the energy source, active transport is regarded as being either *direct* or *indirect* (Figure 8-9). In **direct active transport** (also called *primary active transport*), the accumulation of solute molecules or ions on one side of the membrane is coupled directly to an exergonic chemical reaction, most commonly the hydrolysis of ATP (Figure 8-9a). Transport

(a) Direct active transport
involves a transport system coupled to an exergonic chemical reaction, most commonly the hydrolysis of ATP. As shown here, ATP hydrolysis drives the outward transport of protons, thereby establishing an electrochemical potential for protons across the membrane.

(b) Indirect active transport
involves the coupled transport of a solute S and ions—protons, in this case. The exergonic inward movement of protons provides the energy to move the transported solute, S, against its concentration gradient or electrochemical potential.

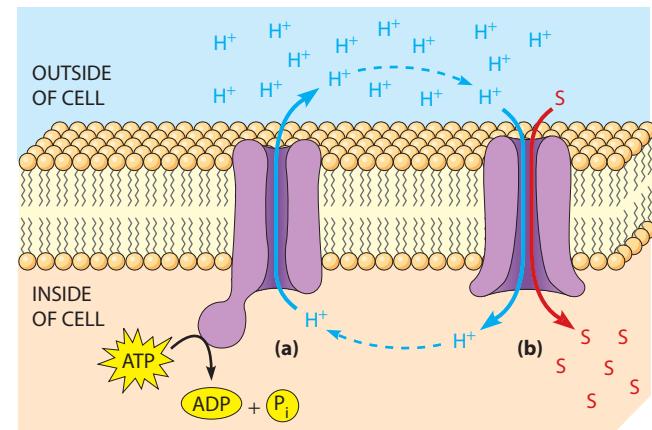

FIGURE 8-9 Comparison of Direct and Indirect Active Transport. Note the circulation of protons across the membrane that results from the coupling of direct and indirect mechanisms of active transport. Note also that transporters are not simply open channels, as depicted in the simplified illustration.

proteins driven directly by ATP hydrolysis are called *transport ATPases* or *ATPase pumps*.

Indirect active transport also requires energy but depends on the simultaneous transport of two solutes, with the favorable movement of one solute *down* its gradient driving the unfavorable movement of the other solute *up* its gradient. The coupling of a favorable process or reaction with an unfavorable one allows both to proceed with an overall decrease in free energy. This dual transport process can be described as either a *symport* or an *antiport*, depending on whether the two solutes move in the same or opposite directions. In most cases, one of the two solutes is an ion that moves exergonically down its electrochemical gradient— Na^+ in animals and H^+ in most other organisms. As it moves, it drives the simultaneous endergonic transport of the second solute (often a monosaccharide or an amino acid) against its concentration gradient or, in the case of ions, its electrochemical potential (Figure 8-9b). Thus indirect active transport is often called *secondary active transport*.

Direct Active Transport Depends on Four Types of Transport ATPases

The most common mechanism employed for direct active transport involves transport ATPases that link active transport to the hydrolysis of ATP. Four main types of transport

Table 8-2 Main Types of Transport ATPases (Pumps)

Solutes Transported	Kind of Membrane	Kind of Organisms	Example of ATPase function
P-type ATPases (P for “phosphorylation”)			
P ₁ K ⁺ , Cu ⁺ , Zn ²⁺ , Cd ²⁺ , Pb ²⁺	Plasma membrane	Bacteria, archaea, plants, fungi, animals	Transport of potassium or heavy metal ions
P ₂ Ca ²⁺ /H ⁺ Na ⁺ /K ⁺ H ⁺ /K ⁺	SR* or plasma membrane	Eukaryotes	Keeps [Ca ²⁺] low in cytosol
	Plasma membrane	Animals	Maintains membrane potential (-60 mV)
	Plasma membrane	Animals	Pumps H ⁺ to acidify stomach
P ₃ H ⁺	Plasma membrane	Plants, fungi	Pumps protons out of cell to generate membrane potential (-180 mV)
P ₄ Phospholipids	Plasma membrane	Eukaryotes	Flippases that maintain asymmetry in the lipid bilayer
P ₅ Various cations	ER, vacuole, lysosome	Eukaryotes	Not well characterized
V-type ATPases (V for “vacuole”)			
H ⁺	Lysosomes, secretory vesicles Vacuolar membrane	Animals Plants, fungi	Keeps pH of compartment low, which activates hydrolytic enzymes
F-type ATPases (F for “factor”); also called ATP synthases			
H ⁺	Inner mitochondrial membrane Plasma membrane Thylakoid membrane	Eukaryotes Bacteria Plants	Uses H ⁺ gradient to drive ATP synthesis
ABC-type ATPases (ABC for “ATP-binding cassette”)			
Importers A variety of solutes**	Plasma membrane, organellar membranes	Bacteria	Nutrients such as vitamin B ₁₂
Exporters Antitumor drugs, toxins, antibiotics, lipids	Plasma membrane	Bacteria, archaea, eukaryotes	Multidrug resistance transporter removes drugs and antibiotics from cell

*Sarcoplasmic reticulum, a specialized type of ER found in animal muscle cells

**Solutes include ions, sugars, amino acids, carbohydrates, vitamins, peptides, and proteins.

ATPases have been identified: *P-type*, *V-type*, *F-type*, and *ABC-type ATPases* (**Table 8-2**). These four types of transport proteins differ in structure, mechanism, localization, and physiological roles, but all of them use the energy of ATP hydrolysis to transport solutes against a concentration gradient or an electrochemical potential.

P-type ATPases. P-type ATPases (P for “phosphorylation”) are members of a large family of proteins that are reversibly phosphorylated by ATP as part of the transport mechanism, with a specific aspartic acid residue becoming phosphorylated in each case. P-type ATPases have 8–10 transmembrane segments in a single polypeptide that crosses the membrane multiple times (see Figure 7-5b). Also, they are sensitive to inhibition by the vanadate ion, VO₄³⁻, which closely resembles the phosphate ion (PO₄³⁻) and thus interferes with phosphorylation. Vanadate sensi-

tivity can therefore be used by researchers as a means of identifying P-type ATPases.

Most P-type ATPases are located in the plasma membrane and, based on sequence and structural similarities, fall into one of five subfamilies. P₁-ATPases have been found in all organisms and are mainly responsible for transporting ions of heavy metals. Several kinds of P₂-ATPases are responsible for maintaining gradients of ions such as Na⁺, K⁺, H⁺, and Ca²⁺ across the plasma membrane of many eukaryotic cells. The best-known example is the Na⁺/K⁺ pump found in almost all animal cells. We will consider this ATPase in more detail shortly. Another example is the Ca²⁺/H⁺ ATPase involved in muscle contraction (see Problem 8-10 and Chapter 16). A third P₂-ATPase is the H⁺/K⁺ ATPase responsible for acidification of the gastric juice in your stomach. This protein is the target of medications known as *proton pump inhibitors*.

that are used to combat excess stomach acid. Similar to these are the P₃-H⁺ ATPases of plants and fungi that pump protons outward across the plasma membrane of these cells, acidifying the external medium.

The P₄-ATPases differ from the preceding types in that they do not pump ions but instead pump relatively hydrophobic molecules such as cholesterol and fatty acids. Also, they do not transport materials completely across membranes but transport lipids from one leaflet of the membrane bilayer to the other, acting as flippases that help to maintain membrane asymmetry. P₅-ATPases are less well characterized but several are known to transport cations. They share sequence homology but not solute specificity. Some are found in the ER, where they appear to function in protein processing, and others are associated with the vacuole (yeast) or lysosome (animals) and have been implicated in hereditary neuronal diseases in humans.

V-type ATPases. V-type ATPases (V for “vacuole”) pump protons into such organelles as vacuoles, vesicles, lysosomes, endosomes, and the Golgi complex. Typically, the proton gradient across the membranes of these organelles ranges from tenfold to over 10,000-fold. V-type pumps are not inhibited by vanadate because they do not undergo phosphorylation as part of the transport process. They have two multisubunit components: an integral component embedded within the membrane and a peripheral component that juts out from the membrane surface. The peripheral component contains the ATP-binding site and hence the ATPase activity.

F-type ATPases. F-type ATPases (F for “factor”) are found in bacteria, mitochondria, and chloroplasts. F-type ATPases are involved in proton transport and have two components, both of them multisubunit complexes. The integral membrane component, called F₀, is a transmembrane pore for protons. The peripheral membrane component, called F₁, includes the ATP-binding site. F-type ATPases can use the energy of ATP hydrolysis to pump protons against their electrochemical potential.

These transport proteins can also facilitate the reverse process to synthesize ATP, as we will see when we study respiration and photosynthesis in Chapters 10 and 11, respectively. In the reverse direction, the exergonic flow of protons down their gradient is used to drive ATP synthesis. When they function in this latter mode, these F-type ATPases are more appropriately called **ATP synthases**. As ATP synthases, these proteins function to use either the energy from sugar oxidation (respiration) or the energy of solar radiation (photosynthesis) to produce a transmembrane proton gradient that drives ATP synthesis.

F-type ATPases illustrate an important principle: *Not only can ATP be used as an energy source to generate and maintain ion gradients, but such gradients can be used as an energy source to synthesize ATP.* This principle, which was discovered in studies of F-type pumps, is the basis of

ATP-synthesizing mechanisms in all eukaryotic organisms and in most prokaryotes as well.

ABC-type ATPases. The fourth major class of ATP-driven pumps is the **ABC-type ATPases**, also called **ABC transporters**. The ABC designation is for “ATP-binding cassette,” where the term *cassette* describes the catalytic domain of the protein that binds ATP as an integral part of the transport process. The more than 150 known ABC-type ATPases comprise a very large family of transport proteins that are found in all organisms. They are related to each other in sequence and probably also in molecular mechanism. Most of the ABC-type ATPases discovered initially were from bacterial species and were *importers* that are involved in uptake of nutrients. But increasing numbers of ABC-type ATPases known as *exporters*, some of great clinical importance, are being reported in eukaryotes as well. As we will soon see, some have been found in human tumor cells, where, unfortunately, they can export antitumor medications. At last count, 48 different genes for ABC-type ATPases have been identified in the human genome.

The typical ABC-type ATPase has four protein domains. Two of these domains are highly hydrophobic and are embedded in the membrane, while the other two are peripheral and are associated with the cytoplasmic side of the membrane. Each of the two embedded domains consists of six membrane-spanning segments that form the channel through which solute molecules pass. The two peripheral domains are the cassettes that bind ATP and couple its hydrolysis to the transport process. These four domains are separate polypeptides in most cases, especially in bacterial cells. However, examples are also known in which the four domains are part of a large, multifunctional polypeptide.

Although the other three classes of ATPases transport only cations, the different ABC-type ATPases handle a remarkable variety of solutes. Most ABC transporters are specific for a particular solute or class of closely related solutes. But the variety of solutes transported by the many members of this superfamily is great, including ions, sugars, amino acids, and even peptides and polysaccharides.

ABC transporters are of considerable medical interest because some of them pump antibiotics or other drugs out of the cell, thereby making the cell resistant to the drug. For example, some human tumors are remarkably resistant to a variety of drugs that are normally quite effective at arresting tumor growth. Cells of such tumors have unusually high concentrations of a large protein called the **multidrug resistance (MDR) transport protein**, which was in fact the first ABC-type ATPase to be identified in humans. The MDR transport protein uses the energy of ATP hydrolysis to pump hydrophobic drugs out of cells, thereby reducing the cytoplasmic concentration of the drugs and hence their effectiveness as therapeutic agents. Unlike most ABC transporters, the MDR protein has a remarkably broad specificity: It can export a wide range of chemically dissimilar drugs commonly used in cancer chemotherapy, so that a cell with the MDR protein in its

plasma membrane becomes resistant to a wide variety of therapeutic agents. Similarly, MDR proteins of some bacteria can transport a variety of antibiotics out of the cell, giving these cells resistance to multiple antibiotics.

Medical interest in this class of transport proteins was heightened when cystic fibrosis was shown to be caused by a genetic defect in a plasma membrane protein that is structurally related to the ABC transporters. We have long known that people with cystic fibrosis accumulate unusually thick mucus in their lungs—a condition that often leads to pneumonia and other lung disorders. Now we understand that the underlying problem is an inability to secrete chloride ions and that the genetic defect is in a protein that functions as a chloride ion channel.

The protein, called the *cystic fibrosis transmembrane conductance regulator* (CFTR), is similar in sequence and likely in topology to the core domains of ABC transporters. However, CFTR is an ion channel; and, unlike most of the ABC-type ATPases, it does not use ATP to drive transport. Instead, ATP hydrolysis appears to be involved in opening the channel. Recent developments in our understanding of cystic fibrosis at the molecular level and attempts at gene therapy to treat this disease are reported in Box 8B.

Indirect Active Transport Is Driven by Ion Gradients

In contrast to direct active transport, which is powered by energy released from a chemical reaction such as ATP hydrolysis, indirect active transport (also called *secondary active transport*) is driven by the movement of an ion down its electrochemical gradient. This principle has emerged from studies of the active uptake of sugars, amino acids, and other organic molecules into cells: The inward transport of molecules *up* their electrochemical gradients is often coupled to, and driven by, the simultaneous inward movement of either sodium ions (for animal cells) or protons (for most plant, fungal, and bacterial cells) *down* their respective electrochemical gradients.

The widespread existence of such symport mechanisms explains why most cells continuously pump either sodium ions or protons out of the cell. In animals, for example, the relatively high extracellular concentration of sodium ions maintained by the Na^+/K^+ pump serves as the driving force for the uptake of a variety of sugars and amino acids (Figure 8-10). The uptake of such compounds is regarded as indirect active transport because it is not directly driven by the hydrolysis of ATP or a related “high-energy” compound. Ultimately, however, uptake still depends on ATP because the Na^+/K^+ pump that maintains the sodium ion gradient is itself driven by ATP hydrolysis. The continuous outward pumping of Na^+ by the ATP-driven Na^+/K^+ pump and inward movement of Na^+ by symport (coupled to the uptake of another solute) establishes a circulation of sodium ions across the plasma membrane of every animal cell, similar to the cycling of H^+ ions shown in Figure 8-9.

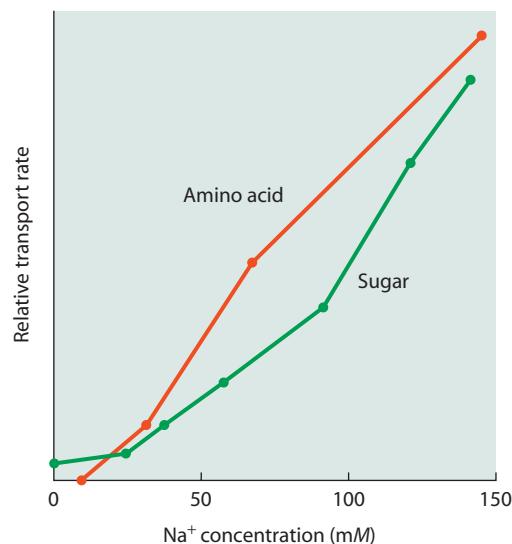

FIGURE 8-10 Effect of External Sodium Ion Concentration on Amino Acid and Sugar Transport. In this experiment, investigators varied the extracellular concentration of sodium ions and measured the transport rate of the amino acid glycine into erythrocytes or the sugar 7-deoxy-D-glucoheptose into intestinal lining cells. Studies of this type provided the first evidence that transport of amino acids and sugars into cells is stimulated by sodium ions present in the extracellular medium.

While animal cells use sodium ions to drive indirect active transport, most other organisms rely on a proton gradient instead. For example, fungi and plants utilize proton symport for the uptake of organic solutes, with an ATP-driven proton pump responsible for the generation and maintenance of the proton electrochemical potential. Many kinds of bacterial cells also make extensive use of proton cotransport to drive the uptake of solute molecules, as do mitochondria. In all such cases, however, the proton gradient is maintained by an electron transfer process that accompanies cellular respiration, as we will see in Chapter 10.

In addition to the symport *uptake* of organic molecules such as sugars and amino acids, sodium ions or proton gradients can be used to drive the *export* of other ions, including Ca^{2+} and K^+ . This type of indirect active transport is usually antiport and may involve the exchange of potassium ions for protons or the exchange of calcium ions for sodium ions, for example.

Examples of Active Transport

Having considered some general features of active transport, we are now ready to look at three specific examples: one example each of direct and indirect active transport from animal cells, and an unusual type of light-driven transport in a bacterium. In each case we will note what kinds of solutes are transported, what the driving force is, and how the energy source is coupled to the transport mechanism. We will focus first on the Na^+/K^+ ATPase (or *pump*) present in all animal cells because it is a well-understood example of

direct active transport by a P-type ATPase. Then we will consider a second example from animal cells: the indirect active transport of glucose by a $\text{Na}^+/\text{glucose symporter}$, using the energy of the sodium ion gradient established by the Na^+/K^+ ATPase. Finally, we will look briefly at light-driven *proton transport* in certain bacteria.

Direct Active Transport: The Na^+/K^+ Pump Maintains Electrochemical Ion Gradients

A characteristic feature of most animal cells is a high intracellular level of potassium ions and a low intracellular level of sodium ions, such that in a typical animal cell the $[\text{K}^+]_{\text{inside}}/[\text{K}^+]_{\text{outside}}$ ratio is about 35:1 and the $[\text{Na}^+]_{\text{inside}}/[\text{Na}^+]_{\text{outside}}$ ratio is about 0.08:1. The resulting electrochemical potentials for potassium and sodium ions are essential as the driving force for coupled transport as well as for the transmission of nerve impulses. Both the inward pumping of potassium ions and the outward pumping of sodium ions are therefore energy-requiring processes, as both ions are being moved up their electrochemical gradients.

The protein responsible for this process was discovered in 1957 by Jens Skou, a Danish physiologist, who was awarded the Nobel Prize in chemistry in 1997. The discovery of this ion-transporting enzyme was in fact the first documented case of active transport. This Na^+/K^+ ATPase, or Na^+/K^+ pump, as this P-type ATPase is usually called, uses the exergonic hydrolysis of ATP to drive the endergonic inward transport of potassium ions and the outward transport of sodium ions against their concentration gradients. The Na^+/K^+ pump is primarily responsible for the asymmetric distribution of ions across the plasma membrane in animal cells. Like most other active transport systems, this pump has inherent directionality: Potassium ions are always pumped inward and sodium ions are always pumped outward. In fact, sodium and potassium ions activate the ATPase only on the side of the membrane they are transported from—sodium ions from the inside, potassium ions from the outside. Three sodium ions are moved out and two potassium ions are moved in per molecule of ATP hydrolyzed.

Figure 8-11 is a schematic illustration of the Na^+/K^+ pump. The pump is a tetrameric transmembrane protein with two α and two β subunits. The α subunits contain binding sites for sodium ions and ATP on the cytoplasmic side and for potassium ions on the external side of the membrane. We know that the β subunits are located outside the α subunits and are glycosylated, but their function is not yet clear.

The Na^+/K^+ pump is an allosteric protein exhibiting two alternative conformational states, referred to as E_1 and E_2 . The E_1 conformation is open to the inside of the cell and has a high affinity for sodium ions, whereas E_2 is open to the outside, with a high affinity for potassium ions. Phosphorylation of the enzyme by ATP, a sodium-triggered event, stabilizes it in the E_2 form. Dephosphorylation, on

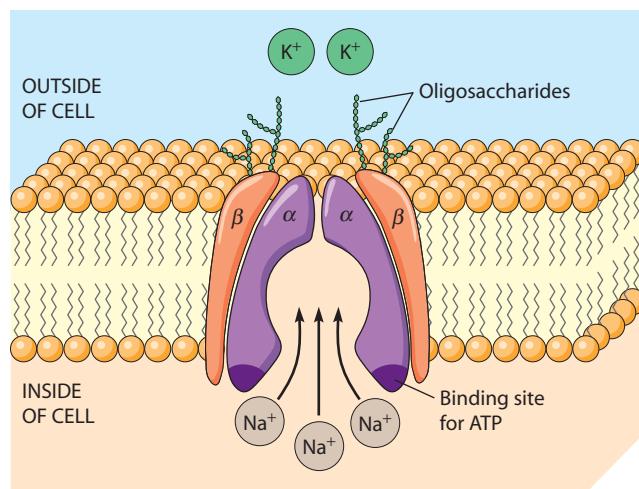

FIGURE 8-11 The Na^+/K^+ Pump. The Na^+/K^+ pump found in most animal cells consists of two α and two β subunits. The α subunits are transmembrane proteins, with binding sites for ATP on the cytoplasmic side. The β subunits are located on the outside of the α subunits and are glycosylated. The pump is shown in the E_1 conformation, which is open to the inside of the cell. Binding of sodium ions causes a conformational change to the E_2 form, which opens to the outside. The transport mechanism in this pump is shown in Figure 8-12.

the other hand, is triggered by K^+ and stabilizes the enzyme in the E_1 form.

As illustrated schematically in **Figure 8-12**, the actual transport mechanism involves an initial binding of three sodium ions to E_1 on the inner side of the membrane **1**, upper right. The binding of sodium ions triggers phosphorylation of the α subunit of the enzyme by ATP **2**, resulting in a conformational change from E_1 to E_2 . As a result, the bound sodium ions are moved through the membrane to the external surface, where they are released to the outside **3**. Then, potassium ions from the outside bind to the α subunits **4**, triggering dephosphorylation and a return to the original conformation **5**. During this process, the potassium ions are moved to the inner surface, where they dissociate, leaving the carrier ready to accept more sodium ions **6**.

The Na^+/K^+ pump is not only one of the best-understood transport systems but also one of the most important for animal cells. Besides maintaining the appropriate intracellular concentrations of both potassium and sodium ions, it is responsible for maintaining the membrane potential that exists across the plasma membrane. The Na^+/K^+ pump assumes still more significance when we take into account the vital role that sodium ions play in the inward transport of organic substrates, a topic we now come to as we consider sodium symport.

Indirect Active Transport: Sodium Symport Drives the Uptake of Glucose

As an example of indirect active transport, let us consider the uptake of glucose by the $\text{Na}^+/\text{glucose symporter}$.

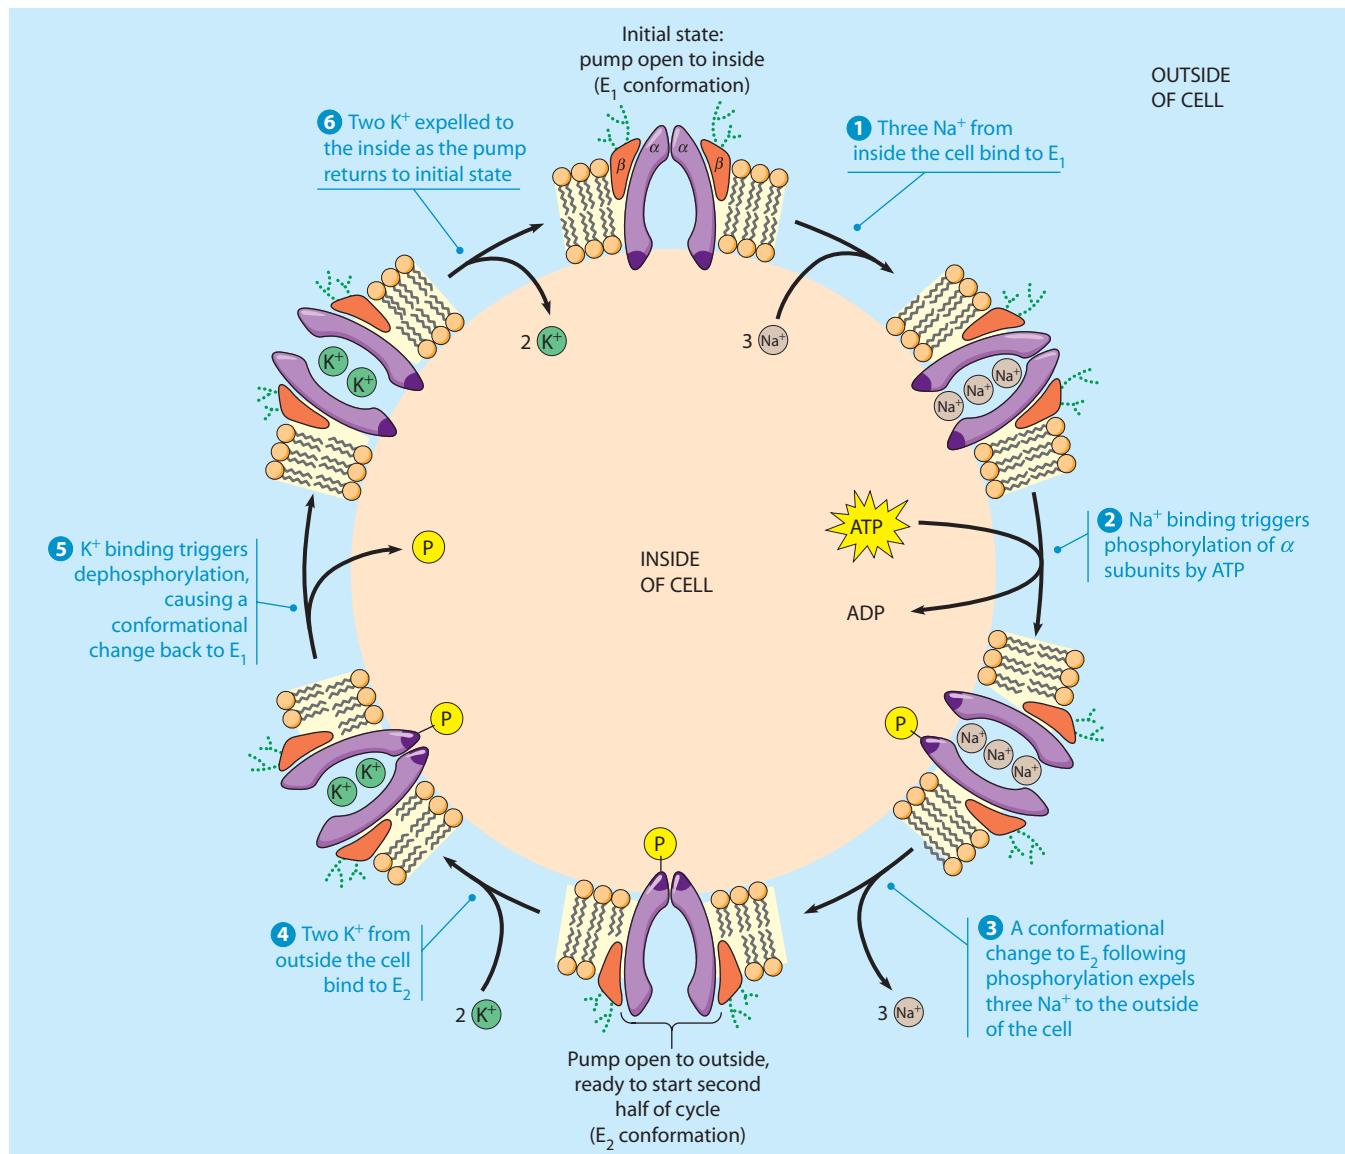

FIGURE 8-12 Model Mechanism for the Na^+/K^+ Pump. The transport process is shown here in six steps arranged at the periphery of a cell. The outward transport of sodium ions is coupled to the inward transport of potassium ions, both against their respective electrochemical potentials. The driving force is provided by ATP hydrolysis, which is required for phosphorylation of the α subunit of the pump at step **2**. E_1 and E_2 are the conformation states of the protein with the channel open to the inside (top of figure) and to the outside (bottom of figure) of the cell.

ACTIVITIES www.thecellplace.com Active transport

Although most glucose transport into or out of cells in your body occurs by facilitated diffusion, as shown in Figure 8-7, the epithelial cells lining your intestines have transport proteins that are able to take up glucose and certain amino acids from the intestines even when their concentrations there are much lower than in the epithelial cells. This energy-requiring process is driven by the simultaneous uptake of sodium ions, which is exergonic because of the steep electrochemical gradient for sodium that is maintained across the plasma membrane by the Na^+/K^+ pump (higher $[\text{Na}^+]$ outside the cell). These *sodium-dependent glucose transporters* are often referred to as *SGLT* proteins.

Figure 8-13 depicts the transport mechanism for the $\text{Na}^+/\text{glucose symporter}$, which requires the inward movement of two sodium ions to drive the simultaneous uptake of one glucose molecule. Transport is initiated by the binding of two external sodium ions to their binding sites on the symporter, which is open to the outer surface of the membrane **1**. This allows a molecule of glucose to bind **2**, followed by a conformational change in the protein that exposes the sodium ions and the glucose molecule to the inner surface of the membrane **3**. There the two sodium ions dissociate in response to the low intracellular sodium ion concentration **4**. This

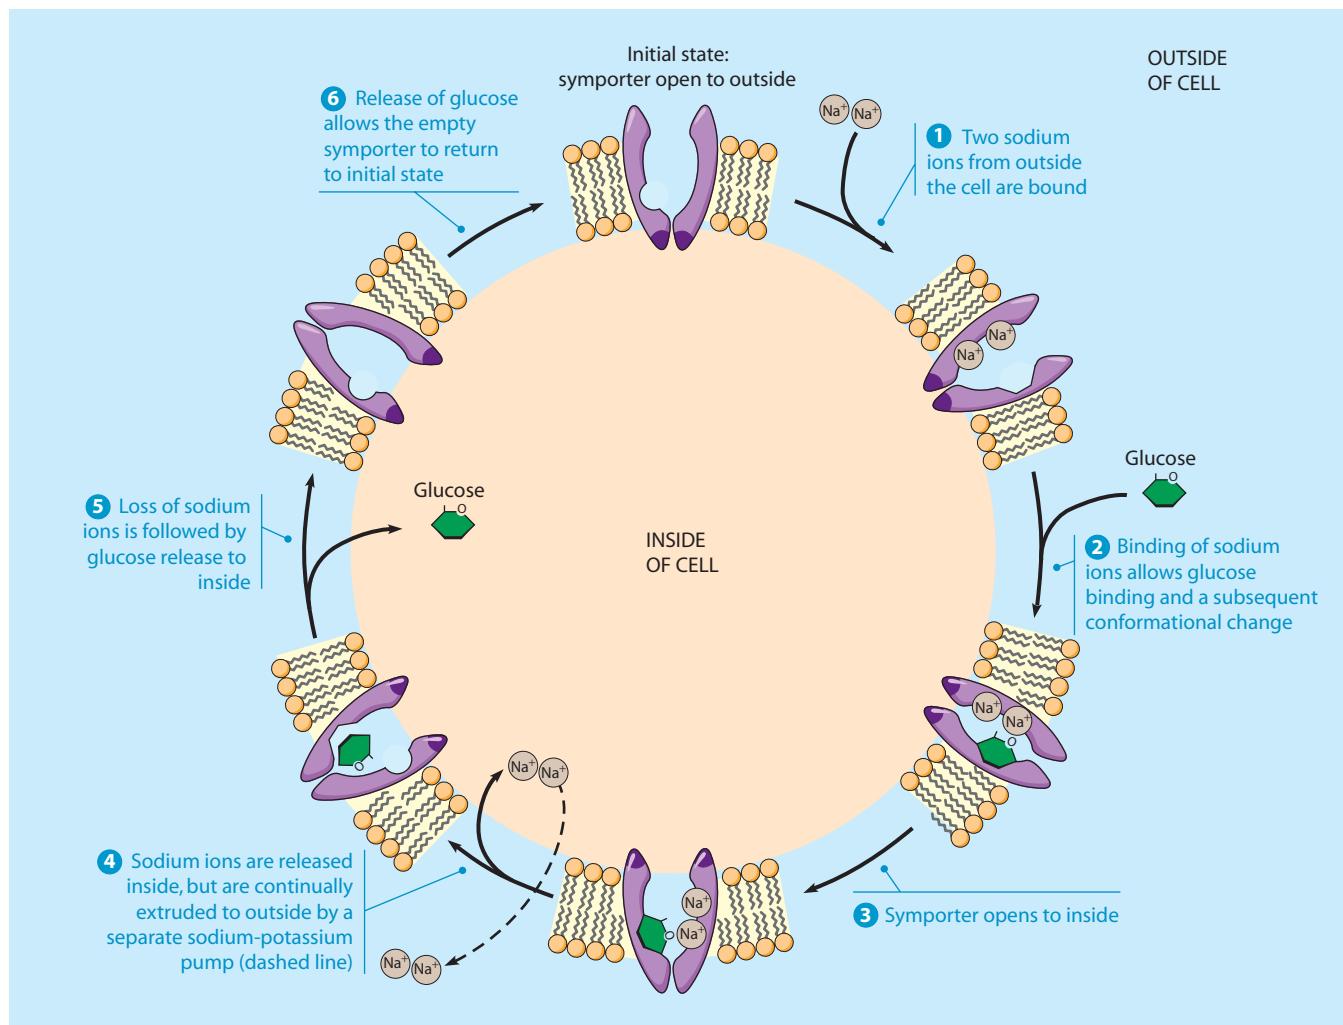

FIGURE 8-13 Model Mechanism for the $\text{Na}^+/\text{Glucose}$ Symporter. The transport process is shown here in six steps arranged at the periphery of a cell. The inward transport of glucose against its concentration gradient is driven by the simultaneous inward transport of sodium ions down their electrochemical gradient. The sodium ion gradient is in turn maintained by the continuous outward transport of sodium ions (dashed arrow) by the Na^+/K^+ pump of Figure 8-12.

locks the transporter in its inward-facing conformation until the glucose molecule dissociates **5**. Then, the empty transporter is free to return to its outward-facing conformation **6**.

The sodium ion gradient is in turn maintained by the continuous outward extrusion of sodium ions (dashed arrow) by the Na^+/K^+ pump of Figure 8-12. As a result, sodium ions circulate across the plasma membrane, pumped outward by the Na^+/K^+ pump and flowing back into the cell as the driving force for sodium symport of molecules such as glucose. Similar mechanisms are involved in the uptake of amino acids and other organic substrates by sodium symport in animal cells and by proton symport in plant, fungal, and bacterial cells.

Knowledge of the $\text{Na}^+/\text{Glucose}$ cotransport mechanism has helped in the treatment of the disease cholera, caused by the bacterium *Vibrio cholera*, which produces a toxin that paralyzes intestinal cells and can lead to

death via dehydration. Oral rehydration is the standard treatment for cholera, and it has been shown that rehydration with a salt and sugar solution is the most effective remedy. Administration of NaCl helps the body to retain water as it strives to maintain salt balance in the tissues, and providing glucose along with the salt therefore allows for more efficient uptake of salt via the $\text{Na}^+/\text{Glucose}$ symporter.

The Bacteriorhodopsin Proton Pump Uses Light Energy to Transport Protons

The final active transport system we will consider is the simplest. Nothing more is involved than a small integral membrane protein called **bacteriorhodopsin**. This protein, briefly introduced in Chapter 7, is a proton pump found in the plasma membrane of halophilic (“salt-loving”) archaea belonging to the genus *Halobacterium*.

In contrast to transport proteins that utilize energy derived from ATP or ion gradients, bacteriorhodopsin uses energy derived from photons of light to drive active transport. Bacteriorhodopsin contains a pigment molecule that traps light energy and uses it to drive the active transport of protons outward across the plasma membrane. It thereby creates an electrochemical proton gradient that powers the synthesis of ATP by an ATP synthase analogous to the F-type ATP synthases found in chloroplasts and mitochondria.

The light-absorbing pigment of bacteriorhodopsin is *retinal*, a carotenoid derivative related to vitamin A. (Retinal also serves as the visual pigment in the retina of your eyes.) Retinal makes bacteriorhodopsin bright purple in color, which is why halobacteria are also called *purple photosynthetic bacteria* (Figure 8-14a). Bacteriorhodopsin appears in the plasma membrane of the *Halobacterium* cell as colored patches called *purple membrane* (Figure 8-14b).

Bacteriorhodopsin is an integral membrane protein with seven α -helical membrane-spanning segments oriented in the membrane to form an overall cylindrical shape (Figure 8-14c). The retinal chromophore is normally present in the all-*trans* form and is covalently linked to the side chain of a lysine residue at position 216 (Figure 8-14d). When the retinal absorbs a photon of light, one of its double bonds isomerizes to the higher-energy *cis* form, thereby photoactivating the bacteriorhodopsin molecule. The photoactivated molecule is then capable of transferring protons from the inside to the outside of the cell. The electrochemical potential produced by pumping protons out of the cell in this way is used by membrane-located halobacterial ATPases to synthesize ATP as the protons flow down their concentration gradient back into the cell. Recently, because it is a light-driven proton pump, the bacteriorhodopsin molecule is being researched as a conducting medium for use in *biomolecular electronics*. This is a relatively new field in which biological molecules with electron- and ion-conducting properties are being studied and used as structural elements of biooptical, biocomputing, and biosensor devices.

Energy-dependent proton pumping is one of the most basic concepts in cellular energetics. Proton pumping, which occurs in all bacteria, mitochondria, and chloroplasts, represents the driving force for all of life on Earth because it is an absolute requirement for the efficient synthesis of ATP. We will discuss the mechanisms underlying the generation of proton gradients and the use of the energy of such gradients in more detail when we discuss respiration and photosynthesis in Chapters 10 and 11.

The Energetics of Transport

Every transport event in the cell is an energy transaction. Energy either is released as transport occurs or is required to drive transport. To understand the energetics of transport, we must recognize that two different factors may be involved. For uncharged solutes, the only variable is the con-

centration gradient across the membrane, which determines whether transport is “down” a gradient (exergonic) or “up” a gradient (endergonic). For charged solutes, however, there is both a concentration gradient and an electrical potential across the membrane. The two may either reinforce each other or oppose each other, depending on the charge on the ion and the direction of transport. We will first look at the transport of uncharged substances and then consider the additional complication that arises when charged substances are moved across membranes.

For Uncharged Solutes, the ΔG of Transport Depends Only on the Concentration Gradient

For solutes with no net charge, we are concerned only with the concentration gradient across the membrane. We can therefore treat the transport process as we would treat a simple chemical reaction, and we can calculate ΔG accordingly.

Calculating ΔG for the Transport of Molecules. The general “reaction” for the transport of molecules of solute S from the outside of a membrane-bounded compartment to the inside can be represented as

From Chapter 5, we know that the free energy change for this reaction can be written as

$$\Delta G = \Delta G^\circ + RT \ln \frac{[S]_{\text{inside}}}{[S]_{\text{outside}}} \quad (8-5)$$

where ΔG is the free energy change, ΔG° is the standard free energy change, R is the gas constant (1.987 cal/mol · K), T is the absolute temperature, and $[S]_{\text{inside}}$ and $[S]_{\text{outside}}$ are the prevailing concentrations of S on the inside and outside of the membrane, respectively. However, the equilibrium constant K_{eq} for the transport of an uncharged solute is always 1 because at equilibrium the solute concentrations on the two sides of the membrane will be the same:

$$K_{\text{eq}} = \frac{[S]_{\text{inside}}}{[S]_{\text{outside}}} = 1.0 \quad (8-6)$$

This means that ΔG° is always zero:

$$\Delta G^\circ = -RT \ln K_{\text{eq}} = -RT \ln 1 = 0 \quad (8-7)$$

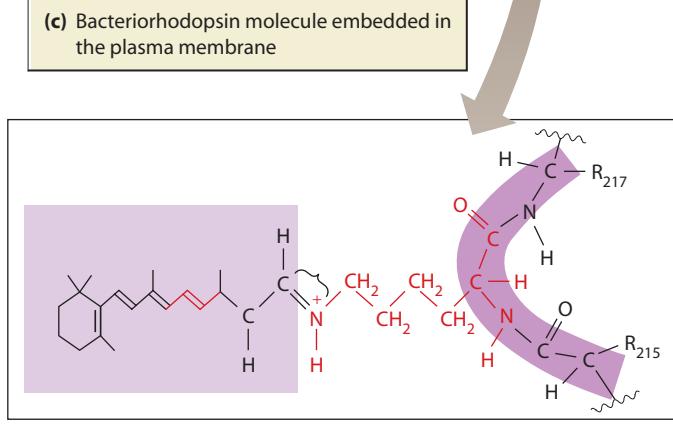

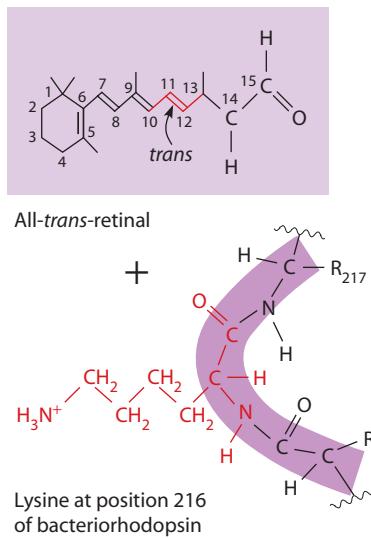

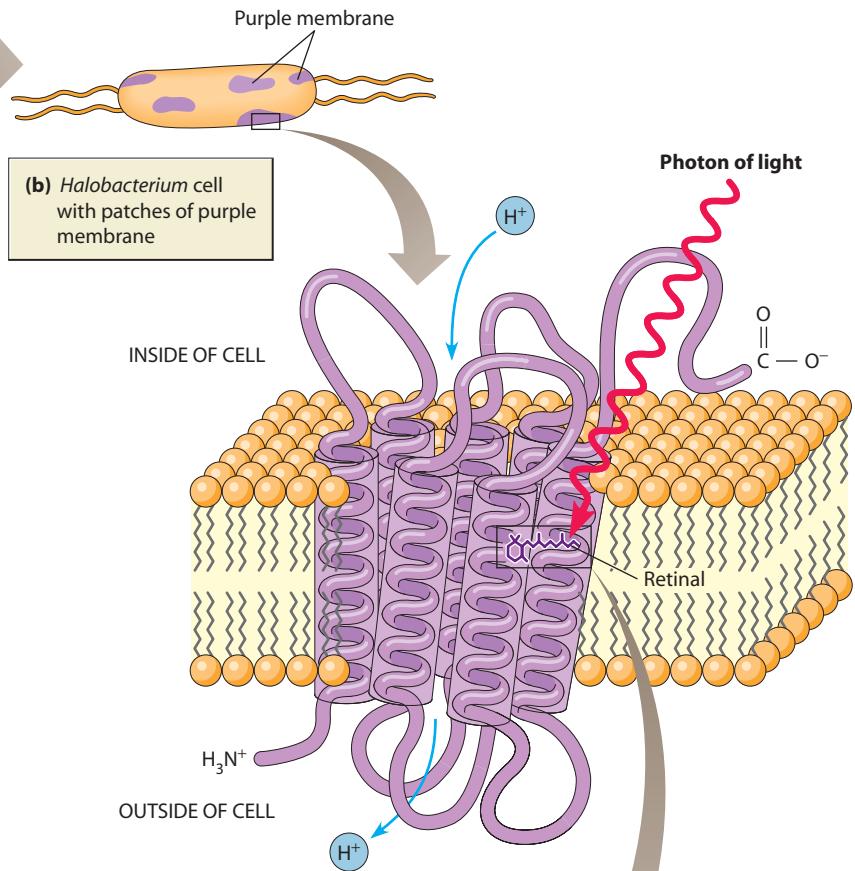

So the expression for ΔG of inward transport of an uncharged solute simplifies to

$$\Delta G_{\text{inward}} = +RT \ln \frac{[S]_{\text{inside}}}{[S]_{\text{outside}}} \quad (8-8)$$

Notice that if $[S]_{\text{inside}}$ is less than $[S]_{\text{outside}}$, ΔG is negative, indicating that the inward transport of substance S is exergonic. It can therefore occur spontaneously, as would be

(a) *Halobacterium* (purple color) grows in the high-salt concentration of solar evaporation ponds used for manufacturing salt around San Francisco Bay

(d) All-trans-retinal linked covalently to the lysine at position 216 of bacteriorhodopsin

FIGURE 8-14 The Bacteriorhodopsin Proton Pump of Halobacteria. **(a)** Archaea belonging to the genus *Halobacterium* are characterized by a purple color that is due to the protein bacteriorhodopsin. **(b)** Bacteriorhodopsin is a light-activated proton pump that is present in the plasma membrane of *Halobacterium* cells as bright purple patches known as purple membrane. **(c)** The seven α -helical transmembrane segments of bacteriorhodopsin are separated by short, nonhelical segments and are oriented in the membrane to form an overall cylindrical shape. **(d)** The chromophore, all-trans-retinal, is linked to the lysine at position 216 in the seventh transmembrane segment of the protein.

expected for facilitated diffusion down a concentration gradient. But if $[S]_{\text{inside}}$ is greater than $[S]_{\text{outside}}$, inward transport of S is against the concentration gradient, and ΔG will be positive. In this case, inward transport of S is endergonic, and the amount of energy required to drive

the active transport of S into the cell is indicated by the magnitude of the positive value of ΔG .

An Example: The Uptake of Lactose. Suppose that the concentration of lactose within a bacterial cell is to be

maintained at 10 mM, while the external lactose concentration is only 0.20 mM. The energy requirement for the inward transport of lactose at 25°C can be calculated from Equation 8-8 as

$$\begin{aligned}\Delta G_{\text{inward}} &= + RT \ln \frac{[\text{lactose}]_{\text{inside}}}{[\text{lactose}]_{\text{outside}}} \\ &= +(1.987)(273 + 25) \ln \frac{0.010}{0.0002} \\ &= +592 \ln 50 \\ &= +2316 \text{ cal/mol} \\ &= +2.32 \text{ kcal/mol}\end{aligned}\quad (8-9)$$

In many bacterial cells, the energy to drive lactose uptake is provided by the electrochemical proton gradient, so lactose uptake in such cells is an example of indirect active transport.

As written, Equation 8-8 applies to inward transport. For outward transport, the positions of S_{inside} and S_{outside} are simply interchanged within the logarithm. As a result, the absolute value of ΔG remains the same, but the sign is changed. As for any other process, a transport reaction that is exergonic in one direction will be endergonic to the same degree in the opposite direction. The equations for calculating ΔG of inward and outward transport of uncharged solutes are summarized in **Table 8-3**.

For Charged Solutes, the ΔG of Transport Depends on the Electrochemical Potential

For charged solutes—ions, in other words—we need to take into account both the concentration gradient and the membrane potential, V_m . For animal cells, V_m usually falls in the range of -60 to -90 mV. In bacterial and plant cells it is significantly more negative, often about -150 mV in bacteria and between -200 and -300 mV in plants. By convention, the minus sign indicates that the negative charge is on the inside of the cell. Thus, the V_m value indicates how negative (or positive, in the case of a plus sign) the *inside* of the cell is compared with the *outside*.

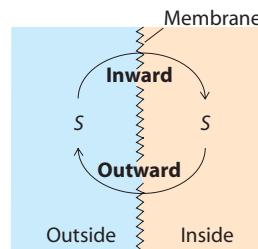

The membrane potential obviously has no effect on uncharged solutes, but it significantly affects the energetics of ion transport. Because it is almost always negative, the membrane potential typically *favors* the inward movement of cations and *opposes* their outward movement. As we mentioned earlier, the net effect of both the concentration gradient and the potential gradient for an ion is called the *electrochemical potential* for that ion.

Calculating ΔG for the Transport of Ions. Both components of the electrochemical potential must be considered when determining the energetics of ion transport. To calculate ΔG for the transport of ions therefore requires an equation with two terms, one to express the effect of the concentration gradient across the membrane and the other to take into account the membrane potential.

Table 8-3

Calculation of ΔG for the Transport of Charged and Uncharged Solutes

Transport Process

ΔG for Transport of Uncharged Solutes:

$$\begin{aligned}\Delta G_{\text{inward}} &= +RT \ln \frac{[S]_{\text{inside}}}{[S]_{\text{outside}}} & R &= 1.987 \text{ cal/mol} \cdot \text{K} \\ \Delta G_{\text{outward}} &= -\Delta G_{\text{inward}} & T &= K = {}^\circ\text{C} + 273\end{aligned}$$

ΔG for Transport of Charged Solutes:

$$\begin{aligned}\Delta G_{\text{inward}} &= +RT \ln \frac{[S]_{\text{inside}}}{[S]_{\text{outside}}} + zFV_m & z &= \text{charge on ion} \\ & & F &= 23,062 \text{ cal/mol} \cdot \text{V} \\ & & V_m &= \text{membrane potential (in volts)} \\ \Delta G_{\text{outward}} &= -\Delta G_{\text{inward}}\end{aligned}$$

If we let S^z represent a solute with a charge z , then we can calculate ΔG for the inward transport of S^z as

$$\Delta G_{\text{inward}} = +RT \ln \frac{[S^z]_{\text{inside}}}{[S^z]_{\text{outside}}} + zFV_m \quad (8-10)$$

where R , T , $[S]_{\text{inside}}$, and $[S]_{\text{outside}}$ are defined as before; z is the charge on S (such as $+1, +2, -1, -2$); F is the Faraday constant ($23,062 \text{ cal/mol} \cdot \text{V}$); and V_m is the membrane potential (in volts). Note that Equation 8-8 is just the simplified version of Equation 8-10 for solutes with a z value of zero—that is, for molecules with no net charge.

For a typical cell, the membrane potential V_m is negative (an excess of negative charge inside the cell). A positive ion ($z > 0$) will cause the term zFV_m to be negative, giving a negative ΔG for inward transport. This indicates that uptake of the positive ion is energetically favorable, as you would expect if the interior of the cell has a net negative charge. The uptake of positive ions becomes more exergonic and more favorable as the membrane potential of the cell decreases. The opposite is true for a negative ion ($z < 0$), which gives a positive value for zFV_m and a positive change in free energy, indicating an unfavorable process that will not occur spontaneously.

For the outward transport of S , ΔG has the same value as for inward transport but is opposite in sign, so we can write

$$\Delta G_{\text{outward}} = -\Delta G_{\text{inward}} \quad (8-11)$$

An Example: The Uptake of Chloride Ions. To illustrate the use of Equation 8-10 and to point out that intuition does not always serve us well in predicting the direction of ion transport—consider what happens when nerve cells with an intracellular chloride ion concentration of 50 mM are placed in a solution containing 100 mM Cl⁻. Since the Cl⁻ concentration is twice as high outside the cell as inside, you might expect chloride ions to diffuse passively into the cell without the need for active transport. However, this expectation ignores the membrane potential of about -60 mV (-0.06 V) that exists across the plasma membrane of nerve cells. The minus sign reminds us that the inside of the cell is negative with respect to the outside, which means that the inward movement of negatively charged anions such as Cl⁻ will be *against* the membrane potential. Thus, the inward movement of chloride ions is *down* the concentration gradient but *up* the charge gradient.

To quantify the relative magnitudes of these two opposing forces at 25°C, we can use Equation 8-10 with the relevant values inserted:

$$\begin{aligned}\Delta G_{\text{inward}} &= +RT \ln \frac{[S]_{\text{inside}}}{[S]_{\text{outside}}} + zFV_m \\ &= +(1.987)(273 + 25) \ln \left(\frac{0.05}{0.10} \right) \\ &\quad + (-1)(23,062)(-0.06) \\ &= +592 \ln (0.5) + (23,062)(0.06) \\ &= -410 + 1384 \\ &= 974 \text{ cal/mol} \\ &= +0.97 \text{ kcal/mol}\end{aligned}\tag{8-12}$$

The sign of ΔG is positive, meaning that even though the chloride ion concentration is twice as high outside the cell as inside, energy will still be required to drive the movement of chloride ions into the cell. This is due to the excess of negative charge inside the cell, represented by the negative value of V_m. The movement of a mole of chloride ions up the charge gradient represented by the membrane potential requires more energy (+1384 calories) than is released by the movement of the mole of chloride ions down their concentration gradient (-410 calories). To guide you in such calculations, the equations for inward and outward transport of charged solutes are included along with those for the transport of uncharged solutes in Table 8-3, which summarizes the thermodynamic properties of each of these processes.

In this chapter, we have focused on the movement of ions and small molecules into and out of cells and organelles and have seen that these solutes pass directly through the membrane, though often with the aid of specific transport proteins. In addition to such traffic, however, many cells are able to take up and release substances that are too large to pass through a membrane regardless of its permeability properties. *Exocytosis* is the process whereby cells release proteins that are synthesized within the cell and sequestered within membrane-bound vesicles, while *endocytosis* involves the uptake of macromolecules and other substances by trapping and engulfing them within an invagination of the plasma membrane. Both of these processes are unique to eukaryotic cells. We will consider exocytosis and endocytosis in detail when we get to Chapter 12.

SUMMARY OF KEY POINTS

Cells and Transport Processes

- The selective transport of molecules and ions across membrane barriers ensures that necessary substances are moved into and out of cells and cell compartments at the appropriate time and at useful rates.
- Nonpolar molecules and small, polar molecules cross the membrane by simple diffusion. Transport of all other solutes, including ions and many molecules of biological relevance, is mediated by specific transport proteins that provide passage through an otherwise impermeable membrane.
- Each such transport protein has at least one, and frequently several, hydrophobic membrane-spanning sequences that embed the protein within the membrane and often act as the channel itself. Typically, a separate regulatory domain controls channel opening and closing.

Simple Diffusion: Unassisted Movement Down the Gradient

- Simple diffusion through biological membranes is limited to small or nonpolar molecules such as O₂, CO₂, and lipids. Water molecules, although polar, are small enough to diffuse across membranes in a manner that is not entirely understood.
- Membranes are permeable to lipids, which can pass through the nonpolar interior of the lipid bilayer. Membrane permeability of most compounds is directly proportional to their partition coefficient—their relative solubility in oil versus water.
- The direction of diffusion of a solute across a membrane is determined by its concentration gradient and always moves toward equilibrium. The solute will diffuse down the gradient from a region of high concentration to a region of low concentration.

- If the membrane is impermeable to the solute, water will move by osmosis from the area of low solute concentration (higher $[H_2O]$) to the area of high solute concentration (lower $[H_2O]$).

Facilitated Diffusion: Protein-Mediated Movement Down the Gradient

- Transport can either be downhill or uphill in relation to an uncharged solute's concentration gradient. For an ion, we must consider its electrochemical potential—the combined effect of the ion's concentration gradient and the charge gradient across the membrane.
- Downhill transport of large, polar molecules and ions, called facilitated diffusion, must be mediated by carrier proteins and channel proteins because these molecules and ions cannot diffuse through the membrane directly.
- Carrier proteins function by alternating between two conformational states. Examples include the glucose transporter and the anion exchange protein found in the plasma membrane of the erythrocyte.
- Transport of a single kind of molecule or ion is called uniport. The coupled transport of two or more molecules or ions at a time may involve movement of both solutes in the same direction (symport) or in opposite directions (antiport).
- Channel proteins facilitate diffusion by forming transmembrane channels lined with hydrophilic amino acids. Three important categories of channel proteins are ion channels (used mainly for transport of H^+ , Na^+ , K^+ , Ca^{2+} , Cl^- , and HCO_3^-), porins (for various high-molecular-weight solutes), and aquaporins (for water).

Active Transport: Protein-Mediated Movement Up the Gradient

- Active transport—the uphill transport of large, polar molecules and ions—requires a protein transporter and an

input of energy. It may be powered by ATP hydrolysis, the electrochemical potential of an ion gradient, or light energy.

- Active transport powered by ATP hydrolysis utilizes four major classes of transport proteins: P-type, V-type, F-type, and ABC-type ATPases. One widely encountered example is the ATP-powered Na^+/K^+ pump (a P-type ATPase), which maintains electrochemical potentials for sodium and potassium ions across the plasma membrane of animal cells.
- Active transport driven by an electrochemical potential usually depends on a gradient of either sodium ions (animal cells) or protons (plant, fungal, and many bacterial cells). For example, the inward transport of nutrients across the plasma membrane is often driven by the symport of sodium ions that were pumped outward by the Na^+/K^+ pump. As they flow back into the cell, they drive inward transport of sugars, amino acids, and other organic molecules.
- In *Halobacterium*, active transport is powered by light energy. As photons of light are absorbed by bacteriorhodopsin, protons are pumped across the cell membrane and out of the cell. As the protons flow back into the cell, ATP is synthesized.

The Energetics of Transport

- The ΔG for transport can be readily calculated. If $\Delta G < 0$, transport will be spontaneous. If $\Delta G > 0$, an input of energy will be required to drive transport. If $\Delta G = 0$, there will be no net movement of the solute.
- For uncharged solutes, ΔG depends only on the concentration gradient. For charged solutes, both the concentration gradient and the membrane potential must be taken into account.

MAKING CONNECTIONS

With what you have learned about the structure and functions of membranes in the last two chapters, you will be well prepared as we study more advanced topics involving membranes. To understand the fluid mosaic model of membrane structure, we built upon our knowledge of chemistry and macromolecules from Chapters 2 and 3 to see how the cell and its various organelles (Chapter 4) are all surrounded by phospholipid bilayers that function as barriers to define these compartments. Within these bilayers are many proteins involved in bioenergetics and catalysis, topics we first studied in Chapters 5 and 6. We will revisit those topics, along with cell signaling and motility, in later chapters. In the next three chapters, we will see how membranes and membrane transport processes in mitochondria and chloroplasts are

critical for cellular energy production. Especially important are membrane-located electron carriers, proton pumps, and ATP synthases. In Chapter 12, we will again appreciate the importance of membranes as we study intracellular trafficking and secretion using membrane-bound vesicles to carry materials into, within, or out of the cell. In the following chapters, we will see the importance of membranes in signal transduction mechanisms—how cells respond to electrical and chemical messages using ion channels and protein receptors in their membranes. After that, we will study the function of the cytoskeleton, cell motility, muscle contraction, the production of extra-cellular structures, and protein import into organelles. All of these functions involve properly functioning membranes.

PROBLEM SET

More challenging problems are marked with a •.

8-1 True or False? Indicate whether each of the following statements about membrane transport is true (T) or false (F). If false, reword the statement to make it true.

- (a) Facilitated diffusion of a cation occurs only from a compartment of higher concentration to a compartment of lower concentration.
- (b) Active transport is always driven by the hydrolysis of high-energy phosphate bonds.
- (c) The K_{eq} value for the diffusion of polar molecules out of the cell is less than one because membranes are essentially impermeable to such molecules.
- (d) A 0.25 M sucrose solution would not be isotonic for a mammalian cell if the cell had sucrose carrier proteins in its plasma membrane.
- (e) The permeability coefficient for a particular solute is likely to be orders of magnitude lower if a transport protein for that solute is present in the membrane.
- (f) Plasma membranes have few, if any, transport proteins that are specific for phosphorylated compounds.
- (g) Carbon dioxide and bicarbonate anions usually move in the same direction across the plasma membrane of an erythrocyte.
- (h) Treatment of an animal cell with an inhibitor that is specific for the Na^+/K^+ pump is not likely to affect the uptake of glucose by sodium cotransport.

8-2 Telling Them Apart. From the following list of properties, indicate which one(s) can be used to distinguish between each of the following pairs of transport mechanisms.

Transport Mechanisms

- (a) Simple diffusion; facilitated diffusion
- (b) Facilitated diffusion; active transport
- (c) Simple diffusion; active transport
- (d) Direct active transport; indirect active transport
- (e) Symport; antiport
- (f) Uniport; coupled transport
- (g) P-type ATPase; V-type ATPase

Properties

1. Directions in which two transported solutes move
2. Direction the solute moves relative to its concentration gradient or its electrochemical potential
3. Kinetics of solute transport
4. Requirement for metabolic energy
5. Requirement for simultaneous transport of two solutes
6. Intrinsic directionality
7. Competitive inhibition
8. Sensitivity to the inhibitor vanadate

8-3 Mechanisms of Transport. For each of the following statements, answer with a D if the statement is true of simple diffusion, with an F if it is true of facilitated diffusion, and with

an A if it is true of active transport. Any, all, or none (N) of the choices may be appropriate for a given statement.

- (a) Requires the presence of an integral membrane protein.
- (b) Depends primarily on solubility properties of the solute.
- (c) Doubling the concentration gradient of the molecule to be transported will double the rate of transport over a broad range of concentrations.
- (d) Involves proteins called ATPases.
- (e) Work is done during the transport process.
- (f) Applies only to small, nonpolar solutes.
- (g) Applies only to ions.
- (h) Transport can occur in either direction across the membrane, depending on the prevailing concentration gradient.
- (i) $\Delta G^\circ = 0$.
- (j) A Michaelis constant (K_m) can be calculated.

8-4 Discounting the Transverse Carrier Model. At one time, membrane biologists thought that transport proteins might act by binding a solute molecule or ion on one side of the membrane and then diffusing across the membrane to release the solute molecule on the other side. We now know that this transverse carrier model is almost certainly wrong. Suggest two reasons that argue against such a model. One of your reasons should be based on our current understanding of membrane structure and the other on thermodynamic considerations.

8-5 Potassium Ion Transport. Most of the cells of your body pump potassium ions inward to maintain an internal K^+ concentration that is 35 times the external concentration.

- (a) What is ΔG (at 37°C) for the transport of potassium ions into a cell that maintains no membrane potential across its plasma membrane?
- (b) For a nerve cell with a membrane potential of -60 mV, what is ΔG for the inward transport of potassium ions at 37°C?
- (c) For the nerve cell in part b, what is the maximum number of potassium ions that can be pumped inward by the hydrolysis of one ATP molecule if the ATP/ADP ratio in the cell is 5:1 and the inorganic phosphate concentration is 10 mM? (Assume $\Delta G^\circ = -7.3 \text{ kcal/mol}$ for ATP hydrolysis.)

8-6 Ion Gradients and ATP Synthesis. The ion gradients maintained across the plasma membranes of most cells play a significant role in cellular energetics. Ion gradients are often either generated by the hydrolysis of ATP or used to make ATP by the phosphorylation of ADP.

- (a) Cite an example in which ATP is used to generate and maintain an ion gradient. What is another way that an ion gradient can be generated and maintained?
- (b) Cite an example in which an ion gradient is used to make ATP. What is another use for ion gradients?
- (c) Assume that the sodium ion concentration is 12 mM inside a cell and 145 mM outside the cell and that the membrane potential is -90 mV. Can a cell use ATP hydrolysis to drive the outward transport of sodium ions on a 2:1 basis (two sodium ions transported per ATP hydrolyzed) if the

ATP/ADP ratio is 5:1, the inorganic phosphate concentration is 50 mM, and the temperature is 37°C? What about on a 3:1 basis? Explain your answers.

- (d) Assume that a bacterial cell maintains a proton gradient across its plasma membrane such that the pH inside the cell is 8.0 when the outside pH is 7.0. Can the cell use the proton gradient to drive ATP synthesis on a 1:1 basis (one ATP synthesized per proton transported) if the membrane potential is +180 mV, the temperature is 25°C, and the ATP, ADP, and inorganic phosphate concentrations are as in part c? What about on a 1:2 basis? Explain your answers.

8-7 Sodium Ion Transport. A marine protozoan is known to pump sodium ions outward by a simple ATP-driven Na^+ pump that operates independently of potassium ions. The intracellular concentrations of ATP, ADP, and P_i are 20, 2, and 1 mM, respectively, and the membrane potential is -75 mV.

- (a) Assuming that the pump transports three sodium ions outward per molecule of ATP hydrolyzed, what is the lowest internal sodium ion concentration that can be maintained at 25°C when the external sodium ion concentration is 150 mM?
 (b) If you were dealing with an uncharged molecule rather than an ion, would your answer for part a be higher or lower, assuming all other conditions remained the same? Explain.

8-8 The Case of the Acid Stomach. The gastric juice in your stomach has a pH of 2.0. This acidity is due to the secretion of protons into the stomach by the epithelial cells of the gastric mucosa. Epithelial cells have an internal pH of 7.0 and a membrane potential of -70 mV (inside is negative) and function at body temperature (37°C).

- (a) What is the concentration gradient of protons across the epithelial membrane?
 (b) Calculate the free energy change associated with the secretion of 1 mole of protons into gastric juice at 37°C.
 (c) Do you think that proton transport can be driven by ATP hydrolysis at the ratio of one molecule of ATP per proton transported?
 (d) If protons were free to move back into the cell, calculate the membrane potential that would be required to prevent them from doing so.

8-9 Charged or Not: Does It Make a Difference? Many solutes that must move into and out of cells exist in either a protonated or ionized form, or they have functional groups that can be either protonated or ionized. Simple molecules such as CO_2 , H_3PO_4 (phosphoric acid), and NH_3 (ammonia) are in this category, as are organic molecules with carboxylic acid groups, phosphate groups, and/or amino groups.

- (a) Consider ammonia as a simple example of such compounds. What is the charged form of ammonia called? What is its chemical formula?
 (b) Which of these two forms will predominate in a solution with a highly acidic pH? Explain your answer.
 (c) For which of these two forms will the uptake across the plasma membrane of a cell be affected by the concentration gradient of that form on the inside versus the outside of the cell? For which, if either, of these two forms will uptake be affected by the membrane potential of the plasma membrane? Explain your answers.

(d) For a cell that must take up ammonia from its environment, will uptake of the charged form require more or less energy than uptake of the uncharged form, assuming that the cell has a negative membrane potential? Explain your answer.

(e) Instead of ammonia, consider the uptake of acetic acid, CH_3COOH , an important intermediate in several biological pathways. What is the charged form in this case? For which of the two forms will the uptake across the plasma membrane of a cell be affected by the concentration gradient of that form on the inside versus the outside of the cell? For which, if either, of these two forms will uptake be affected by the membrane potential of the plasma membrane? Explain your answers.

(f) For a cell that must take up acetic acid from its environment, will uptake of the charged form require more or less energy than uptake of the uncharged form, assuming that the cell has a negative membrane potential? Explain your answer.

• 8-10 The Calcium Pump of the Sarcoplasmic Reticulum.

Muscle cells use calcium ions to regulate the contractile process. Calcium is both released and taken up by the sarcoplasmic reticulum (SR). Release of calcium from the SR activates muscle contraction, and ATP-driven calcium uptake causes the muscle cell to relax afterward. When muscle tissue is disrupted by homogenization, the SR forms small vesicles called *microsomes* that maintain their ability to take up calcium. In the experiment shown in **Figure 8-15**, a reaction medium was prepared to contain 5 mM ATP and 0.1 M KCl at pH 7.5. An aliquot of SR microsomes containing 1.0 mg protein was added to 1 mL of the reaction mixture, followed by 0.4 mmol of calcium. Two minutes later, a calcium ionophore was added. (An ionophore is a substance that facilitates the movement of an ion across a membrane.) ATPase activity was monitored during the additions, with the results shown in the figure.

- (a) What is the ATPase activity, calculated as micromoles of ATP hydrolyzed per milligram of protein per minute?
 (b) The ATPase is calcium-activated, as shown by the increase in ATP hydrolysis when the calcium was added and the decrease in hydrolysis when all the added calcium was taken up into the vesicles 1 minute after it was added. How many calcium ions are taken up for each ATP hydrolyzed?
 (c) The final addition is an ionophore that carries calcium ions across membranes. Why does ATP hydrolysis begin again?

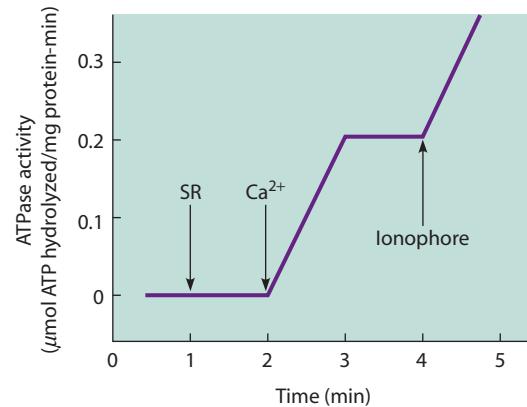

FIGURE 8-15 Calcium Uptake by the Sarcoplasmic Reticulum. See Problem 8-10.

• **8-11 Inverted Vesicles.** An important advance in transport research was the development of methods for making closed membrane vesicles that retain the activity of certain transport systems. One such system uses resealed vesicles from red blood cell membranes, in which the orientation of membrane proteins may be either the same as in the intact cell (right side out) or inverted (inside out). Such vesicles have demonstrable ATP-driven Na^+/K^+ pump activity. By resealing the vesicles in one medium and then placing them in another, it is possible to have ATP, sodium ions, and potassium ions present inside the vesicle, present outside the vesicle, or not present at all.

- (a) Suggest one or two advantages that such vesicles might have compared to intact red blood cells for studying the Na^+/K^+ pump. Can you think of any possible disadvantages?
- (b) For the inverted vesicles, indicate whether each of the following should be present inside the vesicle (I), outside the vesicle (O), or not present at all (N) in order to demonstrate ATP hydrolysis: Na^+ , K^+ , and ATP.

Chemotrophic Energy Metabolism: Glycolysis and Fermentation

As we learned in earlier chapters, cells cannot survive without a source of energy and a source of chemical “building blocks”—the small molecules from which macromolecules such as proteins, nucleic acids, and polysaccharides are synthesized. In many organisms, including you and me, these two requirements are related. The desired energy and small molecules are both present in the food molecules that these organisms produce or ingest.

In this chapter and the next, we will consider how chemotrophs, such as animals and most microorganisms, obtain energy from the food they engulf or ingest, focusing especially on the oxidative breakdown of sugar molecules. Remember that oxidation reactions involve the loss of electrons and hydrogens and release energy. Then, in Chapter 11, we will discuss the process by which phototrophs, such as green plants, algae, and some bacteria, tap the solar radiation that is the ultimate energy source for almost all living organisms. They will use this energy to reduce carbon dioxide (add electrons and hydrogens) in order to produce sugar molecules. Keep in mind that the reactions whereby cells obtain energy also can provide the various small molecules that cells need for synthesis of macromolecules and other cellular constituents.

Metabolic Pathways

When we encountered enzymes in Chapter 6, we considered individual chemical reactions catalyzed by individual enzymes functioning in isolation—but that is not the way cells really operate. To accomplish any major task, a cell requires a series of reactions occurring in an ordered sequence. This, in turn, requires many different enzymes because most enzymes catalyze only a single reaction, and many such reactions are usually needed to accomplish a major biochemical operation.

When we consider all the chemical reactions that occur within a cell, we are talking about **metabolism**

(from the Greek word *metaballein*, meaning “to change”). The overall metabolism of a cell consists, in turn, of many specific **metabolic pathways**, each of which accomplishes a particular task. From a biochemist’s perspective, *life at the cellular level can be defined as a network of integrated and carefully regulated metabolic pathways, each contributing to the sum of activities that a cell must carry out*.

Metabolic pathways are of two general types. Pathways that synthesize cellular components are called **anabolic pathways** (using the Greek prefix *ana-*, meaning “up”), whereas those involved in the breakdown of cellular constituents are called **catabolic pathways** (using the Greek prefix *kata-*, meaning “down”). Anabolic pathways usually involve a substantial increase in molecular order (and therefore a local decrease in entropy) and are *endergonic* (energy-requiring). Polymer synthesis and the biological reduction of carbon dioxide to sugar are examples of anabolic pathways. Often, anabolic pathways synthesize polymers such as starch and glycogen from glucose units in order to store energy for future use. Certain steroid hormones, for example, are called anabolic steroids because they stimulate the synthesis of muscle proteins from amino acids.

Catabolic pathways, by contrast, are degradative pathways that typically involve a decrease in molecular order (increase in entropy) and are *exergonic* (energy-liberating). These reactions often involve hydrolysis of macromolecules or biological oxidations. Catabolic pathways play two roles in cells: They release the free energy needed to drive cellular functions, and they give rise to the small organic molecules, or *metabolites*, that are the building blocks for biosynthesis. However, a catabolic pathway is not simply the reverse of the corresponding anabolic pathway. For example, the catabolic pathway for glucose degradation and the anabolic pathway for glucose synthesis use slightly different enzymes and intermediates.

As we will see shortly, catabolism can be carried out either in the presence or absence of oxygen (i.e., under

either *aerobic* or *anaerobic* conditions). The energy yield per glucose molecule is much greater in the presence of oxygen. However, anaerobic catabolism is also important, not only for organisms in environments that are always devoid of oxygen but also for organisms and cells that are temporarily deprived of oxygen.

ATP: The Universal Energy Coupler

The anabolic reactions of cells are responsible for growth and repair processes, whereas catabolic reactions release the energy needed to drive the anabolic reactions and to carry out other kinds of cellular work. The efficient linking, or *coupling*, of energy-yielding processes to energy-requiring processes is therefore crucial to cell function. This coupling is made possible by specific kinds of molecules that conserve the energy derived from exergonic reactions and release it again when and where energy is needed.

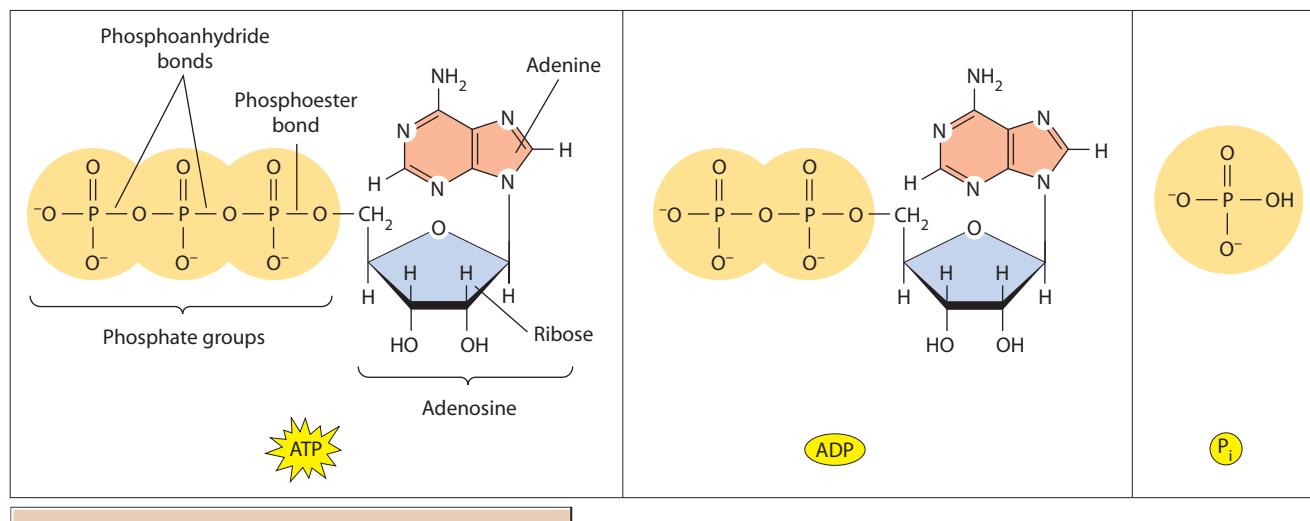

In virtually all cells, the molecule most commonly used as an energy intermediate is the phosphorylated compound **adenosine triphosphate (ATP)**. ATP is, in other words, the primary energy “currency” of the biological world. Keep in mind, however, that ATP synthesis is not the only way that cells store chemical energy. Other high-energy molecules, such as GTP and creatine phosphate, store chemical energy that can be converted to ATP. In addition, chemical energy is stored as *reduced coenzymes*

such as NADH that are a source of reducing power in cells. These molecules are very important in shuttling energy between different metabolic pathways and processes in cells. Because ATP is involved in most cellular energy transactions, it is essential that we first understand its structure and function and appreciate the properties that make this molecule so suitable for its role as the universal energy coupler.

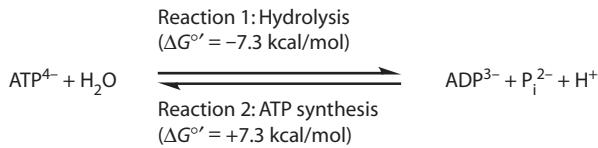

ATP Contains Two Energy-Rich Phosphoanhydride Bonds

As we learned in Chapter 3, ATP is a complex molecule containing the aromatic base adenine, the five-carbon sugar ribose, and a chain of three phosphate groups. The phosphate groups are linked to each other by **phosphoanhydride bonds** and to the ribose by a **phosphoester bond**, as shown for the ATP molecule in **Figure 9–1**. The compound formed by linking adenine and ribose is called **adenosine**. Adenosine may occur in the cell in the unphosphorylated form or with one, two, or three phosphates attached to carbon atom 5 of the ribose, forming **adenosine monophosphate (AMP)**, **diphosphate (ADP)**, and **triphosphate (ATP)**, respectively.

The ATP molecule serves well as an intermediate in cellular energy metabolism because energy is released when ATP undergoes *hydrolysis*—water is used to break the phosphoanhydride bond that links the third (outermost)

(a) Structures of ATP, ADP, and inorganic phosphate (at pH 7)

(b) Balanced chemical equation for ATP hydrolysis and synthesis

FIGURE 9–1 ATP Hydrolysis and Synthesis. (a) ATP consists of adenosine (adenine + ribose) plus three phosphate groups attached to carbon atom 5 of the ribose. (b) Reaction 1: ATP hydrolysis to ADP and inorganic phosphate (P_i) is highly exergonic, with a standard free energy change of -7.3 kcal/mol . Reaction 2: ATP synthesis by phosphorylation of ADP is highly endergonic, with a standard free energy change of $+7.3 \text{ kcal/mol}$.

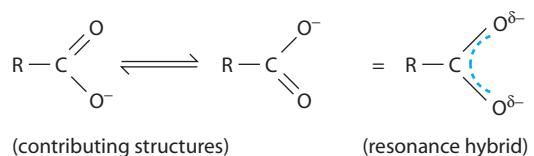

phosphate to the second. Two products are formed: The terminal phosphate receives an —OH from the water molecule and is released as inorganic phosphate (HPO_4^{2-} , often written as P_i), and the resulting ADP molecule gets an —H and immediately loses a proton by ionization. Thus, the hydrolysis of ATP to form ADP and P_i is highly exergonic, with a standard free energy change (ΔG°) of -7.3 kcal/mol (Figure 9-1, Reaction 1). The reverse reaction, whereby ATP is synthesized from ADP and P_i with the loss of a water molecule by condensation, is correspondingly endergonic, with a ΔG° of $+7.3 \text{ kcal/mol}$ (Figure 9-1, Reaction 2). As you can see, energy is required to drive ATP synthesis from ADP and P_i , and energy is released upon ATP hydrolysis.

Biochemists sometimes refer to bonds such as the phosphoanhydride bonds of ATP as “high-energy” or “energy-rich” bonds, a very useful convention introduced in 1941 by Fritz Lipmann, a leading bioenergetics researcher of the time. However, these terms need to be understood correctly to avoid the erroneous impression that the bond somehow contains energy that can be released. All chemical bonds *require* energy to be broken and *release* energy when they form. What we really mean by “energy-rich bond” is that free energy is released when the bond is hydrolyzed. The energy is therefore a characteristic of the reaction the molecule is involved in and not of a particular bond within that molecule. Thus, to call ATP or any other molecule a “high-energy or energy-rich compound” should always be understood as a shorthand way of saying that the hydrolysis of one or more of its bonds is highly exergonic.

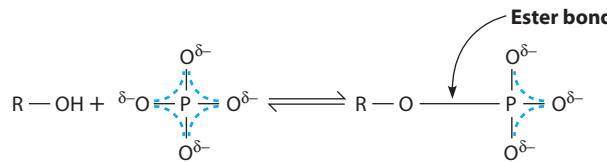

ATP Hydrolysis Is Highly Exergonic Because of Charge Repulsion and Resonance Stabilization

What is it about the ATP molecule that makes the hydrolysis of its phosphoanhydride bonds so exergonic? The answer to this question has three parts: Hydrolysis of ATP to ADP and P_i is exergonic because of *charge repulsion* between the adjacent negatively charged phosphate groups, because of *resonance stabilization* of both products of hydrolysis, and because of their *increased entropy* and solubility.

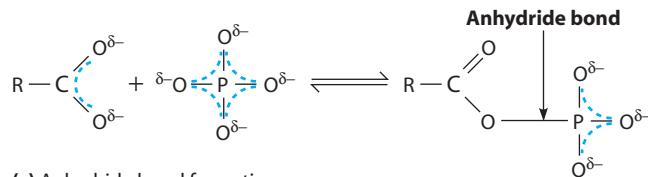

Charge repulsion is easy to understand. By way of analogy, imagine holding two magnets together with like poles touching. The like poles repel each other, and you need to make an effort (i.e., you need to put energy into the system) to force them together. If you let go, the magnets spring apart, releasing the energy. Now consider the three phosphate groups of ATP. As Figure 9-1 shows, each group bears at least one negative charge due to its ionization at the near neutral pH of the cell. These negative charges tend to repel one another, thereby straining the covalent bond linking the phosphate groups together. Similarly, ATP synthesis requires the joining of two negatively charged molecules (ADP^{3-} and P_i^{2-}) that naturally

(a) Resonance stabilization of the carboxylate group

(b) Ester bond formation

(c) Anhydride bond formation

FIGURE 9-2 Decreased Resonance Stabilization of the Carboxyl and Phosphate Groups Following Bond Formation. Resonance stabilization due to electron delocalization (blue dashed lines) is an important feature of both the carboxylate group in (a) and the phosphate groups in (b) and (c). Creation of either (b) an ester bond or (c) an anhydride bond (by removal of water) decreases the opportunity for electron delocalization. As a result, the ester or anhydride product is a higher-energy compound than the reactants, and energy will be released when the bond is broken by hydrolysis.

repel each other, thus requiring an input of energy to overcome this repulsion.

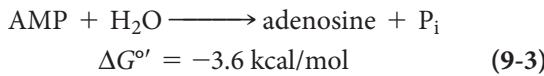

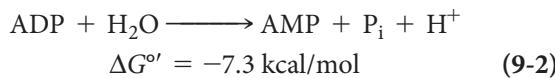

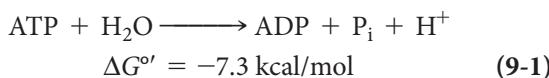

A second important contribution to ATP bond energy is **resonance stabilization**. Although the carboxylate group is formally written with one $\text{C}=\text{O}$ double bond and one $\text{C}\text{—O}$ single bond, it actually has one electron pair that is *delocalized* (equally distributed) over both of the C bonds to oxygen. The true structure of the carboxylate group is actually an average of the two contributing structures shown in **Figure 9-2a** and is called a **resonance hybrid**. Each $\text{C}\text{—O}$ bond is the equivalent of one and a half bonds, and each O atom has only a partial negative charge (represented by the Greek letter δ). When electrons are delocalized in this way, a molecule is in its most stable (lowest-energy) configuration and is said to be *resonance-stabilized*.

Similarly, the phosphate ion is resonance-stabilized because the extra electron pair formally shown as part of a $\text{P}=\text{O}$ double bond is delocalized over all four O atoms adjacent to the central P. When a phosphoester bond is formed between a phosphate ion and an alcohol group, the extra electrons are only delocalized over three O atoms (Figure 9-2b). The resulting molecule is less resonance stabilized and thus has higher energy. A similar decrease

in electron delocalization during anhydride bond formation (Figure 9-2c) also results in a higher energy product.

A third important factor contributing to the exergonic nature of ATP hydrolysis is the overall increase in entropy as a phosphate group is removed from ATP and is no longer fixed in position. The spatial randomization of the ADP and phosphate decreases their free energy and makes the reaction more exergonic. Although a water molecule is added during hydrolysis (a decrease of entropy), it loses a proton, which also has increased entropy as it is randomized in solution. In addition, the ADP and phosphate become more soluble because they are more highly hydrated, and the increased interactions with water molecules lead to a decrease in free energy, adding to the exergonic nature of ATP hydrolysis.

For esters, only a moderate amount of energy is liberated upon hydrolysis, while for anhydrides, the hydrolysis reaction is highly exergonic. In addition to increased resonance stabilization, both products of anhydride hydrolysis are charged and therefore repel each other, which is not the case with ester hydrolysis. Hydrolysis of anhydride and phosphoanhydride bonds releases roughly twice the amount of free energy as does hydrolysis of ester and phosphoester bonds. ATP illustrates this difference well: Hydrolysis of either of the phosphoanhydride bonds that link the second and third phosphate groups to the rest of the molecule has a standard free energy change of about -7.3 kcal/mol , whereas hydrolysis of the phosphoester bond that links the first (innermost) phosphate group to the ribose has a ΔG° of only about -3.6 kcal/mol :

Thus, ATP and ADP are both “higher-energy compounds” than AMP is, to use the shorthand of biochemists.

In fact, because the standard ΔG° value of -7.3 kcal/mol is based on equal concentrations of ATP and ADP (1 M), it typically underestimates the actual free energy change associated with the hydrolysis of ATP to ADP under most biological conditions, in which the concentration of ATP is greater. As we learned in Chapter 5, the actual free energy change, $\Delta G'$, depends on the prevailing concentrations of reactants and products (see Equation 5-22). For the hydrolysis of ATP (Reaction 9-1), $\Delta G'$ is calculated as

$$\Delta G' = \Delta G^\circ + RT \ln \frac{[\text{ADP}][\text{P}_i]}{[\text{ATP}]} \quad (9-4)$$

Table 9-1

Standard Free Energies of Hydrolysis for Phosphorylated Compounds Involved in Energy Metabolism

Phosphorylated Compound and Its Hydrolysis Reaction	ΔG° (kcal/mol)
Phosphoenolpyruvate (PEP)	
$+ \text{H}_2\text{O} \longrightarrow \text{pyruvate} + \text{P}_i$	-14.8
1,3-bisphosphoglycerate	
$+ \text{H}_2\text{O} \longrightarrow 3\text{-phosphoglycerate} + \text{P}_i$	-11.8^1
Phosphocreatine	
$+ \text{H}_2\text{O} \longrightarrow \text{creatine} + \text{P}_i$	-10.3
Adenosine triphosphate (ATP)	
$+ \text{H}_2\text{O} \longrightarrow \text{adenosine diphosphate} + \text{P}_i$	-7.3
Glucose-1-phosphate	
$+ \text{H}_2\text{O} \longrightarrow \text{glucose} + \text{P}_i$	-5.0
Glucose-6-phosphate	
$+ \text{H}_2\text{O} \longrightarrow \text{glucose} + \text{P}_i$	-3.3
Glycerol phosphate	
$+ \text{H}_2\text{O} \longrightarrow \text{glycerol} + \text{P}_i$	-2.2

¹The ΔG° value for 1,3-bisphosphoglycerate is for the hydrolysis of the phosphoanhydride bond on carbon atom 1.

In most cells, the ATP/ADP ratio is significantly greater than 1:1, often in the range of about 5:1. As a result, the term $\ln([\text{ADP}][\text{P}_i]/[\text{ATP}])$ is negative, and $\Delta G'$ is therefore more negative than -7.3 kcal/mol , usually in the range of -10 to -14 kcal/mol .

ATP Is an Important Intermediate in Cellular Energy Metabolism

ATP occupies an intermediate position in the overall spectrum of energy-rich phosphorylated compounds in the cell. Some of the more common phosphorylated intermediates in cellular energy metabolism are ranked according to their ΔG° values in **Table 9-1**. The values are negative, so the compounds closest to the top of the table release the most energy upon hydrolysis of the phosphate group.

This means that, under standard conditions, a compound is capable of exergonically phosphorylating any compound below it but none of the compounds above it. Thus, ATP can be formed from ADP by the transfer of a phosphate group from phosphoenolpyruvate (PEP) but not from glucose-6-phosphate, as **Figure 9-3** illustrates. Similarly, ATP can be used to phosphorylate glucose but not pyruvate. Reactions 9-5 and 9-6 have negative ΔG° values, which we will designate as $\Delta G_{\text{transfer}}^\circ$ values to emphasize that they represent the standard free energy change that accompanies the transfer of a phosphate group from a donor to an acceptor molecule. $\Delta G_{\text{transfer}}^\circ$ values

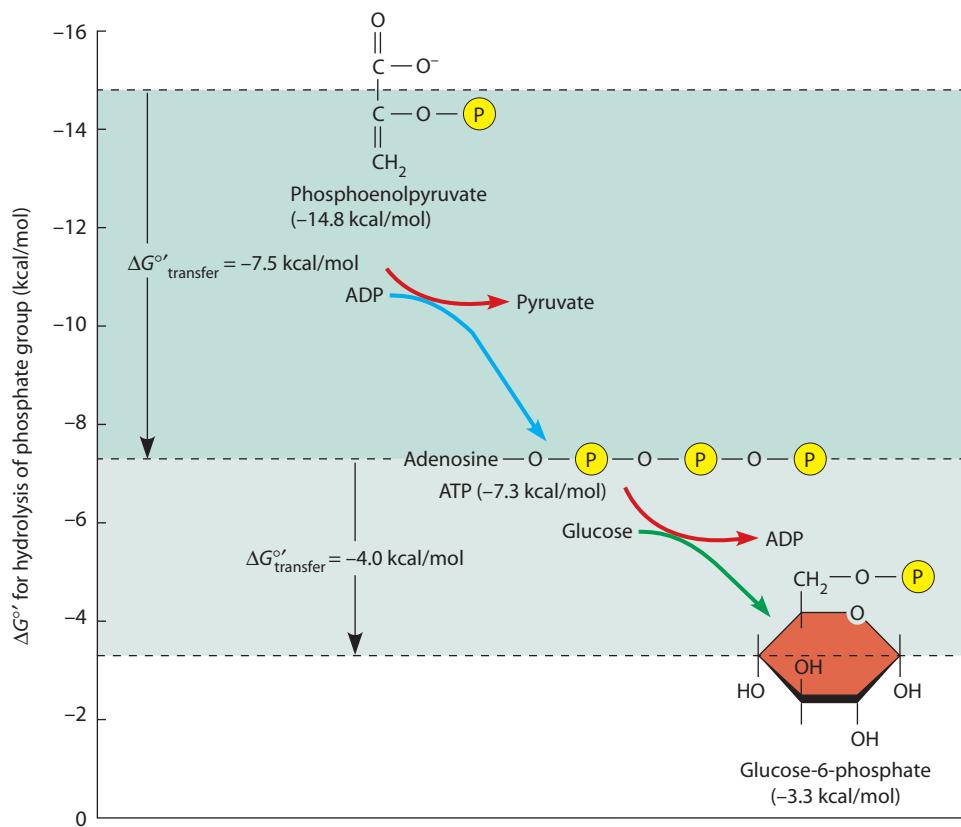

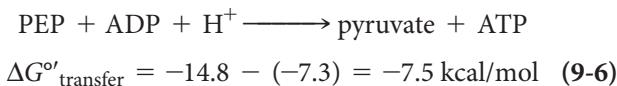

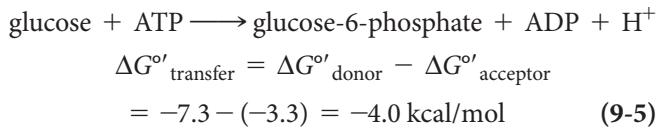

FIGURE 9-3 Examples of Exergonic Transfer of Phosphate Groups. These examples are based on the $\Delta G^{\circ'}$ values for the hydrolysis of the compounds shown in Table 9-1. For the hydrolysis of phosphate groups, phosphoenolpyruvate (PEP; -14.8 kcal/mol) is considered a high-energy compound, ATP (-7.3 kcal/mol) an intermediate-energy compound, and glucose-6-phosphate (-3.3 kcal/mol) a low-energy compound. PEP can therefore transfer its phosphate group exergonically onto ADP to form ATP [$\Delta G^{\circ'}_{\text{transfer}} = \Delta G^{\circ'}_{\text{donor}} - \Delta G^{\circ'}_{\text{acceptor}} = -14.8 - (-7.3) = -7.5 \text{ kcal/mol}$], and ATP can be used to phosphorylate glucose exergonically [$\Delta G^{\circ'}_{\text{transfer}} = -7.3 - (-3.3) = -4.0 \text{ kcal/mol}$], but the reverse reactions are not possible under standard conditions. In fact, the $\Delta G^{\circ'}$ values for these transfers are so highly negative that both reactions are irreversible under typical cellular conditions.

can be predicted from Table 9-1 and calculated as shown:

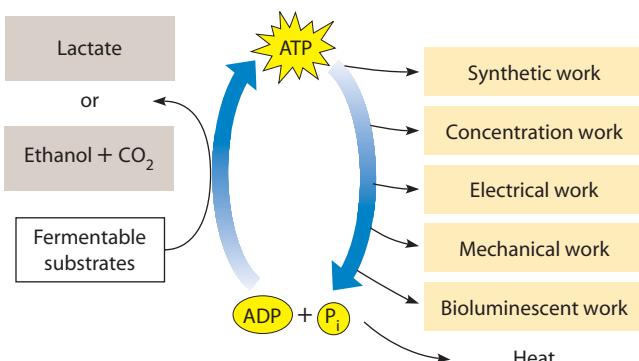

Reactions such as 9-5 and 9-6 that involve the movement of a chemical group from one molecule to another are called **group transfer reactions**. Group transfer reactions represent one of the most common processes in cellular metabolism, and the phosphate group is one of the most frequently transferred groups, especially in energy metabolism.

The most important point to understand from Table 9-1 and Figure 9-3 is that the ATP/ADP pair occupies a crucial *intermediate* position in terms of bond energies. This means that ATP can serve as a phosphate *donor* in some biological reactions and that its dephosphorylated form, ADP, can serve as a phosphate *acceptor* in other reactions because there are compounds both above and below the ATP/ADP pair in energy.

In summary, the ATP/ADP pair represents a reversible means of conserving, transferring, and releasing energy within the cell (Figure 9-4). As catabolic processes occur in the cell, whether anaerobically (Figure 9-4a) or aerobically (Figure 9-4b), the energy-liberating reactions in the sequence are coupled to the ATP/ADP system such that the available free energy drives the formation of ATP from ADP. The free energy released upon hydrolysis of ATP then provides the driving force for the many processes (such as biosynthesis, active transport, charge separation, and muscle contraction) that are essential to life and require the input of energy.

(a) Anaerobic conditions. Under anaerobic (no oxygen) or hypoxic (oxygen-deficient) conditions, a modest amount of ATP is generated by fermentation. Lactate is the most common end-product in some organisms, and ethanol plus carbon dioxide are the most common end-products in other organisms.

(b) Aerobic conditions. In the presence of oxygen, ATP is generated by aerobic respiration as oxidizable nutrients are catabolized completely to carbon dioxide and water. Aerobic respiration yields approximately 20 times more ATP per glucose molecule than does anaerobic fermentation.

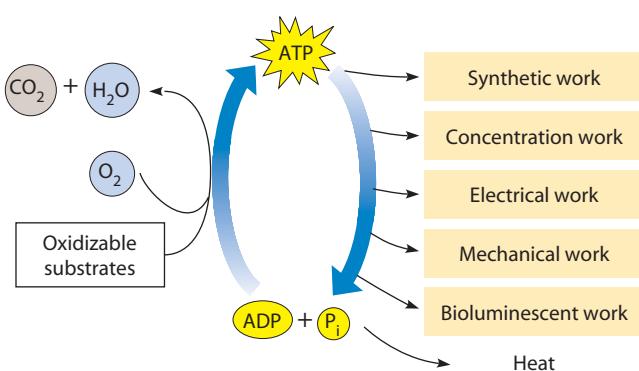

FIGURE 9-4 The ATP/ADP System as a Means of Conserving and Releasing Energy Within the Cell. ATP is generated during (a) anaerobic conditions or (b) aerobic conditions by the oxidative catabolism of nutrients (left side) and is used to do cellular work (right side).

Chemotrophic Energy Metabolism

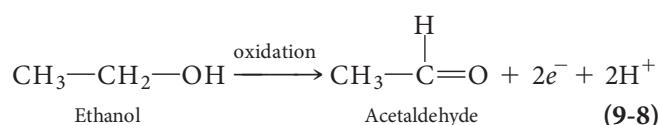

Now we have the essential concepts in hand to take up the main theme of this chapter and the next. We are ready, in other words, to discuss **chemotrophic energy metabolism**—the reactions and pathways by which cells catabolize nutrients and conserve as ATP some of the free energy that is released in this breakdown. Or, to put it more personally, we will be looking at the specific metabolic processes by which the cells of your own body make use of the food you eat to meet your energy needs. We begin our discussion by considering *oxidation* because much of chemotrophic energy metabolism involves energy-yielding oxidative reactions.

Biological Oxidations Usually Involve the Removal of Both Electrons and Protons and Are Highly Exergonic

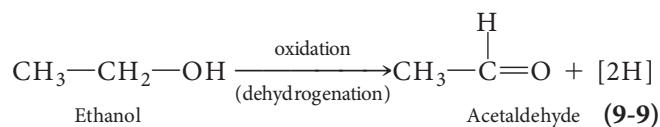

To say that nutrients such as carbohydrates, fats, or proteins are sources of energy for cells means that these are oxidizable organic compounds and that their oxidation is highly exergonic. Recall from chemistry that **oxidation** is the removal of electrons. Thus, for example, a ferrous ion (Fe^{2+}) is oxidizable because it readily gives up an electron as it is converted to a ferric ion (Fe^{3+}):

The only difference in biological chemistry is that the oxidation of organic molecules frequently involves the removal not just of electrons but of hydrogen ions (protons) as well, so that the process is often also one of **dehydrogenation**. Consider, for example, the oxidation of ethanol to the corresponding aldehyde:

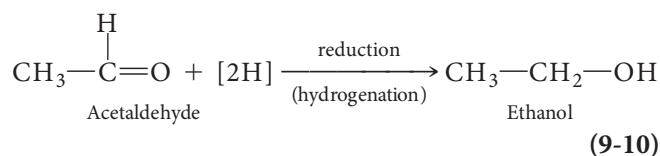

Electrons are removed, so this is clearly an oxidation. But protons are liberated as well, and an electron plus a proton is the equivalent of a hydrogen atom. Therefore what happens, in effect, is the removal of the equivalent of two hydrogen atoms:

Thus, for cellular reactions involving organic molecules, oxidation is almost always manifested as a dehydrogenation reaction. Many of the enzymes that catalyze oxidative reactions in cells are in fact called *dehydrogenases*.

None of the preceding oxidation reactions can take place in isolation, of course; the electrons must be transferred to another molecule, which is *reduced* in the process. **Reduction**, the opposite of oxidation, is defined as the addition of electrons and is an endergonic process. We will soon see that reduction of coenzymes is an important way that cells store chemical energy as reducing power. In biological reductions, as with oxidations, the electrons transferred are frequently accompanied by protons. The overall reaction is therefore a **hydrogenation**:

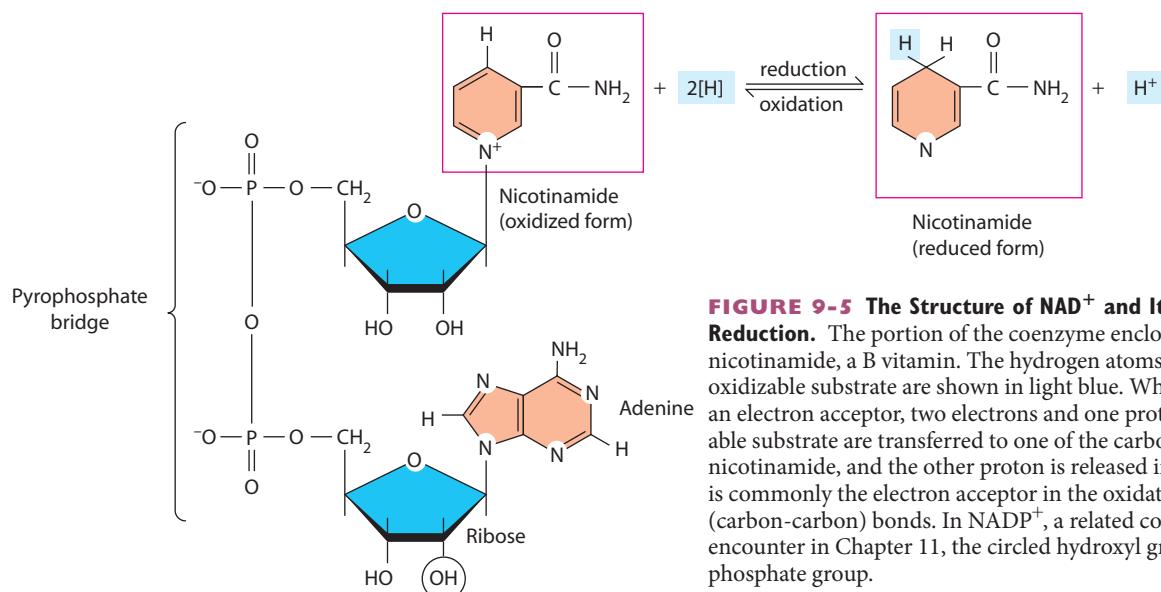

FIGURE 9-5 The Structure of NAD⁺ and Its Oxidation and Reduction. The portion of the coenzyme enclosed in the red box is nicotinamide, a B vitamin. The hydrogen atoms derived from an oxidizable substrate are shown in light blue. When NAD⁺ is used as an electron acceptor, two electrons and one proton from the oxidizable substrate are transferred to one of the carbon atoms of nicotinamide, and the other proton is released into solution. NAD⁺ is commonly the electron acceptor in the oxidation of C—C (carbon-carbon) bonds. In NADP⁺, a related coenzyme we will encounter in Chapter 11, the circled hydroxyl group is replaced by a phosphate group.

Reactions 9-9 and 9-10 also illustrate the general feature that biological oxidation-reduction reactions almost always involve *two-electron* (and therefore two-proton) transfers.

As written, Reactions 9-9 and 9-10 are only *half reactions*, representing an oxidation and a reduction event, respectively. In real reactions, however, *oxidation and reduction always take place simultaneously*. Any time an oxidation occurs, a reduction must occur as well because the electrons (and protons) removed from one molecule must be added to another molecule. The brackets around the 2H in Reactions 9-9 and 9-10 are meant to show that hydrogen atoms are never actually released into solution but are instead transferred to another molecule.

Coenzymes Such as NAD⁺ Serve as Electron Acceptors in Biological Oxidations

In most biological oxidations, electrons and hydrogens removed from the substrate being oxidized are transferred to one of several **coenzymes**. In general, coenzymes are small molecules that function along with enzymes (hence the name), usually by serving as carriers of electrons or small functional groups. As we will see shortly, coenzymes are not consumed but are recycled within the cell, so the relatively low intracellular concentration of a given coenzyme is adequate to meet the needs of the cell.

The most common coenzyme involved in energy metabolism is **nicotinamide adenine dinucleotide NAD⁺**. Its structure is shown in **Figure 9-5**. Despite its formidable name and structure, its function is straightforward: NAD⁺ serves as an electron acceptor by adding two electrons and one proton to its aromatic ring, thereby generating the reduced form, NADH, plus a proton:

As a nutritional note, the nicotinamide of NAD⁺ is a derivative of *niacin*, which we recognize as a *B vitamin*—one of a family of water-soluble compounds essential in the diet of humans and other vertebrates unable to synthesize these compounds for themselves. In Chapter 10, we will meet FAD and CoA, two other coenzymes that also have B vitamin derivatives as part of their structures. It is precisely because these vitamins are components of indispensable coenzymes that they are essential in the diet of any organism that cannot manufacture them. Also, they are required only in small amounts because they are not consumed during the reactions but are recycled as they are alternatively reduced and oxidized.

Most Chemotrophs Meet Their Energy Needs by Oxidizing Organic Food Molecules

We are interested in oxidation because it is the means by which chemotrophs such as humans meet their energy needs. Many different kinds of substances serve as substrates for biological oxidation. For example, a wide variety of microorganisms can use inorganic compounds such as hydrogen gas or reduced forms of iron, sulfur, or nitrogen as their energy sources. These organisms, which utilize rather specialized oxidative pathways, play important roles in the geochemical cycling of nutrients in the biosphere. They also produce a significant amount of biomass—by some estimates, 50% as much as global plant production—and they are important food sources for numerous other organisms in the food chain. However, we and most other chemotrophs depend on organic food molecules as oxidizable substrates, namely, carbohydrates, fats, and proteins. Keep in mind that oxidation of these organic food molecules produces energy for the cell as both ATP and reduced coenzymes.

Glucose Is One of the Most Important Oxidizable Substrates in Energy Metabolism

To simplify our discussion initially and to provide a unifying metabolic theme, we will concentrate on the biological oxidation of the six-carbon sugar **glucose** ($C_6H_{12}O_6$). Glucose is a good choice for several reasons. In many vertebrates, including humans, glucose is the main sugar in the blood and hence the main energy source for most of the cells in the body. Blood glucose comes primarily from dietary carbohydrates such as sucrose or starch and from the breakdown of stored glycogen (see Figures 3-21 to 3-24). Current guidelines recommend a diet of approximately 50% carbohydrate, 30% lipid, and 20% protein. Glucose is therefore an especially important molecule for you personally.

Glucose is also important to plants because it is the monosaccharide released upon starch breakdown. In addition, glucose makes up one-half of the disaccharide sucrose (glucose + fructose), the major sugar in the vascular system of most plants. Moreover, the catabolism of most other energy-rich substances in plants, animals, and microorganisms alike begins with their conversion into one of the intermediates in the pathway for glucose catabolism. Rather than looking at the fate of a single compound, then, we are considering a metabolic pathway that is at the very heart of chemotrophic energy metabolism.

The Oxidation of Glucose Is Highly Exergonic

Glucose is a good potential source of energy because its oxidation is a highly exergonic process, with a ΔG° of -686 kcal/mol for the complete conversion of glucose to carbon dioxide and water using oxygen as the *final electron acceptor*:

As a thermodynamic parameter, ΔG° is unaffected by the route from substrates to products. Therefore, it will have the same value whether the oxidation is by direct combustion, with all of the energy released as heat, or by biological oxidation, with some of the energy conserved as ATP. Thus, oxidation of the sugar molecules in a marshmallow will release the same amount of free energy whether you burn the marshmallow over a campfire or eat it and catabolize the sugar molecules in your body. Biologically, however, the distinction is critical: *Uncontrolled combustion occurs at temperatures that are incompatible with life, and most of the free energy is lost as heat. Biological oxidations involve enzyme-catalyzed reactions that occur without significant temperature changes, and much of the free energy is conserved in chemical form as ATP.*

Glucose Catabolism Yields Much More Energy in the Presence of Oxygen than in Its Absence

Access to the full 686 kcal/mol of free energy in glucose is possible only if glucose is completely oxidized to carbon dioxide and water. Even then, because no energy conver-

sion process is 100% efficient, only part of the energy can be recovered. The complete oxidation of glucose (or other organic nutrients such as proteins and lipids) to carbon dioxide and water in the presence of oxygen is called *aerobic respiration*, a complex, multistep process we will discuss in detail in Chapter 10. Many organisms, typically bacteria, can carry out *anaerobic respiration*, using inorganic electron acceptors other than oxygen. Examples of alternative acceptors include elemental sulfur (S), protons (H^+), and ferric ions (Fe^{3+}).

Even in the absence or scarcity of oxygen or other inorganic electron acceptors, most organisms can still extract limited amounts of energy from the partial oxidation of glucose but with lower energy yields per glucose molecule. They do so by means of *glycolysis*, a pathway that does not require oxygen. Instead, electrons that are removed during glucose oxidation are returned to an organic molecule later in the same pathway. Such an anaerobic process is called *fermentation* and is identified in terms of the principal end-product. In some animal cells and many bacteria, the end-product is lactate, so the process of anaerobic glucose catabolism is called *lactate fermentation*. In most plant cells and in microorganisms such as yeast, the process is termed *alcoholic fermentation* because the end-product is ethanol, an alcohol plus carbon dioxide.

Based on Their Need for Oxygen, Organisms Are Aerobic, Anaerobic, or Facultative

Organisms can be classified in terms of their need for and use of oxygen as an electron acceptor in energy metabolism. Most organisms we see on a daily basis have an absolute requirement for oxygen and are called **obligate aerobes**. You look at such an organism every time you look in the mirror. On the other hand, some organisms, including many bacteria, cannot use oxygen as an electron acceptor and are called **obligate anaerobes**. In fact, oxygen is toxic to these organisms. Not surprisingly, such organisms occupy environments from which oxygen is excluded, such as deep puncture wounds or the sludge at the bottoms of ponds. Most strict anaerobes are bacteria, including organisms responsible for gangrene, food poisoning, and methane production.

Facultative organisms can function under either aerobic or anaerobic conditions. Given the availability of oxygen, most facultative organisms carry out the full aerobic respiratory process. However, they can switch to anaerobic respiration or fermentation if oxygen is limiting or absent. Many bacteria and fungi are facultative organisms, as are most molluscs and annelids (worms). Some cells or tissues of otherwise aerobic organisms can function in the temporary absence or scarcity of oxygen if required to do so. Your skeletal muscle cells are an example; they normally function aerobically but switch to lactate fermentation whenever the oxygen supply becomes limiting—during periods of prolonged or strenuous exercise, for example.

The rest of this chapter is devoted mainly to exploring the anaerobic generation of ATP by the fermentation of glucose. Aerobic energy metabolism then becomes the focus of the next chapter. We will consider fermentation processes first because the glycolytic pathway is common to both fermentation and aerobic respiration. By beginning with fermentation, we will be considering the ways that energy can be extracted from glucose without net oxidation. We will also be laying the foundation for the aerobic processes of the next chapter.

Glycolysis and Fermentation: ATP Generation Without the Involvement of Oxygen

Whether it is an obligate or facultative anaerobe, any organism or cell that obtains its energy using fermentation carries out energy-yielding oxidative reactions without using oxygen as an electron acceptor. The six-carbon glucose molecule is split into two three-carbon molecules, each of which is then partially oxidized by a reaction sequence that is sufficiently exergonic to generate two ATP molecules per molecule of glucose fermented. For most cells, this is the maximum possible energy yield that can be achieved without access to oxygen or to an alternative electron acceptor. However, there are exceptions to this limit. Certain microorganisms can get up to five ATP molecules per glucose by using specialized enzyme systems. Also, some plants and animals that are adapted to

anoxia (oxygen deprivation) can produce more than two ATP molecules per glucose.

Glycolysis Generates ATP by Catabolizing Glucose to Pyruvate

The process of **glycolysis**, also called the **glycolytic pathway**, is a ten-step reaction sequence that converts one molecule of glucose into two molecules of pyruvate, a three-carbon compound. During the partial oxidation of glucose to pyruvate in glycolysis, energy and reducing power are conserved in the form of ATP and NADH, respectively. An overview of the three major phases of glycolysis is shown in **Figure 9-6**, and the detailed pathway is shown in **Figure 9-7**. Glycolysis is common to both aerobic and anaerobic glucose metabolism and is present in virtually all organisms. In most cells, these enzymes occur in the cytosol. In some parasitic protozoans called trypanosomes, however, the first seven enzymes are compartmentalized in membrane-bounded organelles called *glycosomes*.

Historically, the glycolytic pathway was the first major metabolic sequence to be elucidated. Most of the definitive work was done in the 1930s by the German biochemists Gustav Embden, Otto Meyerhof, and Otto Warburg. In fact, an alternative name for the glycolytic pathway is the *Emden–Meyerhof pathway*.

Glycolysis in Overview. In the absence of oxygen, glycolysis leads to fermentation. In the presence of oxygen, glycolysis leads to aerobic respiration, the subject of

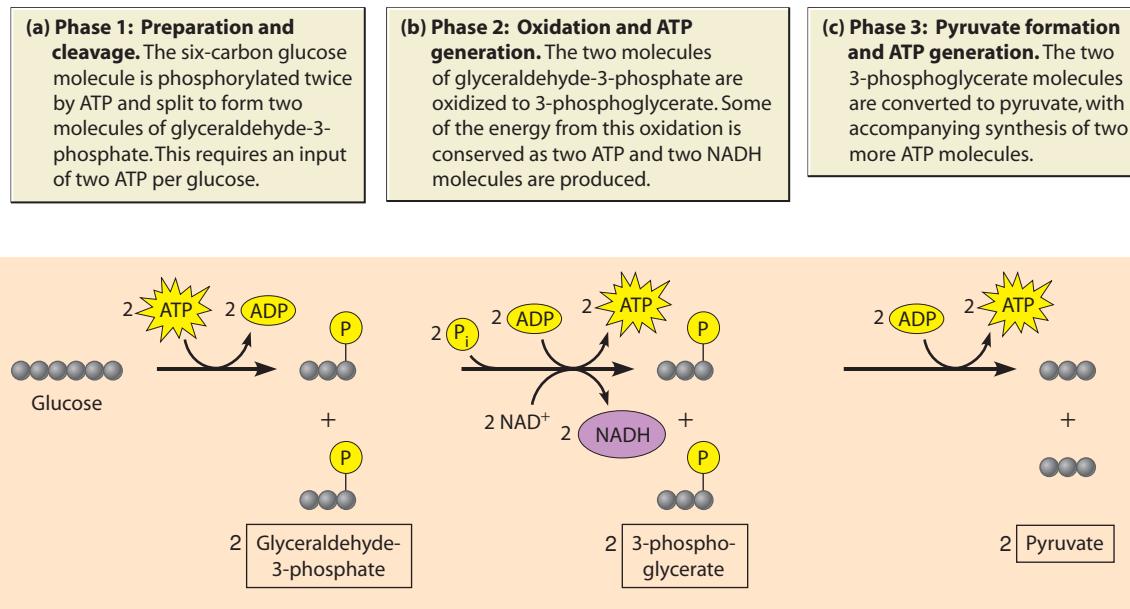

FIGURE 9-6 An Overview of the Glycolytic Pathway. During glycolysis, one molecule of glucose is split and partly oxidized, generating two molecules of pyruvate. In the process, energy is conserved as a net gain of two molecules of ATP and two molecules of NADH. This ten-step process occurs in three main phases (a–c), as shown above. Simplified structures show only carbon atoms (gray) and phosphate groups (yellow).

[ACTIVITIES](http://www.thecellplace.com) www.thecellplace.com Glycolysis

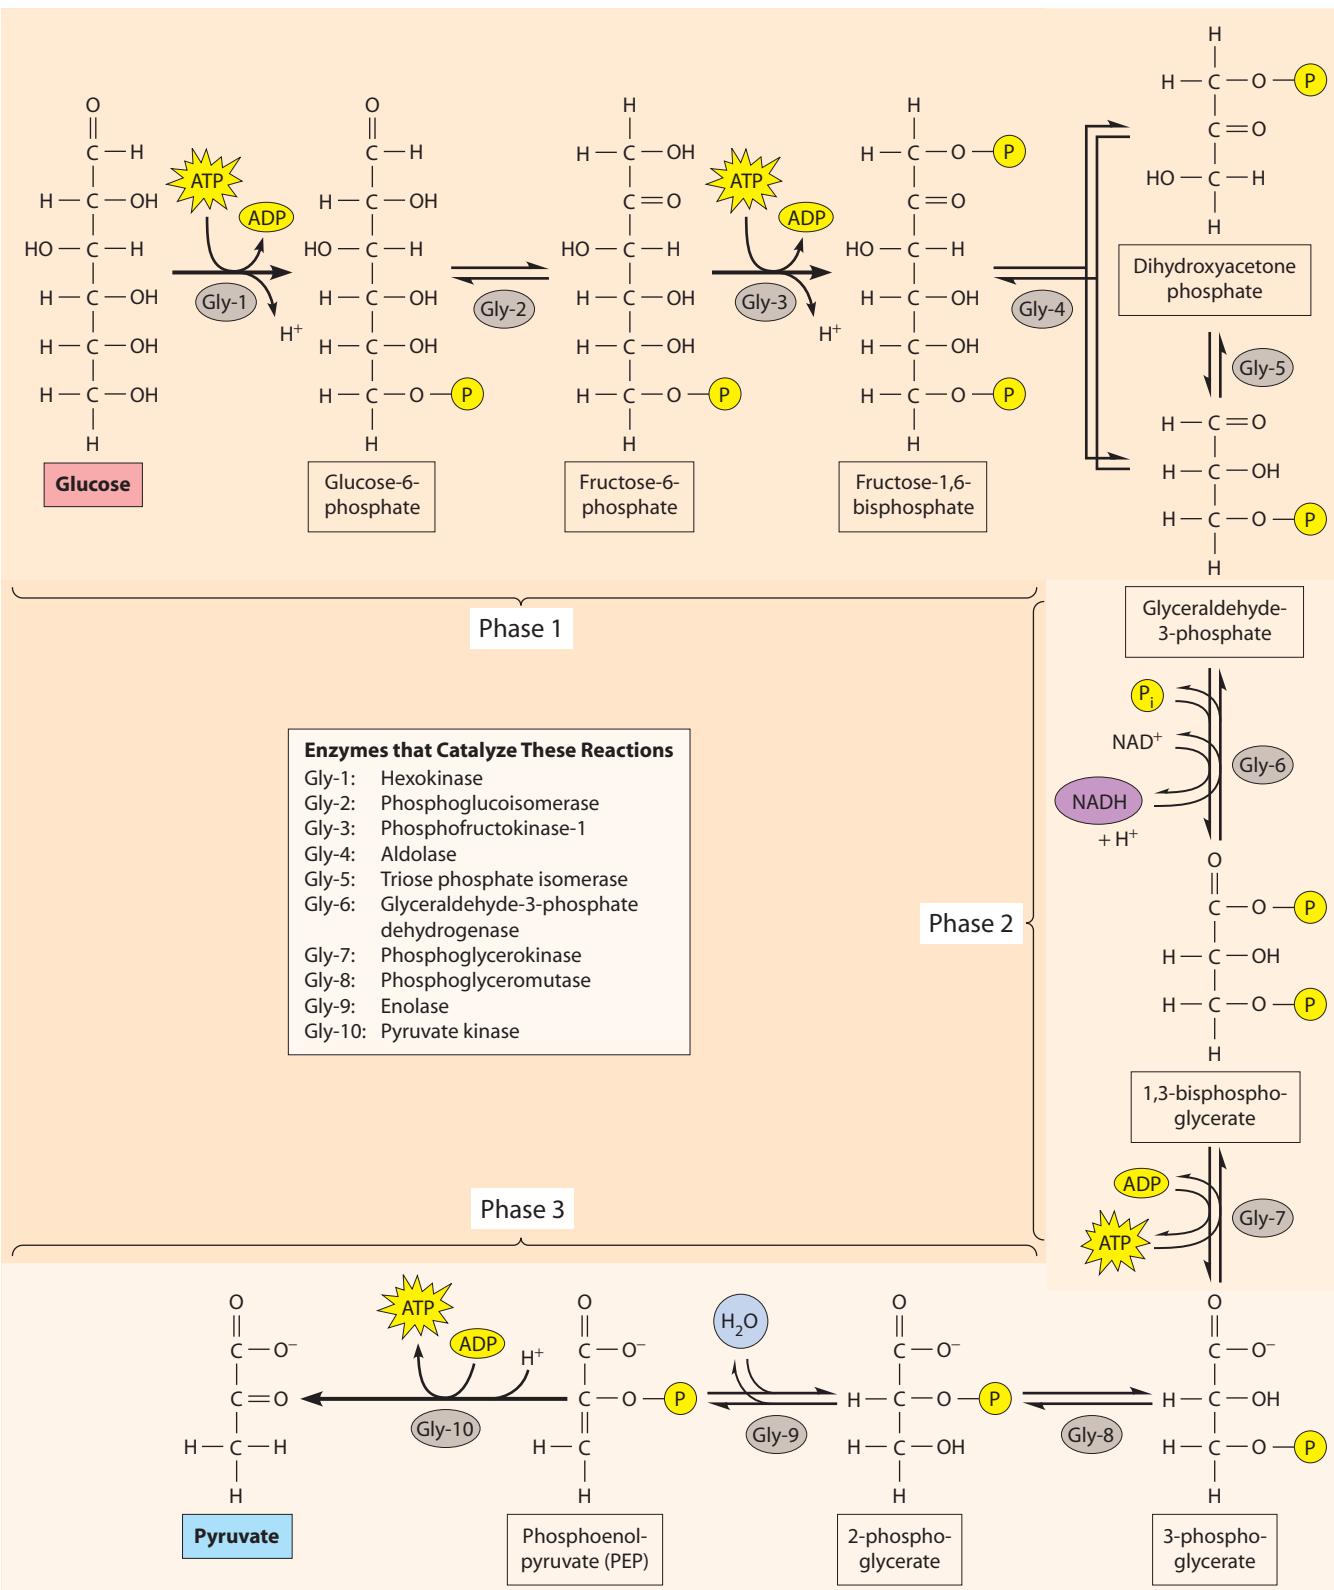

FIGURE 9-7 The Glycolytic Pathway from Glucose to Pyruvate. Glycolysis is a sequence of ten reactions in which glucose is catabolized to pyruvate, with a single oxidative reaction (Gly-6) and two ATP-generating steps (Gly-7 and Gly-10). The enzymes that catalyze these reactions are identified in the center box.

Chapter 10. The ten reactions in the glycolytic pathway are numbered in sequence (Gly-1 through Gly-10), and the enzymes that catalyze the reactions are identified in the center box of Figure 9-7. The essence of the process is suggested by its very name because the term *glycolysis* derives from two Greek roots: *glykos*, meaning “sweet,” and *lysis*, meaning “loosening” or “splitting.” The splitting occurs at Reaction Gly-4 in Figure 9-7, at which point the six-carbon sugar is cleaved into two three-carbon molecules. One of these molecules, glyceraldehyde-3-phosphate, is the only molecule that undergoes oxidation in this pathway.

Important features of the glycolytic pathway are the initial input of ATP (Gly-1), the sugar-splitting reaction for which the sequence is named (Gly-4), the oxidative event that generates NADH (Gly-6), and the two specific steps at which the reaction sequence is coupled to ATP generation (Gly-7 and Gly-10). These features will be emphasized as we consider the overall pathway in three phases, as outlined in Figure 9-6: the preparatory and cleavage steps (Gly-1 through Gly-5); the oxidative sequence, which is also the first ATP-generating event (Gly-6 and Gly-7); and the second ATP-generating event (Gly-8 through Gly-10).

Phase 1: Preparation and Cleavage. To begin our consideration of glycolysis, note that the net result of the first three reactions is to convert an unphosphorylated molecule (glucose) into a doubly phosphorylated molecule (*fructose-1,6-bisphosphate*). This requires the transfer of two phosphate groups from ATP to glucose, one on each terminal carbon. Looking at glucose, it is easy to see how phosphorylation can take place on carbon atom 6 in Reaction Gly-1 because the hydroxyl group there can be readily linked to a phosphate group to form the phosphoester glucose-6-phosphate. ATP hydrolysis provides not only the phosphate group but also the driving force that renders the phosphorylation reaction strongly exergonic ($\Delta G' = -4.0 \text{ kcal/mol}$), making it essentially irreversible in the direction of glucose phosphorylation.

Notice, by the way, that the bond formed when glucose is phosphorylated is a *phosphoester bond*, a lower-energy bond than the phosphoanhydride bond linking the terminal phosphate to ATP. This difference is what makes the transfer of the phosphate group from ATP to glucose exergonic (see Reaction 9-5 and Figure 9-3). The enzyme that catalyzes this first reaction is called *hexokinase*; as the name suggests, it is not specific for glucose but catalyzes the phosphorylation of other hexoses (six-carbon sugars) as well. (Liver cells contain an additional enzyme, *glucokinase*, that phosphorylates only glucose.)

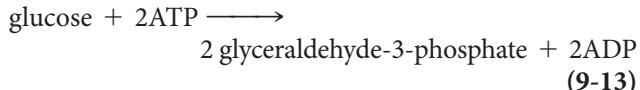

The carbonyl group on carbon atom 1 of the glucose molecule is not as readily phosphorylated as the hydroxyl group on carbon atom 6. But in the next reaction (Gly-2), the aldose sugar glucose-6-phosphate is converted to the corresponding ketosugar, fructose-6-phosphate, which has a hydroxyl group on carbon atom 1. That hydroxyl

group can then be phosphorylated using another molecule of ATP, yielding the doubly phosphorylated sugar, fructose-1,6-bisphosphate (Reaction Gly-3).

Again, the energy difference between the anhydride bond of ATP and the phosphoester bond on the fructose molecule renders the reaction highly exergonic and therefore essentially irreversible in the glycolytic direction ($\Delta G' = -3.4 \text{ kcal/mol}$). This reaction is catalyzed by *phosphofructokinase-1* (*PFK-1*), an enzyme that is especially important in the regulation of glycolysis, as we will see later. The designation PFK-1 is to distinguish this enzyme from PFK-2, a similar enzyme also involved in regulation.

Next comes the actual cleavage reaction from which glycolysis derives its name. Fructose-1,6-bisphosphate is split reversibly by the enzyme *aldolase* to yield two trioses (three-carbon sugars) called dihydroxyacetone phosphate and glyceraldehyde-3-phosphate (Reaction Gly-4), which are readily interconvertible (Reaction Gly-5). Since only the latter of these compounds is directly oxidizable in the next phase of glycolysis, interconversion of the two trioses enables dihydroxyacetone phosphate to be catabolized simply by conversion to glyceraldehyde-3-phosphate.

We can summarize this first phase of the glycolytic pathway (Gly-1 to Gly-5) as follows:

Note that in this and subsequent reactions, H^+ ions and H_2O molecules are not necessarily included if not needed for the overall understanding of the reaction.

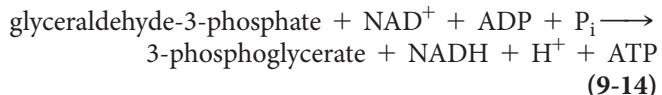

Phase 2: Oxidation and ATP Generation. So far, the original glucose molecule has been doubly phosphorylated and cleaved into two interconvertible triose phosphates. Notice, however, that the energy yield is negative thus far: Two molecules of ATP have been *consumed* per molecule of glucose in Phase 1. But the ATP debt is about to be repaid with interest as we encounter the two energy-yielding phases of glycolysis. In Phase 2, ATP production is linked directly to an oxidative event, and then in Phase 3 an energy-rich phosphorylated form of the pyruvate molecule serves as the driving force behind ATP generation.

The oxidation of glyceraldehyde-3-phosphate to the corresponding three-carbon acid, 3-phosphoglycerate, is highly exergonic—sufficiently so, in fact, to drive both the reduction of the coenzyme NAD^+ (Gly-6) and the phosphorylation of ADP with inorganic phosphate, P_i (Gly-7). Historically, this was the first example of a reaction sequence in which the coupling of ATP generation to an oxidative event was understood.

The important features of this highly exergonic sequence are the involvement of NAD^+ as the electron acceptor and the coupling of the oxidation to the formation of a high-energy, doubly phosphorylated intermediate,

1,3-bisphosphoglycerate. The phosphoanhydride bond on carbon atom 1 of this intermediate has such a highly negative ΔG° of hydrolysis (-11.8 kcal/mol ; see Table 9-1) that the transfer of the phosphate to ADP, catalyzed by the enzyme *phosphoglycerate kinase*, is a highly exergonic reaction. ATP generation by the direct transfer of a high-energy phosphate group to ADP from a phosphorylated substrate such as 1,3-bisphosphoglycerate is called **substrate-level phosphorylation**.

To summarize the substrate-level phosphorylation of Reactions Gly-6 and Gly-7, we can write an overall reaction that accounts for one of the two glyceraldehyde-3-phosphate molecules generated from each glucose molecule in the first phase of glycolysis:

Keep in mind that each reaction in the glycolytic pathway beyond glyceraldehyde-3-phosphate occurs twice per starting molecule of glucose so that, on a per-glucose basis, two molecules of NADH need to be reoxidized in order to regenerate the NAD^+ that is needed for continual oxidation of glyceraldehyde-3-phosphate. It also means that the initial investment of two ATP molecules in Phase 1 is recovered here in Phase 2, so the net ATP yield to this point is now zero.

Next, in the final phase of glycolysis, we will see the generation of two more ATP molecules. Thus, for glycolysis overall, there is a net gain of two ATP molecules per glucose metabolized to pyruvate.

Phase 3: Pyruvate Formation and ATP Generation. Generating another molecule of ATP from 3-phosphoglycerate depends on the phosphate group on carbon atom 3. At this stage, the phosphate group is linked to the carbon atom by a phosphoester bond with a low free energy of hydrolysis ($\Delta G^\circ = -3.3 \text{ kcal/mol}$). In the final phase of the glycolytic pathway, this phosphoester bond is converted to a *phosphoenol bond*, the hydrolysis of which is highly exergonic ($\Delta G^\circ = -14.8 \text{ kcal/mol}$; see Table 9-1). This increase in the amount of free energy released upon hydrolysis involves a rearrangement of internal energy within the molecule. To accomplish this, the phosphate group of 3-phosphoglycerate is moved to the adjacent carbon atom, forming 2-phosphoglycerate (Reaction Gly-8). Water is then removed from 2-phosphoglycerate by the enzyme enolase (Reaction Gly-9), thereby generating the high-energy compound phosphoenolpyruvate (PEP).

If you look carefully at the structure of PEP (see Figure 9-7, Reaction Gly-9), you will notice that, unlike the phosphoester bonds of either 3- or 2-phosphoglycerate, the phosphoenol bond of PEP has a phosphate group on a carbon atom that is linked by a double bond to another carbon atom. This characteristic makes the hydrolysis of

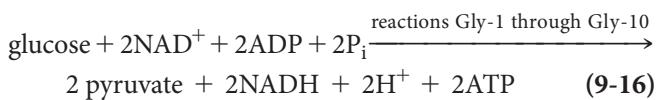

the phosphoenol bond of PEP one of the most exergonic hydrolytic reactions known in biological systems.

PEP hydrolysis is exergonic enough to drive ATP synthesis in Reaction Gly-10, which involves the transfer of a phosphate group from PEP to ADP, generating another molecule of ATP in another substrate-level phosphorylation. This transfer, catalyzed by the enzyme *pyruvate kinase*, is highly exergonic ($\Delta G^\circ = -7.5 \text{ kcal/mol}$; see Figure 9-3 and Reaction 9-6) and is therefore essentially irreversible in the direction of pyruvate and ATP formation.

To summarize the third phase of glycolysis, Gly-8 to Gly-10, we can write an overall reaction for pyruvate formation:

Summary of Glycolysis. Two molecules of ATP were initially invested in Reactions Gly-1 and Gly-3, and two were returned in the first phosphorylation event (Gly-7), so the two molecules of ATP formed per molecule of glucose by the second phosphorylation event (Gly-10) represent the net ATP yield of the glycolytic pathway. This becomes clear when we add up the three reactions that summarize the three phases of the pathway (Reactions 9-13, 9-14, and 9-15). The latter two reactions are multiplied by 2 to account for both triose molecules generated in Reaction 9-13. The result is an overall expression for the pathway from glucose to pyruvate:

This pathway is highly exergonic in the direction of pyruvate formation. Under typical intracellular conditions in your body, for example, $\Delta G'$ for the overall pathway from glucose to pyruvate with the generation of two molecules each of ATP and NADH is about -20 kcal/mol .

The glycolytic pathway is one of the most common and highly conserved metabolic pathways known. Virtually all cells possess the ability to extract energy from glucose by oxidizing it to pyruvate. Some of this energy is conserved in the form of two molecules of ATP per molecule of glucose. What happens next, however, usually depends on the availability of oxygen because catabolism beyond pyruvate is quite different under aerobic conditions than it is under anaerobic conditions.

The Fate of Pyruvate Depends on Whether Oxygen Is Available

Pyruvate occupies a key position as a branching point in chemotrophic energy metabolism (Figure 9-8). Its fate depends on the kind of organism involved, the specific cell type, and whether oxygen is available. In the presence of oxygen, pyruvate undergoes further oxidation to a molecule called acetyl coenzyme A (abbreviated as acetyl

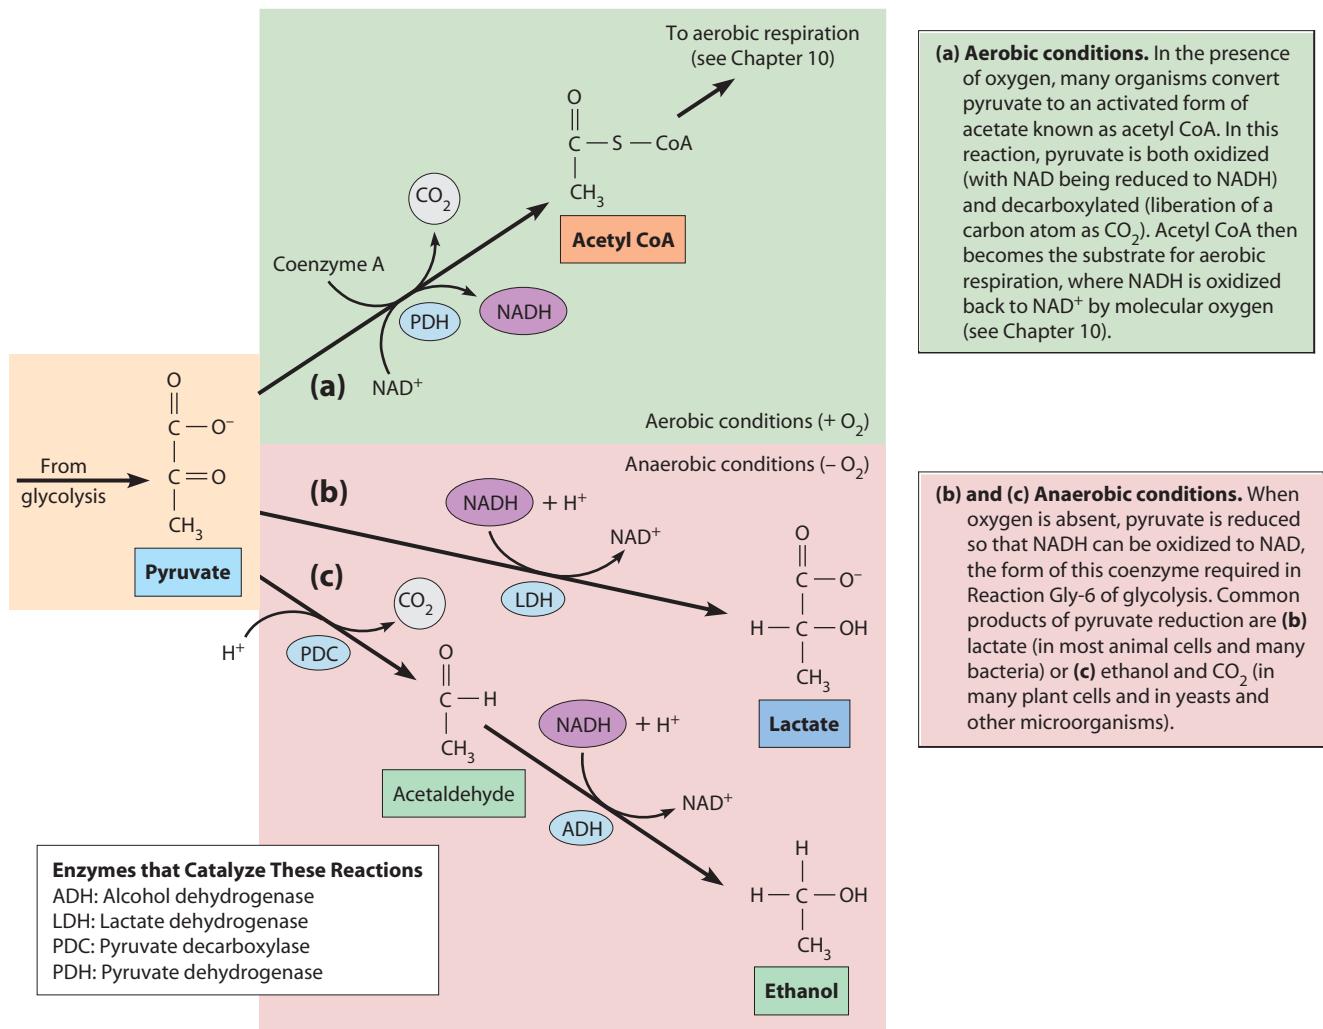

FIGURE 9-8 The Fate of Pyruvate Under Aerobic and Anaerobic Conditions. The fate of pyruvate depends on the organism involved and on whether oxygen is available. The enzymes that catalyze these reactions are identified in the box.

ACTIVITIES www.thecellplace.com Fermentation

CoA), which in turn can be completely oxidized to CO₂, generating more than 30 ATP per glucose.

An important feature of glycolysis, however, is that it can also take place in the absence of oxygen. Under anaerobic conditions, no further oxidation of pyruvate occurs, no acetyl CoA is formed, and no additional ATP can be generated. Instead, the energy needs of the cell are met by the modest ATP yield of two ATP per glucose in the glycolytic pathway, and cells must consume glucose much more rapidly in order to maintain steady-state cellular ATP levels. In anaerobic conditions, rather than being oxidized, pyruvate is reduced by accepting the electrons (and protons) that must be removed from NADH. As Figure 9-8 illustrates, the most common products of pyruvate reduction are lactate (part b) or ethanol and carbon dioxide (part c).

(a) Aerobic conditions. In the presence of oxygen, many organisms convert pyruvate to an activated form of acetate known as acetyl CoA. In this reaction, pyruvate is both oxidized (with NAD being reduced to NADH) and decarboxylated (liberation of a carbon atom as CO₂). Acetyl CoA then becomes the substrate for aerobic respiration, where NADH is oxidized back to NAD⁺ by molecular oxygen (see Chapter 10).

(b) and (c) Anaerobic conditions. When oxygen is absent, pyruvate is reduced so that NADH can be oxidized to NAD, the form of this coenzyme required in Reaction Gly-6 of glycolysis. Common products of pyruvate reduction are (b) lactate (in most animal cells and many bacteria) or (c) ethanol and CO₂ (in many plant cells and in yeasts and other microorganisms).

In the Absence of Oxygen, Pyruvate Undergoes Fermentation to Regenerate NAD⁺

As usually defined, the glycolytic pathway ends with pyruvate. Fermentative processes cannot end there, however, because of the need to regenerate NAD⁺, the oxidized form of the coenzyme. As Reaction 9-16 indicates, the conversion of glucose to pyruvate requires that one molecule of NAD⁺ is reduced to NADH per molecule of pyruvate generated. Coenzymes are present in cells at only modest concentrations, however, so the conversion of NAD⁺ to NADH during glycolysis would cause cells to run out of NAD⁺ very quickly if there were not some mechanism for regenerating NAD⁺. Cells also have mechanisms to continually monitor and stabilize the NAD⁺/NADH ratio, which is an indicator of the cell's redox state, the general level of oxidation of cellular components. Excessive oxidation of cellular components can be damaging to the cell, as free radicals and other harmful

compounds are produced. Large changes in this ratio are a signal that the cell is under oxidative stress, and cellular mechanisms will try to keep it relatively constant.

In the presence of oxygen, NADH is reoxidized by the transfer of its electrons to oxygen, as we will see in Chapter 10. Under anaerobic conditions, however, the electrons are transferred to pyruvate, which has a carbonyl group that can be readily reduced to a hydroxyl group (see Figure 9-8 b, c). The two most common pathways for fermentation use pyruvate as the electron acceptor, converting it either to lactate or to CO_2 and ethanol. We will consider both of these alternatives briefly.

Lactate Fermentation. The anaerobic process that terminates in lactate is called **lactate fermentation**. As Figure 9-8b indicates, lactate is generated by the direct transfer of electrons from NADH to the carbonyl group of pyruvate, reducing it to the hydroxyl group of lactate. On a per-glucose basis, this reaction can be represented as

This reaction is readily reversible; in fact, the enzyme that catalyzes it is called *lactate dehydrogenase* because of its ability to catalyze the oxidation, or dehydrogenation, of lactate to pyruvate.

By adding Reactions 9-16 and 9-17, we can write an overall reaction for the metabolism of glucose to lactate under anaerobic conditions:

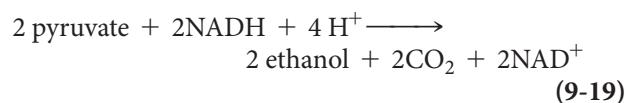

Lactate fermentation is the major energy-yielding pathway in many anaerobic bacteria, as well as in animal cells operating under anaerobic or hypoxic conditions. Lactate fermentation is important to us commercially because the production of cheese, yogurt, and other dairy products depends on microbial fermentation of lactose, the main sugar found in milk.

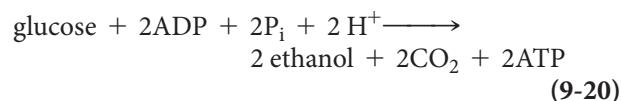

A more personal example of lactate fermentation involves your own muscles during periods of strenuous exertion. Whenever muscle cells use oxygen faster than it can be supplied by the circulatory system, the cells become temporarily hypoxic. Pyruvate is then reduced to lactate instead of being further oxidized, as it is under aerobic conditions. The lactate produced in this way is transported by the circulatory system from the muscle to the liver. There it is converted to glucose again by the process of *gluconeogenesis*. As we will see later in this chapter, gluconeogenesis is essentially the reverse of lactate fermentation but with several critical differences that enable it to proceed exergonically in the direction of glucose formation.

Alcoholic Fermentation. Under anaerobic conditions, plant cells can carry out **alcoholic fermentation** (in waterlogged roots, for example), as do yeasts and other

microorganisms. In this process, pyruvate loses a carbon atom (as CO_2) to form the two-carbon compound acetaldehyde. Acetaldehyde reduction by NADH gives rise to ethanol, the alcohol for which the process is named. This reductive sequence is catalyzed by two enzymes, *pyruvate decarboxylase* and *alcohol dehydrogenase* (Figure 9-8c). The overall reaction can be summarized as follows:

By adding this reductive step to the overall equation for glycolysis (Reaction 9-16), we arrive at the following summary equation for alcoholic fermentation:

Alcoholic fermentation by yeast cells is a key process in the baking, brewing, and winemaking industries. The yeast cells in bread dough break down glucose anaerobically, generating both CO_2 and ethanol. Carbon dioxide is trapped in the dough, causing it to rise, and the alcohol is driven off during baking and becomes part of the pleasant aroma of baking bread. For the brewer, both CO_2 and ethanol are essential; ethanol makes the product an alcoholic beverage, and CO_2 accounts for the carbonation.

Other Fermentation Pathways. Although lactate and ethanol are the fermentation products of greatest physiological or economic significance, they by no means exhaust the microbial fermentation repertoire. In *propionate fermentation*, for example, bacteria reduce pyruvate to propionate ($\text{CH}_3\text{—CH}_2\text{—COO}^-$), an important reaction in the production of Swiss cheese. Many bacteria that cause food spoilage do so by *butylene glycol fermentation*. Other fermentation processes yield acetone, isopropyl alcohol, or butyrate, the latter of which is responsible for the rotten smell of rancid food or vomit. However, all these reactions are just metabolic variations on the common theme of reoxidizing NADH by the transfer of electrons to some organic acceptor.

Fermentation Taps Only a Fraction of the Substrate's Free Energy but Conserves That Energy Efficiently as ATP

An essential feature of every fermentative process is that *no external electron acceptor is involved and no net oxidation occurs*. In both lactate and alcoholic fermentation, for example, the NADH generated by the single oxidative step of glycolysis (Reaction Gly-6) is reoxidized in the final reaction of the sequence (Reactions 9-17 and 9-19). Because no net oxidation occurs, fermentation gives a modest ATP yield—two molecules of ATP per molecule of glucose, in the case of either lactate or alcoholic fermentation.

Most of the free energy of the glucose molecule is still present in the two lactate or ethanol molecules. In the case of lactate fermentation, for example, the two lactate molecules produced from every glucose molecule contain most of the 686 kcal of free energy present per mole of glucose because the complete aerobic oxidation of lactate has a ΔG° of -319.5 kcal/mol . In other words, about 93% (639 kcal) of the original free energy of glucose is still present in the two lactate molecules, and only about 7% (47 kcal/mol) of the free energy potentially available from glucose was obtained during fermentation.

Although the energy yield from lactate fermentation is low, the available free energy is conserved efficiently as ATP. Using standard free energy changes, these two molecules of ATP represent $2 \times 7.3 = 14.6 \text{ kcal/mol}$. This corresponds to an efficiency of energy conservation of about 30% ($14.6/47 \times 100\%$). Based on actual $\Delta G'$ values for ATP hydrolysis under cellular conditions (often in the range of -10 to -14 kcal/mol), two molecules of ATP represent at least 20 kcal/mol, which means that the efficiency of energy conservation probably exceeds 40%.

Alternative Substrates for Glycolysis

So far, we have assumed glucose to be the starting point for glycolysis and thus, by implication, for all of cellular energy metabolism. Glucose is certainly a major substrate for both fermentation and respiration in a variety of organisms and tissues. It is not the only such substrate, however. For many organisms and some tissues within organisms, glucose is not significant at all. So it is important to ask two questions: What are some of the major alternatives to glucose, and how are they handled by cells?

One principle quickly emerges: *Regardless of the chemical nature of the alternative substrate, it is often converted into an intermediate in the main pathway for glucose catabolism.* Most carbohydrates, for example, are converted to intermediates in the glycolytic pathway. To emphasize this point, we will briefly consider two classes of alternative carbohydrate substrates—other sugars and storage carbohydrates. In Chapter 10, we will see how proteins and lipids can be converted into intermediates in the tricarboxylic acid (TCA) cycle, the next stage of aerobic respiration.

Other Sugars and Glycerol Are Also Catabolized by the Glycolytic Pathway

Many sugars other than glucose are available to cells, depending on the food sources of the organism in question. Most of them are either monosaccharides (usually hexoses or pentoses) or disaccharides that can be readily hydrolyzed into their component monosaccharides. Ordinary table sugar (sucrose), for example, is a disaccharide consisting of the hexoses glucose and fructose, and milk sugar (lactose) contains glucose and galactose (see Figure 3-23). Besides glucose, fructose, and galactose, mannose is another relatively common dietary hexose.

Figure 9-9 illustrates the reactions that bring various carbohydrates into the glycolytic pathway. In general, disaccharides are hydrolyzed into their component monosaccharides, and each monosaccharide is converted to a glycolytic intermediate in one or a few steps. Glucose and fructose enter most directly after phosphorylation on carbon atom 6. Mannose is converted to mannose-6-phosphate and then to fructose-6-phosphate, a glycolytic intermediate. The entry of galactose requires a somewhat more complex reaction sequence involving five steps to convert it to glucose-6-phosphate (Figure 9-9).

Phosphorylated pentoses can also be channeled into the glycolytic pathway but only after being converted to hexose phosphates. That conversion is accomplished by a metabolic sequence called the *phosphogluconate pathway*, also known as the *pentose phosphate pathway*. Glycerol, a three-carbon molecule resulting from lipid breakdown, enters glycolysis after conversion to dihydroxyacetone phosphate (Figure 9-9). Thus, the typical cell has metabolic capabilities to convert most naturally occurring sugars (and a variety of other compounds as well) to one of the glycolytic intermediates for further catabolism under either anaerobic or aerobic conditions.

Polysaccharides Are Cleaved to Form Sugar Phosphates That Also Enter the Glycolytic Pathway

Although glucose is the immediate substrate for both fermentation and respiration in many cells and tissues, the concentration of the free monosaccharide in cells is low. Instead, it occurs primarily in the form of storage polysaccharides, most commonly starch in plants and glycogen in animals. One advantage of storing glucose as starch and glycogen is that these two glucose polymers are insoluble in water and thus do not overload the limited solute capacity of the cell. As indicated in **Figure 9-10**, these storage polysaccharides can be mobilized by a process called *phosphorolysis*. Phosphorolysis resembles hydrolysis but uses inorganic phosphate rather than water to break a chemical bond. Inorganic phosphate is used to break the $\alpha(1 \rightarrow 4)$ bond between successive glucose units, liberating the glucose monomers as glucose-1-phosphate. The glucose-1-phosphate that is formed in this way can be converted to glucose-6-phosphate, which is then catabolized by the glycolytic pathway.

Notice that glucose stored in polymerized form enters the glycolytic pathway as glucose-6-phosphate, without the input of the ATP that would be required for the initial phosphorylation of the free sugar. Consequently, the overall energy yield for glucose is greater by one molecule of ATP when it is catabolized from the polysaccharide level than when it is catabolized with the free sugar as the starting substrate. This is not a case of getting something for nothing, however, because energy was required to activate the glucose units that were added to the polysaccharide chain during starch or glycogen synthesis.

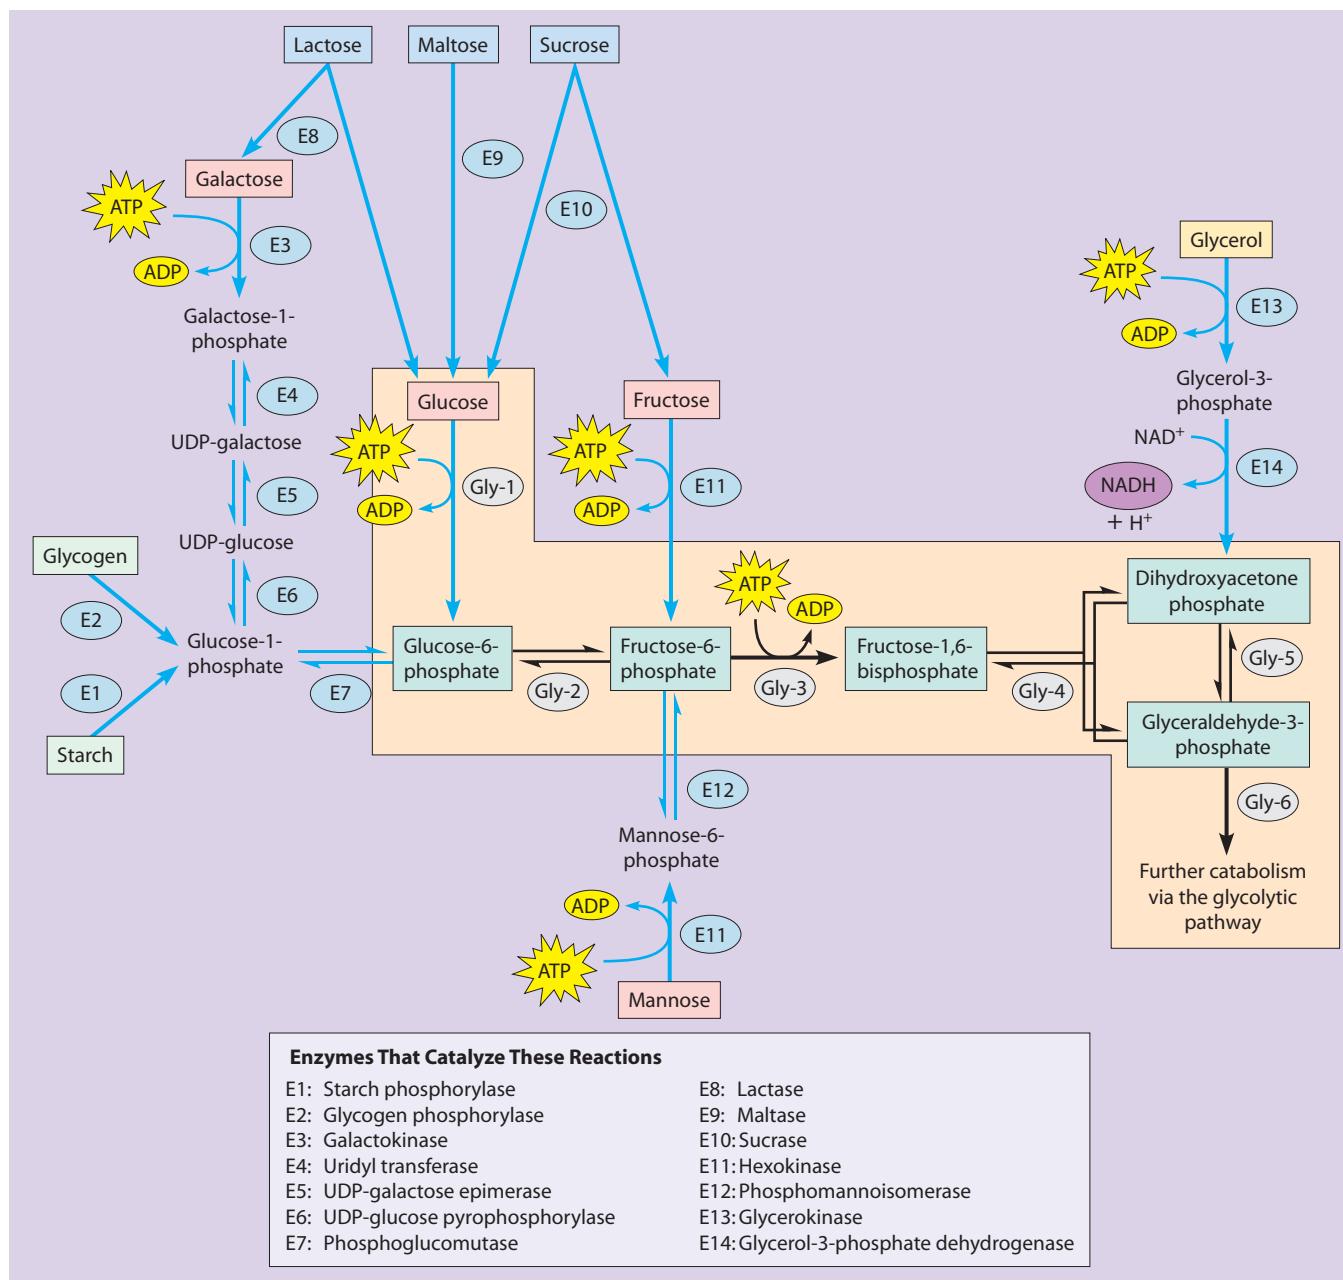

FIGURE 9-9 Carbohydrate Catabolism by the Glycolytic Pathway. Carbohydrate substrates that can be metabolized by conversion to an intermediate in the glycolytic pathway are enclosed in colored boxes. These include the hexoses galactose, glucose, fructose, and mannose; the disaccharides lactose, maltose, and sucrose; the polysaccharides glycogen and starch; and the three-carbon compound glycerol. The conversion reactions are shown by blue arrows. The enzymes that catalyze these reactions are identified in the box at the bottom. The first six reactions of the glycolytic pathway are highlighted in tan; for the names of the enzymes that catalyze these reactions, see Figure 9-7. In some cases, other enzymes or reaction sequences may be involved, depending on the organism and tissue.

Gluconeogenesis

Cells are able to catabolize glucose and other carbohydrates to meet their energy needs, and they can synthesize sugars and polysaccharides needed for other purposes. The process of glucose synthesis is called **gluconeogenesis**, which literally means “the genesis (formation) of new glucose.” More specifically, gluconeogenesis is defined as

the process by which cells synthesize glucose from three-carbon and four-carbon precursors that are usually noncarbohydrate in nature. The most common starting materials are pyruvate and its fermentation product lactate. Gluconeogenesis occurs in all organisms and in animals occurs mainly in the liver and kidneys.

The gluconeogenesis and glycolysis pathways share much in common; in fact, seven of the ten reactions in the

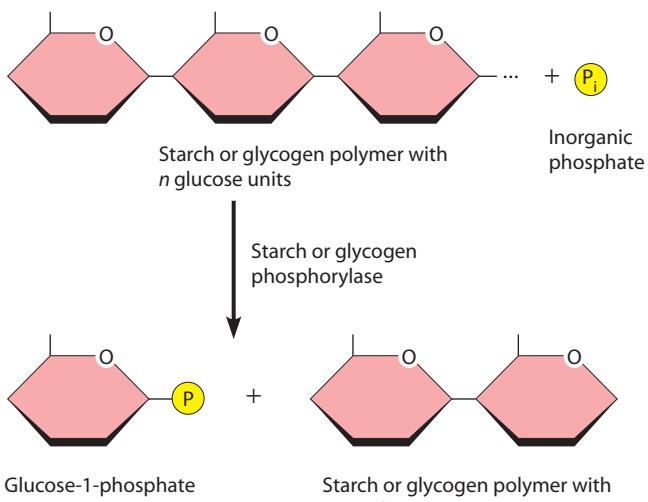

FIGURE 9-10 Phosphorolytic Cleavage of Storage

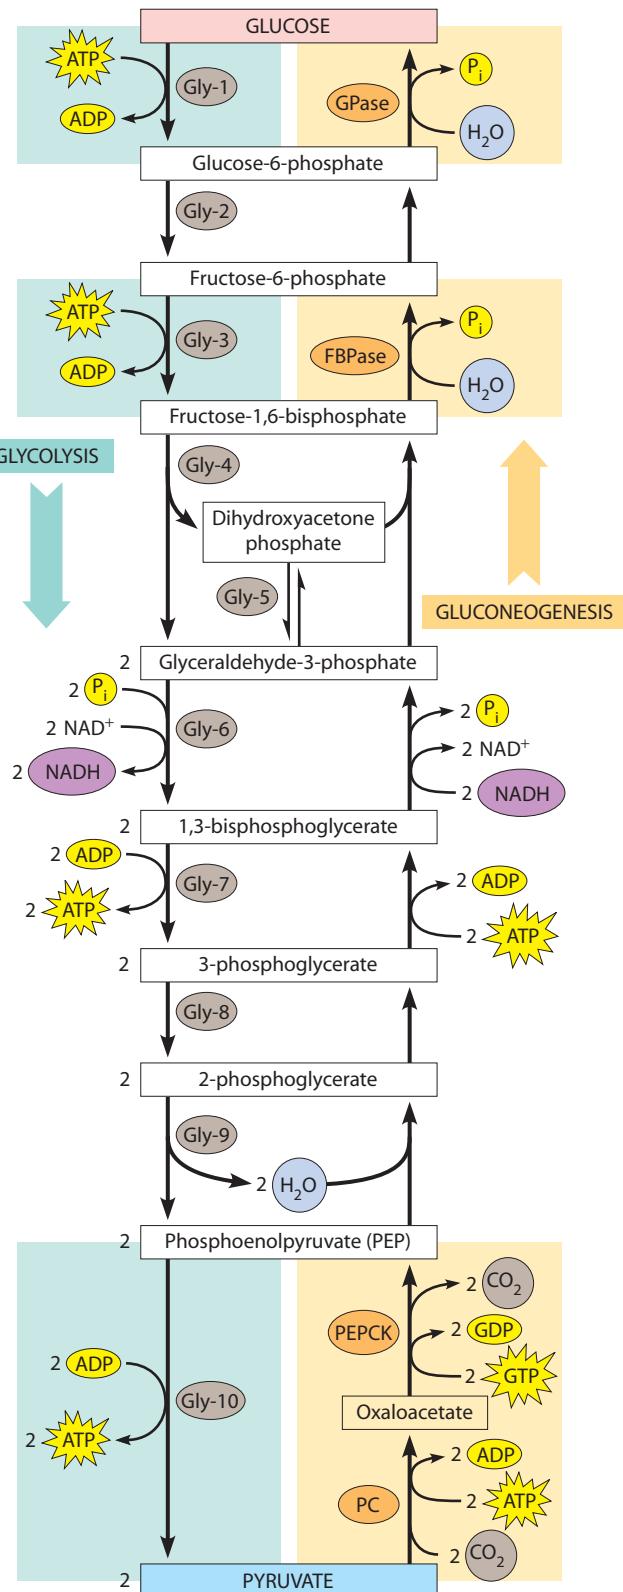

Polysaccharides. Glucose units (pink hexagons) of storage polysaccharides such as starch or glycogen are liberated as glucose-1-phosphate by phosphorolytic cleavage. The glucose-1-phosphate is then converted to glucose-6-phosphate and catabolized by the glycolytic pathway, as shown in Figure 9-7.

gluconeogenic pathway occur by simple reversal of the corresponding reactions in glycolysis, using the same enzyme in both directions. However, not all of the steps of the gluconeogenic pathway are just the reversal of glycolytic reactions. As **Figure 9-11** illustrates, three of the reactions of the glycolytic pathway—Gly-1, Gly-3, and Gly-10—are accomplished by other means in the direction of gluconeogenesis. These three reactions are the most highly exergonic reactions of glycolysis and thus are thermodynamically difficult to reverse. In fact, these differences clearly illustrate an important principle of cellular metabolism: *Biosynthetic anabolic pathways are seldom just the reversal of the corresponding catabolic pathways.*

For a metabolic pathway to be thermodynamically favorable in a specific direction, it must be sufficiently exergonic in that direction. That certainly is true of glycolysis; recall that the overall sequence from glucose to pyruvate as summarized by Reaction 9-16 has a $\Delta G'$ value of about -20 kcal/mol under typical intracellular conditions in the

FIGURE 9-11 Pathways for Glycolysis and Gluconeogenesis Compared.

The pathways for glycolysis (left) and gluconeogenesis (right) have nine intermediates and seven enzyme-catalyzed reactions in common. The three essentially irreversible reactions of the glycolytic pathway (in green shading) are circumvented in gluconeogenesis by four bypass reactions (in yellow shading). Gluconeogenesis, on the other hand, is an anabolic pathway, requiring the coupled hydrolysis of six phosphoanhydride bonds (four from ATP, two from GTP) to drive it in the direction of glucose formation. The enzymes that catalyze the bypass reactions are shown in gold and are identified in the box. (For the names of the glycolytic enzymes, see Figure 9-7.) In animals, glycolysis occurs in muscle and various other tissues, whereas gluconeogenesis occurs mainly in the liver and to a lesser degree in the kidneys.

Enzymes That Catalyze the Bypass Reactions of Gluconeogenesis

PC:	Pyruvate carboxylase
PEPCK:	Phosphoenolpyruvate carboxykinase
FBPase:	Fructose-1,6-bisphosphatase
GPase:	Glucose-6-phosphatase

human body. Clearly, then, $\Delta G'$ for the reverse process would be about +20 kcal/mol, making glucose synthesis by the direct reversal of glycolysis highly endergonic and therefore thermodynamically impossible.

Gluconeogenesis is possible because the three most exergonic reactions in the glycolytic pathway (Gly-1, Gly-3, and Gly-10) do not simply “run in reverse” in the gluconeogenic direction. Instead, the gluconeogenic pathway has *bypass reactions* at each of those three sites—alternative reactions that circumvent the three glycolytic reactions that would be the most difficult to drive in the reverse direction. In fact, the three reactions of the glycolytic pathway that are bypassed in gluconeogenesis in Figure 9-11 are shown as unidirectional in Figure 9-7.

In the case of Gly-1 and Gly-3, using the exact reverse reaction would require synthesis of ATP, so instead it is bypassed by a simple hydrolytic reaction that liberates inorganic phosphate (Figure 9-11). Notice how effectively this simple metabolic ploy overcomes the thermodynamic hurdle. In the case of the conversion of glucose to glucose-6-phosphate in glycolysis, the reaction is exergonic because of the input of an ATP molecule. And in the gluconeogenic direction, it is exergonic due to the hydrolysis of the phosphoester bond, which has a ΔG° of -3.3 kcal/mol.

The third site of irreversibility in the glycolytic pathway, Reaction Gly-10, is bypassed in gluconeogenesis by a two-reaction sequence (Figure 9-11). Both of these reactions are driven by the hydrolysis of a phosphoanhydride bond, from ATP in one case and from the related compound GTP in the other. (GTP is the abbreviation for guanosine triphosphate; see Figure 3-15 for the structure of guanine.) First, CO_2 is added to pyruvate in a *carboxylation* reaction, forming a four-carbon compound called oxaloacetate. Next, the carboxyl group is removed in a *decarboxylation* reaction to form phosphoenolpyruvate (PEP). In this case, both the phosphate group and the energy are provided by GTP, which is energetically the equivalent of ATP.

What these bypass reactions accomplish becomes clear when the glycolytic and gluconeogenic pathways are compared directly (Figure 9-11). As a catabolic pathway, glycolysis is inherently exergonic, producing two ATPs per glucose. Gluconeogenesis, on the other hand, is an anabolic pathway, requiring the equivalent of six ATP molecules consumed per molecule of glucose synthesized. The difference of four ATP molecules per glucose represents enough energy to ensure that gluconeogenesis proceeds exergonically in the direction of glucose synthesis.

While it is important to acquire an academic understanding of processes like glycolysis and gluconeogenesis, it is also important to appreciate what this knowledge means for you as a person. **Box 9A** describes what is happening right now to the sugars you ate at breakfast this morning if you had a bowl of cereal with milk and will help you understand what happens in the cells of your body following your next meal.

The Regulation of Glycolysis and Gluconeogenesis

Because cells have enzymes to catalyze the reactions of both the glycolytic and the gluconeogenic pathways, it is crucial to keep both pathways from proceeding simultaneously in the same cell in an obviously futile cycle. How can the synthesis and breakdown of glucose be controlled to keep this from happening? One solution in our bodies is spatial regulation—having these pathways operate in separate cells, as shown for our muscle cells (glycolysis) and liver cells (gluconeogenesis) in Figure 9A-2. We will later examine another solution—temporal regulation, in which glycolysis and gluconeogenesis operate at different times within a single cell.

Like all metabolic pathways, glycolysis and gluconeogenesis are regulated to function at rates that are responsive to cellular and organismal needs for their products, which are ATP and glucose, respectively. Not surprisingly, glycolysis and gluconeogenesis are regulated in a reciprocal, or inverse, manner: Intracellular conditions known to stimulate one pathway usually have an inhibitory effect on the other. In addition, glycolysis is closely coordinated with other major pathways of energy generation and utilization in the cell, especially the pathways involved in aerobic respiration that we will be considering in Chapter 10.

Key Enzymes in the Glycolytic and Gluconeogenic Pathways Are Subject to Allosteric Regulation

Recall from Chapter 6 that **allosteric regulation** of enzyme activity involves the interconversion of an enzyme between two forms, one of them catalytically active (or more active) and the other inactive (or less active). An enzyme molecule will be active or inactive, depending on whether a specific allosteric effector is bound to the allosteric site as well as on whether that effector is an allosteric activator or an allosteric inhibitor (see Figure 6-16).

Figure 9-12 shows the key regulatory enzymes of the glycolytic and gluconeogenic pathways and the allosteric effectors that regulate each enzyme. For glycolysis, the key enzymes are hexokinase, phosphofructokinase-1 (PFK-1), and pyruvate kinase. For gluconeogenesis, fructose-1,6-bisphosphatase and pyruvate carboxylase are the key regulatory enzymes. Based primarily on studies with liver cells, each allosteric effector shown in Figure 9-12 is identified as either an activator (+) or an inhibitor (-) of the enzyme(s) it binds to. Several points become apparent from the figure. Notice, for instance, that *each of the regulatory enzymes is unique to its pathway*, so each pathway can be regulated independently of the other. Notice also the *reciprocal nature of the regulation of the two pathways*: AMP and acetyl CoA, the two effectors to which both pathways are sensitive, have opposite effects in the two directions. AMP, for example, activates glycolysis but inhibits gluconeogenesis. Acetyl CoA activates gluconeogenesis but inhibits glycolysis.

"What Happens to the Sugar?"

Now that you have studied the pathways of glycolysis and gluconeogenesis in detail, we hope you can use this information to understand how your body meets its energy needs and what it does with the nutrients that you eat. To put it more specifically, can you relate what you are learning in these chapters to what the cells in your body are doing with the food you had for breakfast this morning? As you add sugar to your coffee or cereal, can you answer the question, "What happens to the sugar?" This essay will address these questions and might help you appreciate the relevance of these chapters by letting you see how the information they contain applies to your daily life.

To keep the topic manageable, let's focus on a bowl of cereal (**Figure 9A-1**), considering the disaccharide sucrose (from the sugar bowl), the disaccharide lactose (in the milk), and the polysaccharide starch (in the cereal). First we'll follow the sugars and starch through your digestive tract; then we'll consider the glucose in your blood and the several ways the cells in different parts of your body use it.

Let's start with a spoonful of cereal you've just eaten. The sucrose and lactose remain intact until they reach your small intestine, but the digestion of starch begins in your mouth because saliva contains salivary amylase, an enzyme that splits starch into smaller polysaccharides. Further digestion occurs in your small intestine, where pancreatic amylase completes the breakdown of starch to the disaccharide maltose.

The maltose generated from starch is hydrolyzed to glucose in your intestine by the enzyme maltase. Maltase is one of a family of

intestinal disaccharidases, each specific for a different disaccharide. The lactose from the milk and the sucrose that you sprinkled on the cereal are hydrolyzed by other members of this family—lactase and sucrase, respectively. Lactose yields one molecule each of glucose and galactose, whereas sucrose is hydrolyzed to one molecule each of glucose and fructose (see Figure 9-9). In some people, intestinal lactase disappears gradually after age 4 or so, when milk drinking usually decreases. If such people ingest milk or other dairy products, they are likely to experience cramps and diarrhea, a condition called *lactose intolerance*.

Glucose, galactose, and fructose molecules are absorbed by intestinal epithelial cells. These cells have numerous microvilli that project into the lumen of the intestine, thereby greatly increasing the absorptive surface of the cell (see Figure 1-1g and Figure 4-2). Moreover, only two layers of epithelial cells separate nutrients in the lumen of your intestine from the blood in your capillaries. Some sugars, such as fructose, move across the plasma membrane of an epithelial cell by facilitated diffusion because the concentrations of these sugars are lower in capillary blood than in the intestinal lumen. Glucose, however, is moved by active transport because of its high concentration in blood.

Fructose and galactose are transported by your bloodstream to the various tissues of your body. These sugars are eventually absorbed by body cells and converted to intermediates in the glycolytic pathway, as shown in Figure 9-9. The pathway for galactose utilization is more complex than that of most other simple sugars, with five reactions required to convert a molecule of galactose into glucose-6-phosphate. A genetic defect in this pathway may result in an inability to metabolize galactose, resulting in high levels of galactose in the blood and high levels of galactose-1-phosphate in tissues. This disorder, called *galactosemia*, has serious consequences, including mental retardation. Not surprisingly, it occurs most commonly in infants because the major dietary source of galactose is milk. Provided the condition is detected early, the symptoms can be prevented or alleviated by removing milk and dairy products from the diet.

The main sugar in the blood, of course, is glucose. Its concentration in your blood a few hours after a meal is probably about 80 mg/dL (80 mg per deciliter [100 mL] of blood, or about 4.4 mM). The level may rise to 120 mg/dL (6.6 mM) shortly after you've eaten. In general, however, the blood glucose level is maintained within rather narrow limits. Maintenance of the blood glucose level is one of the most important regulatory functions in your body, particularly for proper functioning of your brain and nervous system. Your blood glucose level is under the control of several hormones, including insulin, glucagon, epinephrine, and norepinephrine (see Chapter 14).

Once in your bloodstream, glucose is transported to cells in all parts of your body, where it has four main fates: It can be oxidized completely by aerobic respiration to CO₂, it can be fermented anaerobically to lactate, it can be used to synthesize the polysaccharide glycogen, or it can be converted to body fat.

Aerobic respiration is the most common fate of blood glucose because most of the tissues in your body function aerobically most

FIGURE 9A-1 What Happens to the Sugar? In this essay we will see what happens in different parts of your body to the sugars and starch in a breakfast of milk and cereal.

of the time. Your brain is particularly noteworthy as an aerobic organ. It needs large amounts of energy to maintain the membrane potentials essential for the transmission of nerve impulses, and it normally depends solely on glucose to meet this need. In fact, your brain needs about 120 g of glucose per day, which is about 15% of your total energy consumption. When you are at rest, your brain accounts for about 60% of your glucose usage. The brain also accounts for about 20% of your total oxygen consumption. As the brain has no significant stores of glycogen, the supply of both oxygen and glucose must be continuous. Even a short interruption of either has dire consequences. Your heart has similar requirements because it is also a completely aerobic organ and has little or no energy reserves. The supply of oxygen and fuel molecules must therefore be constant, though the heart—unlike the brain—can use a variety of fuel molecules, including glucose, lactate, and fatty acids.

In addition to aerobic respiration in a wide variety of tissues, glucose can be catabolized anaerobically (fermented to lactate), especially in red blood cells and skeletal muscle cells. Red blood cells have no mitochondria and depend exclusively on glycolysis to meet their energy needs. Skeletal muscle can function in either the presence or the absence of oxygen. When you exert yourself strenuously, oxygen becomes limiting, so the rate of glycolysis exceeds that of aerobic respiration and excess pyruvate is converted to lactate. Lactate is released into the blood and taken up not only by your heart for use as fuel but also by gluconeogenic tissues, especially your liver. When lactate molecules enter a liver cell they are reoxidized to pyruvate, which is then used to make glucose by gluconeogenesis (see Figure 9-11). The glucose is returned to the bloodstream, where it can be taken up by muscle (or any other) cells again.

Skeletal muscle is the main source of blood lactate, and the liver is the primary site of gluconeogenesis, so a cycle is set up, as shown in **Figure 9A-2**. Lactate produced by glycolysis in hypoxic (oxygen-deficient) muscle cells is transported via the blood to the liver. There, gluconeogenesis converts the lactate to glucose, which is released into the blood. This process is called the *Cori cycle*, for Carl and Gerti Cori, whose studies in the 1930s and 1940s described it. The next time you are resting after strenuous exercise, think of what is happening: The lactate your muscle cells have just released into the bloodstream is being taken up by liver cells and converted back to glucose. The reason you are breathing heavily is to provide the oxygen your body needs to return your muscle cells to aerobic conditions and to generate all the ATP and GTP needed for gluconeogenesis in your liver and for rebuilding body glycogen stores.

Glycogen storage is the third significant fate of blood glucose. Glycogen is stored primarily in the cells of your liver and skeletal muscle. Muscle glycogen is used to supply glucose during times of strenuous exertion. Liver glycogen, on the other hand, is used as a source of glucose when the liver is stimulated hormonally to release glucose into the bloodstream to maintain the blood glucose level.

The fourth possible fate of blood glucose is its use for the synthesis of body fat. The route to fat is via pyruvate to acetyl CoA, just as in the initial phase of aerobic respiration. Whenever you eat

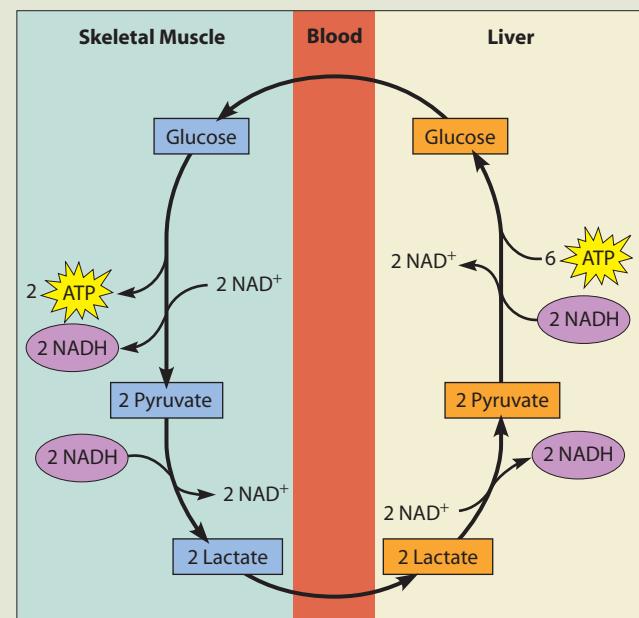

FIGURE 9A-2 The Cori Cycle: The Link Between Glycolysis in Muscle Cells and Gluconeogenesis in the Liver. Skeletal muscle cells derive much of their energy from glycolysis, especially during anaerobic periods of strenuous exercise. The lactate produced in this way is transported by the bloodstream to the liver, where it is reoxidized to pyruvate. Pyruvate is used as the substrate for gluconeogenesis within the liver, generating glucose that is then returned to the blood.

more food than your body needs for energy and for the biosynthesis of other molecules, excess glucose is oxidized to acetyl CoA, used for the synthesis of triacylglycerols, and then stored as body fat, especially in adipose tissue that is specialized for this purpose. Thus, your body has three sources of energy at all times: the glucose in your blood, the glycogen in your liver and skeletal muscle cells, and the triacylglycerols stored in adipose tissue.

To conclude, let's come back to our original question: "What happens to the sugar?" All the glucose and other sugars in your body come originally from the food you eat—either as monosaccharides directly or from the breakdown of disaccharides and polysaccharides in your intestinal tract. The ultimate fate of that glucose is oxidation to CO_2 and water, which you then exhale and excrete. But in the meantime, glucose molecules can circulate in your bloodstream or be stored as glycogen in liver or muscle cells. In its circulating form, glucose can be oxidized immediately by aerobic tissues such as the brain, it can be converted to lactate and become a part of the Cori cycle, or it can be used to synthesize glycogen or fat for storage.

So although it may look like just a modest spoonful of sugar as you sprinkle it on your cereal or add it to your coffee, it plays an important role in the energy metabolism of all of the cells in your body.

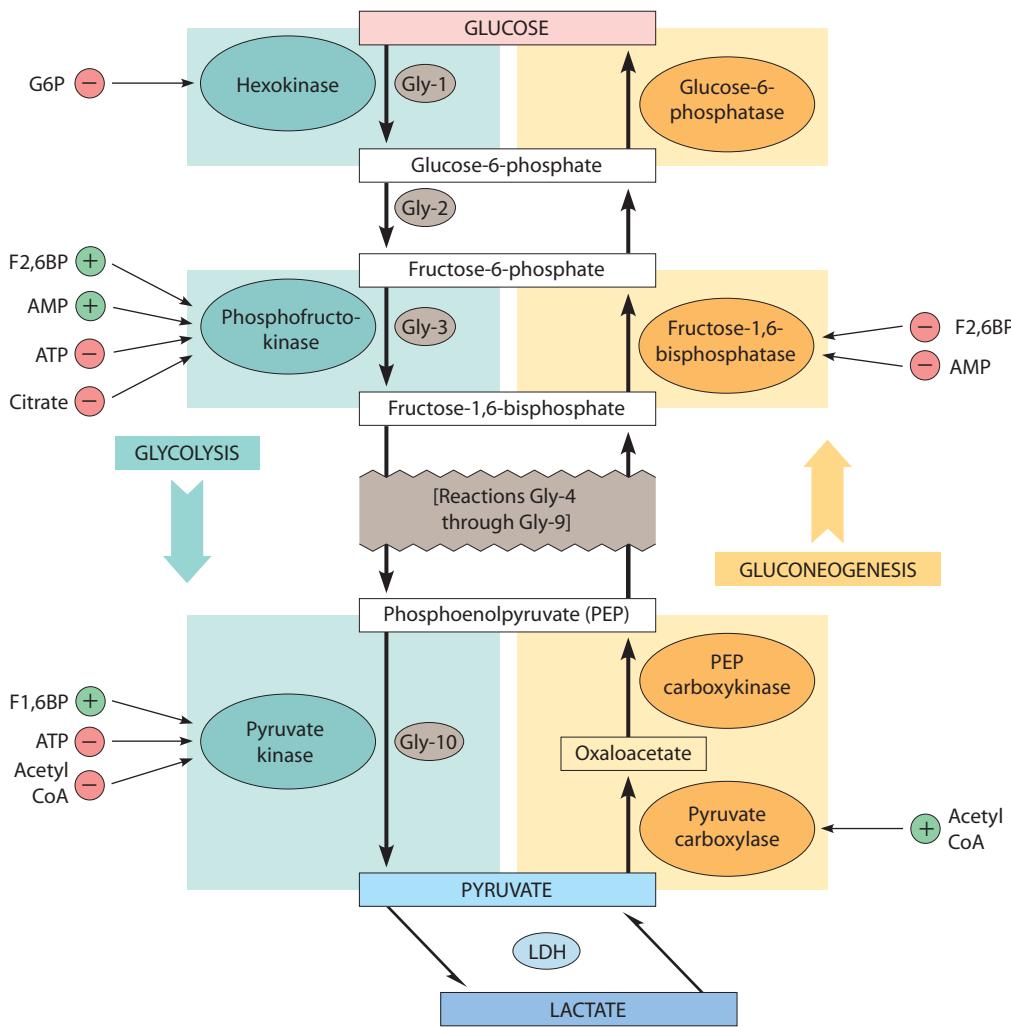

FIGURE 9-12 The Regulation of Glycolysis and Gluconeogenesis. Glycolysis and gluconeogenesis are regulated in a reciprocal manner. In both cases, regulation involves allosteric activation (+) or inhibition (−) of enzymes that catalyze reactions unique to the pathway. For glycolysis, the key regulatory enzymes are those that catalyze the three irreversible reactions unique to this pathway (green). For gluconeogenesis, two of the four bypass enzymes (gold) that are unique to this pathway are the main sites of allosteric regulation. Allosteric regulators include acetyl CoA, AMP, ATP, citrate, fructose-1,6-bisphosphate (F1,6BP), fructose-2,6-bisphosphate (F2,6BP), and glucose-6-phosphate (G6P). Acetyl CoA and citrate are intermediates in aerobic respiration. F2,6BP is synthesized by phosphofructokinase-2 (PFK-2), as shown in Figure 9-13b.

Moreover, the effects of the regulatory agents make sense—that is, they are invariably in the direction one would predict, based on an understanding of the role each pathway plays in the cell. Consider, for example, the effects of ATP and AMP. When the concentration of ATP is low and the AMP concentration is high, the cell is clearly low on energy, so it is reasonable for AMP to activate glycolysis. Conversely, as the ATP concentration increases and the AMP concentration decreases, the stimulatory effects of AMP on glycolysis lessen. The inhibitory effect of ATP on both PFK-1 and pyruvate kinase comes into play, reducing the rate of glycolysis.

You may be surprised to learn that ATP is an allosteric inhibitor of PFK-1 because this enzyme uses ATP as a substrate. That seems contradictory because increases in substrate concentration should *increase* the rate of an

enzyme-catalyzed reaction. This apparent contradiction is readily explained, however. As an allosteric enzyme, PFK-1 has both an active site and an allosteric site. The active site of PFK-1 has a high affinity for ATP, whereas the allosteric site has a low affinity for ATP. Thus, at low ATP concentrations, binding occurs at the catalytic site but not at the allosteric site, so most of the PFK-1 molecules remain in the active form and glycolysis proceeds. As the ATP concentration increases, however, binding is enhanced at the allosteric site, stabilizing the inactive form of PFK-1 and thereby serving to slow down the whole glycolytic sequence.

Both the glycolytic and the gluconeogenic pathways (Figure 9-12) are also subject to allosteric regulation by compounds involved in respiration. As we will learn in the next chapter, acetyl CoA and citrate are key intermediates in an aerobic pathway called the *tricarboxylic acid cycle*.

High levels of acetyl CoA and citrate indicate that the cell is well supplied with substrate for the next phase of respiratory metabolism beyond pyruvate. Thus, it is not surprising to find that acetyl CoA and citrate both have inhibitory effects on glycolysis, thereby decreasing the rate at which pyruvate is formed. Similarly, the stimulatory effect of acetyl CoA on gluconeogenesis is consistent with the availability of pyruvate for conversion to glucose.

Fructose-2,6-Bisphosphate Is an Important Regulator of Glycolysis and Gluconeogenesis

Although each of the preceding mechanisms plays a significant role in the regulation of glycolysis and gluconeogenesis, the most important regulator of both pathways is **fructose-2,6-bisphosphate (F2,6BP)**. F2,6BP is synthesized by the ATP-dependent phosphorylation of fructose-6-phosphate on carbon number 2. This is the same type of reaction that produces fructose-1,6-bisphosphate in Reaction Gly-3 in the glycolytic pathway by phosphorylation of fructose-6-phosphate on carbon number 1. However, synthesis of F2,6BP is catalyzed by a separate form of phosphofructokinase, which is called **phosphofructokinase-2 (PFK-2)** to distinguish it from PFK-1, the glycolytic enzyme. As we saw in Figure 9-12, F2,6BP activates the glycolytic enzyme (PFK-1) that phosphorylates fructose-6-phosphate, and it inhibits the gluconeogenic enzyme (FBPase) that catalyzes the reverse reaction.

Figure 9-13 depicts these regulatory roles of PFK-2 and F2,6BP in the human body in more detail. The activity of PFK-2 depends on the phosphorylation status of one of its subunits. The kinase activity of the enzyme is high when that subunit is in the unphosphorylated form and low when it is phosphorylated. The phosphorylation of PFK-2 by ATP is catalyzed by a protein kinase (Figure 9-13b). The activity of this enzyme depends, in turn, on cyclic AMP (cAMP), which is a key intermediate in many cellular signal transduction pathways (see Figure 14-6).

In addition to its *phosphofructokinase* activity responsible for synthesis of F2,6BP, PFK-2 has a *fructose-2,6-bisphosphatase* activity that removes the phosphate group from F2,6BP, converting the compound back to fructose-6-phosphate (Figure 9-13). This activity is also regulated by cAMP-stimulated phosphorylation, but in this case phosphorylation increases the activity of the enzyme. Because it has two separate catalytic activities, PFK-2 is called a *bifunctional enzyme*.

As noted earlier, F2,6BP activates the glycolytic enzyme PFK-1 (Figure 9-13d) and inhibits the gluconeogenic enzyme FBPase (Figure 9-13e). cAMP, in turn, affects the F2,6BP concentration in two ways: It inactivates the PFK-2 kinase activity and stimulates the F2,6BPase phosphatase activity. Both of these effects tend to decrease the concentration of F2,6BP in the cell. This change leads, in turn, to less stimulation of PFK-1 and less inhibition of fructose-1,6-bisphosphatase, thereby decreasing the glycolytic activity and increasing the gluconeogenic activity.

The effects of cAMP shown in Figure 9-13 are important in hormonal regulation because the cAMP level in liver cells is controlled primarily by the hormones glucagon and epinephrine (adrenalin). These hormones cause an increase in cAMP concentration, thereby stimulating gluconeogenesis when more glucose is needed. Moreover, the increase in cAMP concentration stimulates a regulatory cascade that increases the rate of glycogen breakdown (see Figure 14-22). Not surprisingly, the effect of cAMP on glycogen synthesis is just the opposite: Whether triggered by glucagon or epinephrine, an increase in liver cAMP concentration leads to a decrease in the rate of glycogen formation. For further details on hormonal regulation and the role of cAMP in mediating hormonal effects, see the discussion on hormonal signal transduction in Chapter 14.

Novel Roles for Glycolytic Enzymes

It is easy to get the impression that, for a fundamental and ubiquitous pathway like glycolysis, we have fully described its individual steps and learned “all there is to know” about the enzymes involved. But, as we often discover in biology, there may be surprises in store. One such surprise is the discovery that several of the glycolytic enzymes have regulatory functions that, at first glance, seem unrelated to their roles as catalysts in specific reactions in glycolysis. These functions include transcriptional regulation, stimulation of cell motility, and regulation of *apoptosis*—the process of programmed cell death.

For example, the enzyme hexokinase, which catalyzes the ATP-dependent phosphorylation of glucose to initiate the glycolytic sequence (Gly-1 in Figure 9-7), has been shown to be a transcriptional regulator in yeast cells. An isoform known as hexokinase 2 becomes localized in the nucleus in response to high levels of glucose. In the nucleus, it acts as a transcriptional repressor to down-regulate the expression of genes required for catabolism of sugars other than glucose. In mammals, four isoforms of hexokinase have been discovered. One isoform displays increased expression in tumor cells, which show increased glycolysis even in the presence of oxygen. Another isoform binds to mitochondria and is believed to coordinate glycolysis with mitochondrial respiration. It also appears to act as an inhibitor of apoptosis in cells with a plentiful supply of glucose. As you can see, we have much more to learn about a gene once thought to serve merely a “housekeeping” function in supplying cellular energy.

Other glycolytic enzymes, including glyceraldehyde-3-phosphate dehydrogenase (GAPDH; Gly-6) and enolase (Gly-9), also have DNA-binding abilities and can act as transcriptional regulators. GAPDH—along with lactate dehydrogenase, the enzyme that converts pyruvate to lactate in fermentation—can act as a transcriptional activator during cell division. GAPDH activity in this role is stimulated by NAD⁺ and inhibited by NADH. Thus, GAPDH is thought to serve as a link between energy metabolism and regulation of cell division, a process requiring a plentiful

(a) Regulation of PFK-2 activities by reversible phosphorylation. In response to glucagon and epinephrine, cAMP levels rise and PFK-2 is phosphorylated by a cAMP-activated protein kinase. In the absence of cAMP, it is dephosphorylated by a phosphatase. The phosphorylation state of PFK-2 determines which of its two catalytic activities it will have.

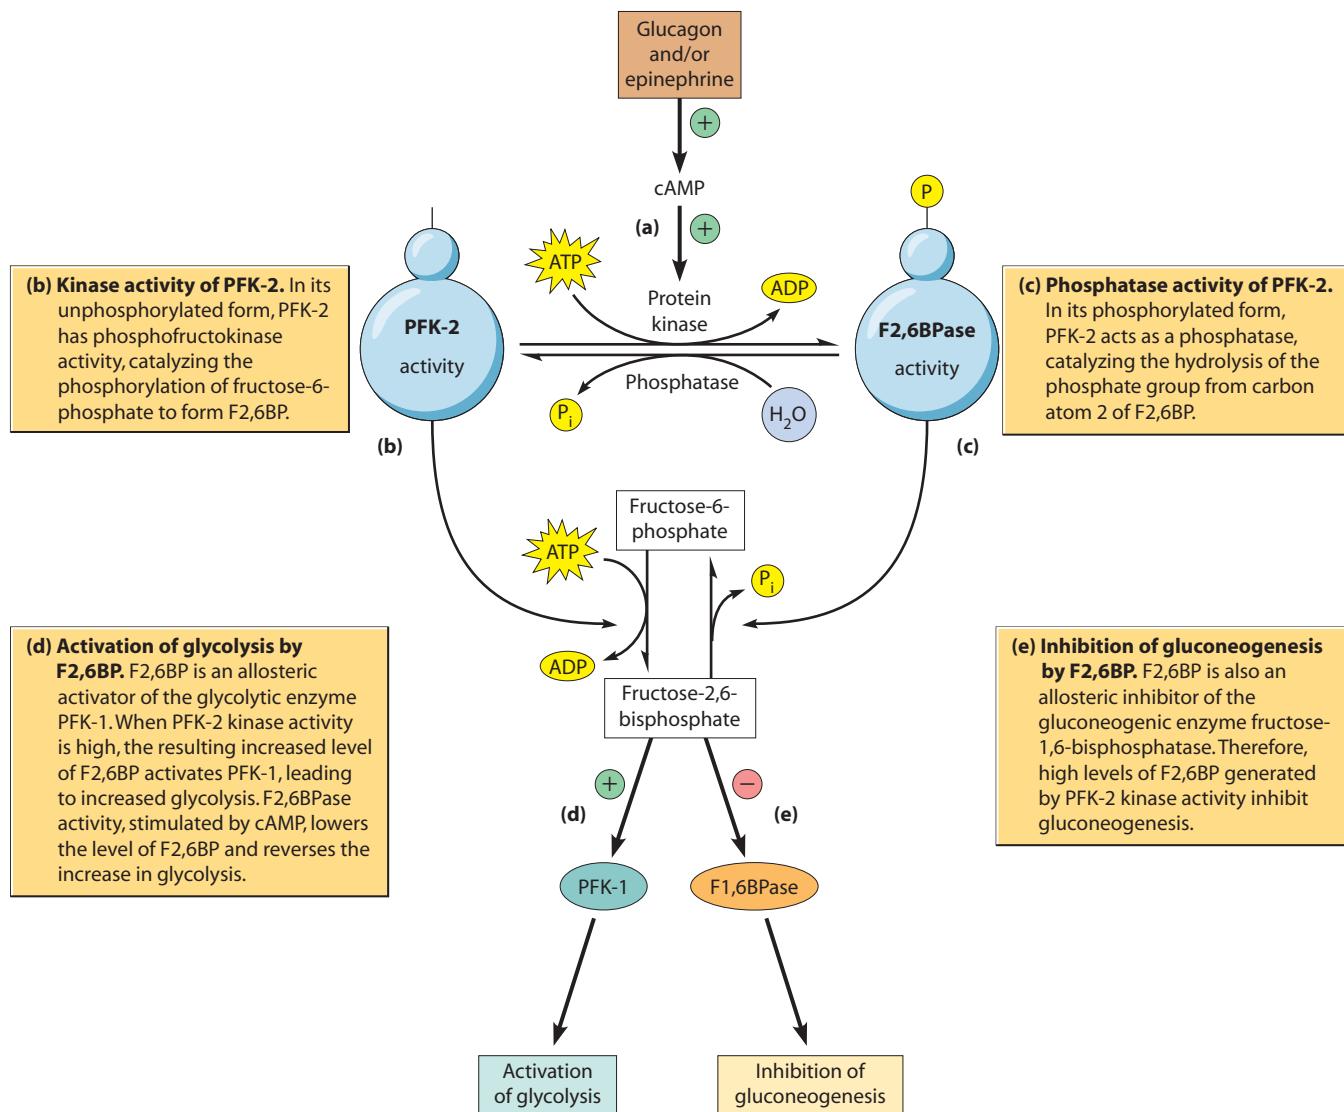

FIGURE 9-13 The Regulatory Roles of PFK-2 and F2,6BP. Phosphofructokinase-2 (PFK-2) is a bifunctional enzyme with two opposing catalytic activities that depend upon its own phosphorylation state (a–c). Which of the two activities it has depends on the presence of hormonal signals and determines the level of fructose-2,6-bisphosphate (F2,6BP), an activator of glycolysis (d) and inhibitor of gluconeogenesis (e).

supply of ATP. GAPDH is overexpressed in cells undergoing programmed cell death in response to cellular injury and accumulates in the nuclei of these cells. It is proposed to be an intracellular sensor of oxidative stress, with a possible link to neurodegenerative diseases.

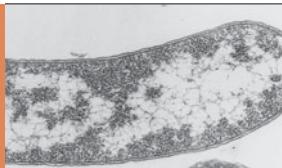

Other recent work suggests that enolase (Gly-9) can also act as a transcriptional repressor. It inhibits expression of the cancer-inducing *MYC* oncogene, which encodes a protein overexpressed in a wide variety of tumor cells. Enolase expression was shown to be down-regulated in lung cancer cells, and low expression of enolase correlates with poor survival of lung cancer patients.

Another surprising role for a glycolytic enzyme was revealed in work showing the involvement of phosphoglucoisomerase (PGI; Gly-2) in cell motility and migration during cancer cell *metastasis* (metastasis is the release of cells from malignant tumors into the bloodstream, where they can be transported throughout the body to establish secondary tumors). As an enzyme in the cell cytoplasm, PGI catalyzes the conversion of glucose-6-phosphate to fructose-6-phosphate. However, PGI has also been shown to be secreted from tumor cells, and the secreted form of PGI stimulates high levels of cell migration and proliferation. Moreover, PGI promotes the

growth of fibroblasts (connective tissue cells), and the overexpression of PGI induces transformation of fibroblasts to cancer cells.

Clearly, there is much more to learn about the glycolytic enzymes, which for many years were thought to play relatively mundane roles as catalysts in energy-producing reactions. We now know that several of these enzymes have regulatory roles as well. They may help to integrate

metabolic pathways with energy-dependent cell functions, such as cell division, apoptosis, and cell motility. So, as you learn about aerobic respiration and photosynthesis in the next two chapters, we hope you will avoid the urge to think that you must simply memorize “all there is to know” about these well-characterized biochemical pathways. Instead, keep in mind that some of the enzymes involved are revealing surprising new secrets.

SUMMARY OF KEY POINTS

Metabolic Pathways

- Metabolic pathways in cells are usually either anabolic (synthetic) or catabolic (degradative). Catabolic reactions provide the energy necessary to drive the anabolic reactions.

ATP: The Universal Energy Coupler

- ATP is useful for storing chemical energy in cells because its terminal anhydride bond has an intermediate free energy of hydrolysis. This allows ATP to serve as a donor of phosphate groups to a number of biologically important molecules such as glucose. It also allows ADP to serve as an acceptor of phosphate groups from molecules such as PEP.

Chemotrophic Energy Metabolism

- Most chemotrophs derive the energy needed to generate ATP from the catabolism of organic nutrients such as carbohydrates, fats, and proteins. They do so either by fermentative processes in the absence of oxygen or by aerobic respiratory metabolism in the presence of oxygen.
- Although glycolysis may seem overly complex, it represents a mechanism by which glucose can be degraded in dilute solution at temperatures compatible with life, with a large portion of the free energy yield conserved as ATP.

Glycolysis and Fermentation: ATP Generation Without the Involvement of Oxygen

- Using glucose as a prototype substrate, catabolism under both anaerobic and aerobic conditions begins with glycolysis, a ten-step pathway that converts glucose into pyruvate. In most cases, this leads to the production of two molecules of ATP per molecule of glucose.
- In the absence of oxygen, the reduced coenzyme NADH generated during glycolysis must be reoxidized at the expense of pyruvate, leading to fermentation end-products such as lactate or ethanol plus carbon dioxide.

Alternative Substrates for Glycolysis

- Although usually written with glucose as the starting substrate, the glycolytic sequence is also the mainstream

pathway for catabolizing a variety of related sugars, such as fructose, galactose, and mannose.

- Glycolysis is also used to metabolize the glucose-1-phosphate derived by phosphorolytic cleavage of storage polysaccharides such as starch or glycogen.

Gluconeogenesis

- Gluconeogenesis is, in a sense, the opposite of glycolysis because it is the pathway used by some cells to synthesize glucose from three- and four-carbon starting materials such as pyruvate. However, the gluconeogenic pathway is not just glycolysis in reverse.
- The two pathways have seven enzyme-catalyzed reactions in common, but the three most exergonic reactions of glycolysis are bypassed in gluconeogenesis by reactions that render the pathway exergonic in the gluconeogenic direction by the input of energy from ATP and GTP.

The Regulation of Glycolysis and Gluconeogenesis

- Glycolysis and gluconeogenesis are regulated by modifying the activity of enzymes that are unique to each pathway. These enzymes are regulated by one or more key intermediates in aerobic respiration, including ATP, ADP, AMP, acetyl CoA, and citrate.
- An important allosteric regulator of both glycolysis and gluconeogenesis is fructose-2,6-bisphosphate. Its concentration depends on the relative kinase and phosphatase activities of the bifunctional enzyme PFK-2.
- PFK-2 in turn is regulated by the hormones glucagon and epinephrine via their effects on the cyclic AMP concentration in cells.

Novel Roles for Glycolytic Enzymes

- In addition to their roles as catalysts, several well-known glycolytic enzymes have recently been shown to play regulatory roles in cells, affecting processes such as cell division, programmed cell death, and cancer cell migration.

MAKING CONNECTIONS

In this chapter, you have learned how cells get energy from the partial oxidation of glucose in glycolysis and how they conserve this energy as ATP. These processes require the concerted action of various highly regulated enzymes, operating according to the principles of bioenergetics presented in Chapters 5 and 6. Next, in Chapter 10, you will see how the pyruvic acid from glycolysis is further oxidized to CO_2 during aerobic respiration in the mitochondria of eukaryotic cells, generating considerably more ATP. In mitochondria, ATP production is dependent upon several integral membrane proteins, which were introduced in Chapters 7 and 8. In later chapters, you will see how

enzymes are produced using the information in a cell's DNA and how they are processed and targeted to their correct locations in the cell (Chapters 12, 21, and 22). Perhaps you are wondering: Where did the glucose come from in the first place? In Chapter 11, you will learn how, during photosynthesis, energy captured from the sun is used to drive the endergonic reduction of CO_2 to glucose and other carbohydrates. As with all cellular processes we will study, a solid understanding of macromolecular biochemistry (Chapters 2 and 3) and cellular organelles (Chapter 4) will help you to appreciate how the cell functions as a discrete biological unit.

PROBLEM SET

More challenging problems are marked with a •.

9-1 High-Energy Bonds. When first introduced by Fritz Lipmann in 1941, the term *high-energy bond* was considered a useful concept for describing the energetics of biochemical molecules and reactions. However, the term can lead to confusion when relating ideas about cellular energy metabolism to those of physical chemistry. To check out your own understanding, indicate whether each of the following statements is true (T) or false (F). If false, reword the statement to make it true.

- (a) Energy is stored in special high-energy bonds in molecules such as ATP and is released when these bonds are broken.
- (b) Energy is always released whenever a covalent bond is formed and is always required to break a covalent bond.
- (c) To a physical chemist, *high-energy bond* means a very stable bond that requires a lot of energy to break; whereas to a biochemist, the term is likely to mean a bond that releases a lot of energy upon hydrolysis.
- (d) The terminal phosphate of ATP is a high-energy phosphate that takes its high energy with it when it is hydrolyzed.
- (e) Phosphoester bonds are low-energy bonds because they require less energy to break than the high-energy bonds of phosphoanhydrides.
- (f) The term *high-energy molecule* should be thought of as a characteristic of the reaction the molecule is involved in—not as an intrinsic property of a particular bond within that molecule.

9-2 The History of Glycolysis. Following are several historical observations that led to the elucidation of the glycolytic pathway. In each case, suggest a metabolic basis for the observed effect, and explain the significance of the observation for the elucidation of the pathway.

- (a) Alcoholic fermentation in yeast extracts requires a heat-labile fraction originally called *zymase* and a heat-stable fraction (*cozymase*) that is necessary for the activity of zymase.
- (b) Alcoholic fermentation does not take place in the absence of inorganic phosphate.

(c) In the presence of iodoacetate, a known inhibitor of glycolysis, fermenting yeast extracts accumulate a doubly phosphorylated hexose.

(d) In the presence of fluoride ion, another known glycolytic inhibitor, fermenting yeast extracts accumulate two phosphorylated three-carbon acids.

9-3 Glycolysis in 25 Words or Less. Complete each of the following statements about the glycolytic pathway in 25 words or less.

- (a) Although the brain is an obligately aerobic organ, it still depends on glycolysis because ...
- (b) Although one of its reactions is an oxidation, glycolysis can proceed in the absence of oxygen because ...
- (c) What happens to the pyruvate generated by the glycolytic pathway depends on ...
- (d) If you bake bread or brew beer, you depend on glycolysis for ...
- (e) Two organs in your body that can use lactate are ...
- (f) The synthesis of glucose from lactate in a liver cell requires more molecules of nucleoside triphosphates (ATP and GTP) than are formed during the catabolism of glucose to lactate in a muscle cell because ...

9-4 Energetics of Carbohydrate Utilization. The anaerobic fermentation of free glucose has an ATP yield of two ATP molecules per molecule of glucose. For glucose units in a glycogen molecule, the yield is three ATP molecules per molecule of glucose. The corresponding value for the disaccharide sucrose is two ATP molecules per molecule of monosaccharide if the sucrose is eaten by an animal, but two and a half ATP molecules per molecule of monosaccharide if the sucrose is metabolized by a bacterium.

- (a) Explain why the glucose units present in glycogen have a higher ATP yield than free glucose molecules.
- (b) What is the likely mechanism for sucrose breakdown in the gut of an animal to explain the energy yield of two ATP molecules per molecule of monosaccharide?
- (c) Based on what you know about the process of glycogen breakdown, suggest a mechanism for bacterial sucrose

metabolism that is consistent with an energy yield of two and a half ATP molecules per molecule of monosaccharide.

- (d) What energy yield (in molecules of ATP per molecule of monosaccharide) would you predict for the bacterial catabolism of raffinose, a trisaccharide?

9-5 Glucose Phosphorylation. The direct phosphorylation of glucose by inorganic phosphate is a thermodynamically unfavorable reaction:

In the cell, glucose phosphorylation is accomplished by coupling the reaction to the hydrolysis of ATP, a highly exergonic reaction:

Typical concentrations of these intermediates in yeast cells are as follows:

$$[\text{glucose-6-phosphate}] = 0.08 \text{ mM} \quad [\text{ATP}] = 1.8 \text{ mM}$$
$$[\text{P}_i] = 1.0 \text{ mM} \quad [\text{ADP}] = 0.15 \text{ mM}$$

Assume a temperature of 25°C for all calculations.

- (a) What minimum concentration of glucose would have to be maintained in a yeast cell for direct phosphorylation (Reaction 9-21) to be thermodynamically spontaneous? Is this physiologically reasonable? Explain your reasoning.
- (b) What is the overall equation for the coupled (ATP-driven) phosphorylation of glucose? What is its ΔG° value?
- (c) What minimum concentration of glucose would have to be maintained in a yeast cell for the coupled reaction to be thermodynamically spontaneous? Is this physiologically reasonable?
- (d) By about how many orders of magnitude is the minimum required glucose concentration reduced when the phosphorylation of glucose is coupled to the hydrolysis of ATP?
- (e) Assuming a yeast cell to have a glucose concentration of 5.0 mM, what is $\Delta G'$ for the coupled phosphorylation reaction?

9-6 Ethanol Intoxication and Methanol Toxicity. The enzyme alcohol dehydrogenase was mentioned in this chapter because of its role in the final step of alcoholic fermentation. However, the enzyme also occurs commonly in aerobic organisms, including humans. The ability of the human body to catabolize the ethanol in alcoholic beverages depends on the presence of alcohol dehydrogenase in the liver. One effect of ethanol intoxication is a dramatic decrease in the NAD^+ concentration in liver cells, which decreases the aerobic utilization of glucose. Methanol, on the other hand, is not just an intoxicant; it is a deadly poison due to the toxic effect of the formaldehyde to which it is converted in the liver.

- (a) Why does ethanol consumption lead to a reduction in NAD^+ concentration and to a decrease in aerobic respiration?
- (b) Most of the unpleasant effects of hangovers result from an accumulation of acetaldehyde and its metabolites. Where does the acetaldehyde come from?
- (c) The medical treatment for methanol poisoning usually involves administration of large doses of ethanol. Why is this treatment effective?

9-7 Propionate Fermentation. Although lactate and ethanol are the best-known products of fermentation, other pathways are also known, some with important commercial applications. Swiss cheese production, for example, depends on the bacterium *Propionibacterium freudenreichii*, which converts pyruvate to propionate ($\text{CH}_3-\text{CH}_2-\text{COO}^-$). Fermentation of glucose to propionate always generates at least one other product as well.

- (a) Why is it not possible to devise a scheme for the fermentation of glucose with propionate as the sole end-product?
- (b) Suggest an overall scheme for propionate production that generates only one additional product, and indicate what that product might be.
- (c) If you know that Swiss cheese production actually requires both propionate and carbon dioxide and that both are produced by *Propionibacterium* fermentation, what else can you now say about the fermentation process that this bacterium carries out?

9-8 Glycolysis and Gluconeogenesis. As Figure 9-11 indicates, gluconeogenesis is accomplished by what is essentially the reverse of the glycolytic pathway but with bypass reactions in place of the first, third, and tenth reactions in glycolysis.

- (a) Explain why it is not possible to accomplish gluconeogenesis by a simple reversal of all the reactions in glycolysis.
- (b) Write an overall reaction for gluconeogenesis that is comparable to Reaction 9-16 for glycolysis.
- (c) Explain why gluconeogenesis requires the input of six molecules of nucleoside triphosphates (four ATPs and two GTPs) per molecule of glucose synthesized, whereas glycolysis yields only two molecules of ATP per molecule of glucose.
- (d) Assuming concentrations of ATP, ADP, and P_i are such that $\Delta G'$ for the hydrolysis of ATP is about -10 kcal/mol , what is the approximate $\Delta G'$ value for the overall reaction for gluconeogenesis that you wrote in part b?
- (e) With all of the enzymes for glycolysis and gluconeogenesis present in a liver cell, how does the cell "know" whether it should be synthesizing or catabolizing glucose at any given time?

• 9-9 Trypanosomes, Glycosomes, and the Compartmentalization of Glycolysis. In most organisms, all of the glycolytic enzymes occur in the cytosol. However, in certain parasitic protozoa known as *trypanosomes*, the enzymes that catalyze the first seven steps of glycolysis are compartmentalized in membrane-bounded organelles called *glycosomes*.

- (a) What experimental evidence most likely led to the discovery that seven of the ten glycolytic enzymes are localized in an organelle rather than in the cytosol?
- (b) What benefit do you think trypanosomes derive from this compartmentalization of glycolysis?
- (c) What specific transport proteins do you predict are present in the glycosomal membrane? Explain.
- (d) Glycosomes are usually regarded as a specialized kind of peroxisome. What other enzymes would you therefore expect to find in this organelle? Explain.

• 9-10 You've Got Some Explaining to Do. Explain each of the following observations:

- (a) In his classic studies of glucose fermentation by yeast cells, Louis Pasteur observed that the rate of glucose consumption

by yeast cells was much higher under anaerobic conditions than under aerobic conditions.

- (b) In 1905, Arthur Harden and William Young found that addition of inorganic phosphate to a yeast extract stimulated and prolonged the fermentation of glucose.
- (c) An alligator is normally very sluggish but, if provoked, is capable of rapidly moving its legs, jaws, and tail. However, such bursts of activity must be followed by long periods of recovery.
- (d) Fermentation of glucose to lactate is an energy-yielding process, although it involves no net oxidation (i.e., even though the oxidation of glyceraldehyde-3-phosphate to glyceraldehyde-2-keto-3-deoxy-6-phosphate is accompanied by the reduction of pyruvate to lactate and no net accumulation of NADH occurs).

• 9-11 Arsenate Poisoning. Arsenate (HAsO_4^{2-}) is a potent poison to almost all living systems. Among other effects, arsenate is known to uncouple the phosphorylation event from the oxidation of glyceraldehyde-3-phosphate. This uncoupling occurs because the enzyme involved, glyceraldehyde-3-phosphate dehydrogenase, can utilize arsenate instead of inorganic phosphate, forming glyceraldehyde-1-arseno-3-phosphate. This product is a highly unstable compound that immediately undergoes nonenzymatic hydrolysis into glyceraldehyde-3-phosphate and free arsenate.

- (a) In what sense might arsenate be called an *uncoupler* of substrate-level phosphorylation?
- (b) Why is arsenate such a toxic substance for an organism that depends critically on glycolysis to meet its energy needs?
- (c) Can you think of other reactions that are likely to be uncoupled by arsenate in the same way as the glyceraldehyde-3-phosphate dehydrogenase reaction?

9-12 Life without phosphofructokinase. Many bacteria do not have phosphofructokinase-1 (Gly-3) and thus cannot convert glucose to fructose-1,6-bisphosphate. Instead they use a

pathway known as the Entner–Doudoroff pathway to partially oxidize glucose and convert it to two three-carbon molecules. See if you can draw the products of the first three steps of the pathway based on the following description:

- (a) In the first step, the ring form of glucose-6-phosphate is oxidized at carbon 1 to form 6-phosphogluconolactone, as the coenzyme NADP^+ is reduced to $\text{NADPH} + \text{H}^+$.
- (b) Next, the ring is broken by hydrolysis to form the carboxylic acid 6-phosphogluconate, which resembles glucose-6-phosphate but is more oxidized at carbon 1.
- (c) After a molecule of water is removed, a molecule of 2-keto-3-deoxy-6-phosphogluconate is formed.
- (d) Because an aldolase splits this six-carbon molecule into pyruvate plus glyceraldehyde-3-phosphate (which is then converted to another molecule of pyruvate), how will the final ATP yield per glucose compare with typical glycolysis?
- (e) Given an alternate source of cellular ATP, how would you predict lactic acid production might be affected by the addition of arsenate (see Problem 9-11) in these bacteria compared to bacteria performing standard glycolysis?

• 9-13 Regulation of Phosphofructokinase-1. Shown in **Figure 9-14** are plots of initial reaction velocity (expressed as % of V_{\max}) vs. fructose-6-phosphate concentration for liver phosphofructokinase (PFK-1) in the presence and absence of fructose-2,6-bisphosphate (F2,6BP) (Figure 9-14a) and in the presence of a low or high concentration of ATP (Figure 9-14b).

- (a) Explain the effect of F2,6BP on enzyme activity as shown in Figure 9-14a.
- (b) Explain the effect of the ATP concentration on the data shown in Figure 9-14b.
- (c) What assumptions do you have to make about the concentration of ATP in Figure 9-14a and about the concentration of F2,6BP in Figure 9-14b? Explain.

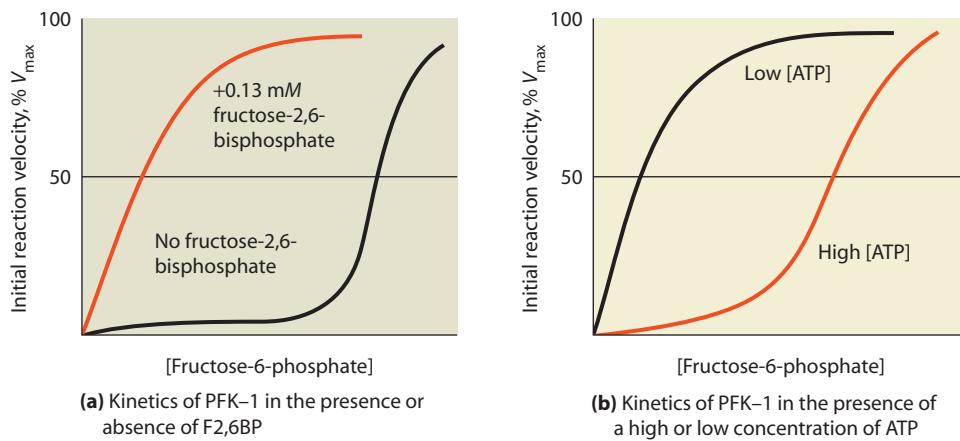

FIGURE 9-14 Allosteric Regulation of Phosphofructokinase-1. Shown here are Michaelis–Menten plots of liver phosphofructokinase (PFK-1) activity, depicting (a) the dependence of initial reaction velocity on concentration of the substrate fructose-6-phosphate in the presence (red line) or absence (black line) of fructose-2,6-bisphosphate and (b) the dependence of initial reaction velocity on fructose-6-phosphate concentration at high (red line) or low (black line) ATP concentrations. In both cases, initial reaction velocity is expressed as a percentage of V_{\max} , the maximum velocity. See Problem 9-13.

Chemotrophic Energy Metabolism: Aerobic Respiration

In the previous chapter, we learned that some cells meet their energy needs by anaerobic fermentation, either because they are strict anaerobes or because they are facultative cells functioning temporarily in the absence or scarcity of oxygen. However, we also noted that fermentation yields only modest amounts of energy due to the absence of an external electron acceptor. The electrons that are removed from glucose as it is partially oxidized during fermentation are transferred to pyruvate, and only two molecules of ATP can be generated per molecule of glucose.

In short, fermentation can meet energy needs, but the ATP yield is low because the cell has access to only a limited portion of the total free energy potentially available from the oxidizable molecules it uses as substrates. In addition, fermentation often results in the accumulation of waste products such as ethanol or lactate, which can be toxic to the cells if they accumulate.

Cellular Respiration: Maximizing ATP Yields

All of this changes dramatically when we come to **cellular respiration**, or **respiration** for short. With an external electron acceptor available, complete oxidation of substrates to CO₂ becomes possible, and ATP yields are much higher. By “external” we mean an electron acceptor that is not a by-product of glucose catabolism. When an “internal” electron acceptor such as pyruvate or acetaldehyde is used (as during fermentation) to accept electrons from NADH (see Figure 9-8), the by-products are not completely oxidized to CO₂.

As a formal definition, *cellular respiration is the flow of electrons, through or within a membrane, from reduced coenzymes to an external electron acceptor, usually accompanied by the generation of ATP*. We have already encountered NADH as the reduced coenzyme generated by the glycolytic catabolism of sugars or related compounds. As we will see shortly, two other coenzymes, FAD (for *flavin adenine*

dinucleotide) and *coenzyme Q* (or *ubiquinone*), also collect the electrons that are removed from oxidizable organic substrates and pass them to the terminal electron acceptor via a series of electron carriers, generating ATP in the process.

For many organisms, including us, the terminal electron acceptor is *oxygen*, the reduced form of this terminal electron acceptor is *water*, and the overall process is called **aerobic respiration**. Note that, in medical terminology at an organismal level, respiration refers to breathing, the uptake of oxygen. However, while many chemotrophs on Earth carry out aerobic respiration, a variety of terminal electron acceptors other than molecular oxygen can be used by other organisms, especially bacteria and archaea. Examples of alternative acceptors and their reduced forms include elemental sulfur (S/H₂S), protons (H⁺/H₂), and ferric ions (Fe³⁺/Fe²⁺). Respiratory processes that involve electron acceptors such as these require no molecular oxygen and are therefore examples of **anaerobic respiration**. Anaerobic respiratory processes play important roles in nutrient cycling and the overall energy economy of the biosphere. Here, however, we will concentrate on aerobic respiration because it is the basis of energy metabolism in the aerobic world of which we and most other familiar organisms are a part.

We will focus much of our attention on the *mitochondrion* (Figure 10-1) because most aerobic ATP production in eukaryotic cells takes place within this organelle. In bacterial cells, the roles of the plasma membrane and cytoplasm in energy production are analogous to the roles of the mitochondrial inner membrane and matrix, respectively.

Aerobic Respiration Yields Much More Energy than Fermentation Does

With oxygen available as the terminal electron acceptor, pyruvate can be oxidized completely to CO₂ instead of being used to accept electrons from NADH. Therefore,

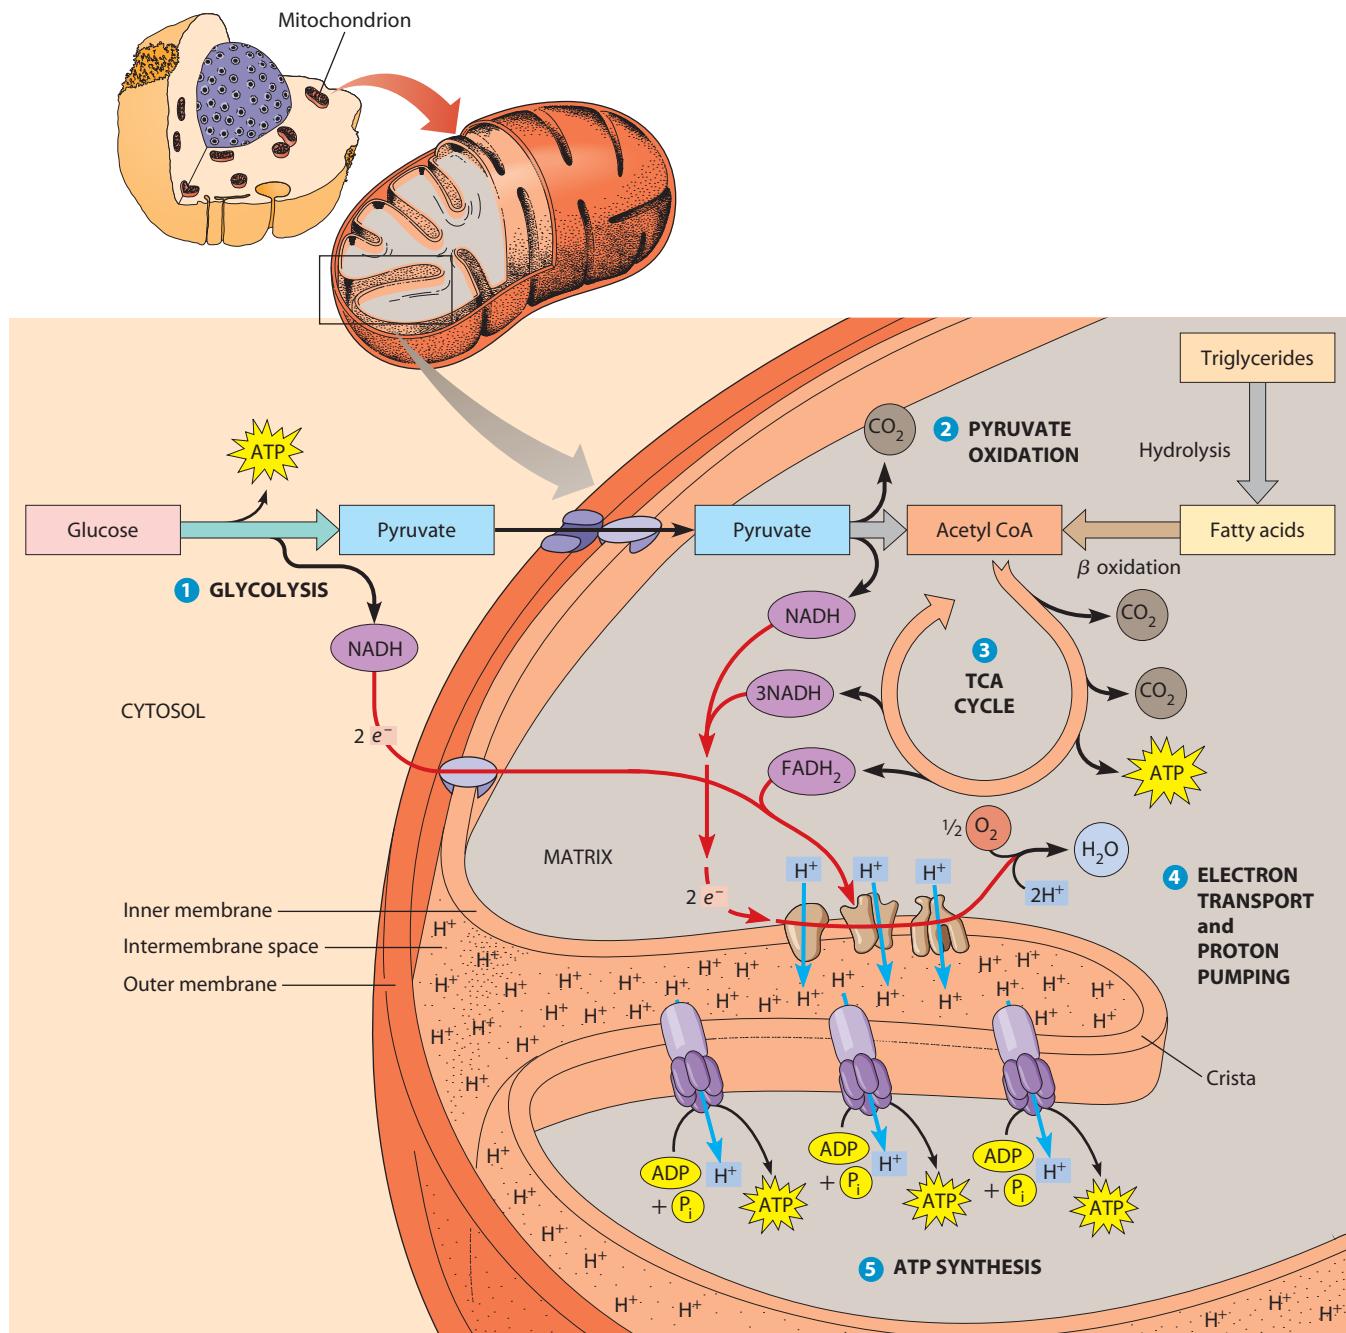

FIGURE 10-1 The Role of the Mitochondrion in Aerobic Respiration. The mitochondrion plays a central role in aerobic respiration. Most respiratory ATP production in eukaryotic cells occurs in this organelle. Oxidation of glucose and other sugars begins in the cytosol with glycolysis (stage 1), producing pyruvate. Pyruvate is transported across the inner mitochondrial membrane and is oxidized within the matrix to acetyl CoA (stage 2), the primary substrate of the tricarboxylic acid (TCA) cycle (stage 3). Acetyl CoA can also be formed by β oxidation of fatty acids. Electron transport is coupled to proton pumping (stage 4), with the energy of electron transport conserved as an electrochemical proton gradient across the inner membrane of the mitochondrion (or across the plasma membrane, in the case of prokaryotes). The energy of the proton gradient is used in part to drive the synthesis of ATP from ADP and inorganic phosphate (stage 5).

BioFlix® www.thecellplace.com Cellular respiration

aerobic respiration has the potential of generating up to 38 ATP molecules per glucose.

Oxygen makes all of this possible by serving as the terminal electron acceptor, thereby providing a means for the continuous reoxidation of NADH and other reduced

coenzymes. After these coenzyme molecules accept electrons from pyruvate and other oxidizable substrates, they can then transfer these electrons to oxygen. Aerobic respiration therefore involves oxidative pathways in which electrons are removed from organic substrates and

transferred to coenzyme carriers, which then transfer these electrons to oxygen, accompanied indirectly by the generation of ATP.

Respiration Includes Glycolysis, Pyruvate Oxidation, the TCA Cycle, Electron Transport, and ATP Synthesis

We will consider aerobic respiration in five stages, as shown in Figure 10-1. The first three stages involve substrate oxidation and the simultaneous reduction of coenzymes, and the second two involve coenzyme reoxidation and the generation of ATP. In cells, of course, all five stages occur continuously and simultaneously.

Stage ① is the *glycolytic pathway* that we encountered in Chapter 9. The steps of glycolysis are the same under aerobic and anaerobic conditions and result in the oxidation of glucose to pyruvate. However, in the presence of oxygen, the fate of the pyruvate is different (see Figure 9-8). Instead of serving as an electron acceptor, as occurs in anaerobic fermentation, pyruvate is further oxidized. In stage ②, pyruvate is oxidized to generate *acetyl coenzyme A* (*acetyl CoA*), which enters the *tricarboxylic acid (TCA) cycle* (stage ③). The TCA cycle completely oxidizes acetyl CoA to CO_2 and conserves most of the energy as high-energy reduced coenzyme molecules.

Stage ④ involves *electron transport*, or the transfer of electrons from reduced coenzymes to oxygen, coupled to the *active transport (pumping)* of protons across a membrane. The transfer of electrons from coenzymes to oxygen is exergonic and provides the energy that drives the pumping of protons across the membrane containing the carriers. This generates an *electrochemical proton gradient* across the membrane. In stage ⑤, the energy of this proton gradient is used to drive ATP synthesis in a process known as *oxidative phosphorylation*.

Our goal in this chapter is to understand the processes following glycolysis—the complete oxidation of pyruvate in the TCA cycle, electron transport from pyruvate via coenzymes to oxygen, and the formation of a proton gradient that drives ATP synthesis. We will begin our discussion of aerobic energy metabolism with a close look at the mitochondrion because of its prominent role in eukaryotic energy metabolism.

The Mitochondrion: Where the Action Takes Place

Our discussion of aerobic respiration starts with a description of the **mitochondrion** because most of aerobic energy metabolism in eukaryotic cells takes place within this organelle. Because of this, the mitochondrion is often called the “energy powerhouse” of the eukaryotic cell. As early as 1850, the German biologist Rudolph Kölliker described the presence of what he called “ordered arrays of particles” in muscle cells. Isolated particles were found to swell in water, leading Kölliker to conclude that each

particle was surrounded by a semipermeable membrane. These particles are now called *mitochondria* (singular: *mitochondrion*) and are believed to have arisen when bacterial cells were engulfed by larger cells but survived, taking up permanent residence in the host cell cytoplasm (see the Endosymbiotic Theory, Box 11A, page 298–299).

Evidence suggesting a role for this organelle in oxidative events began to accumulate almost a century ago. In 1913, for example, Otto Warburg showed that these particles could consume oxygen. However, most of our understanding of the role of mitochondria in energy metabolism came since the development of differential centrifugation, pioneered by Albert Claude (see Figure 12A-1, 327). Intact, functionally active mitochondria were first isolated by this technique in 1948 and were subsequently shown by Eugene Kennedy, Albert Lehninger, and others to be capable of carrying out all the reactions of the TCA cycle, electron transport, and oxidative phosphorylation.

Mitochondria Are Often Present Where the ATP Needs Are Greatest

Mitochondria are found in virtually all aerobic cells of eukaryotes and are prominent features of many cell types when examined by electron microscopy (Figure 10-2). Mitochondria are present in both chemotrophic and phototrophic cells and are therefore found not only in

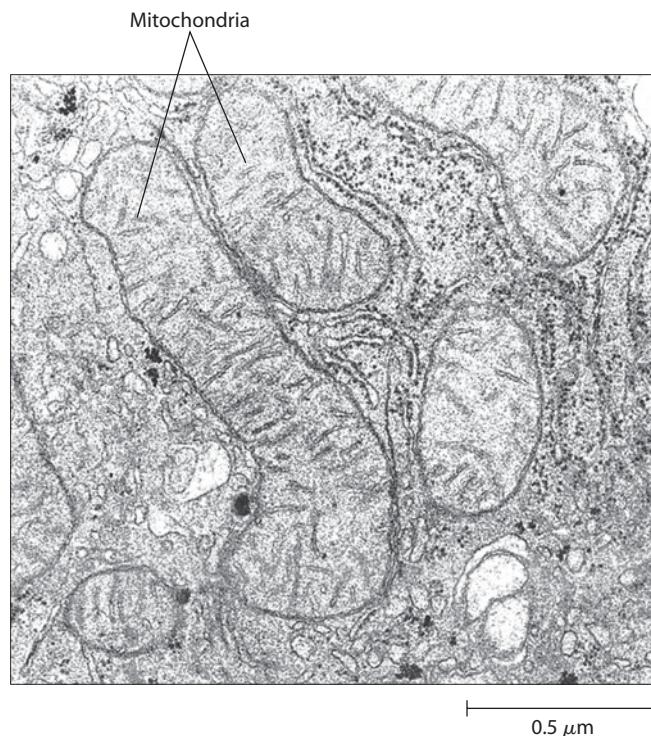

FIGURE 10-2 Mitochondria: One or Many? Mitochondria are prominent features in this cross section of a rat liver cell and were traditionally thought to be discrete oval structures. However, current research suggests that these may be separate slices through a single large multilobed mitochondrion (TEM).

animals but also in plants. Their occurrence in phototrophic cells reminds us that even photosynthetic organisms rely on respiration to meet energy and carbon needs during periods of darkness—and at all times in nonphotosynthetic tissue, such as the roots of plants.

The crucial role of the mitochondrion in meeting cellular ATP needs is often reflected in the localization of mitochondria within the cell. Frequently, mitochondria are clustered in regions of cells with the most intense metabolic activity and the greatest need for ATP. An especially good example is in muscle cells (see Figure 4-13). The mitochondria in these muscle cells are organized in rows along the fibrils responsible for contraction. A similar strategic localization of mitochondria occurs in flagella and cilia, as well as in sperm tails (see Figure 4-12).

Are Mitochondria Interconnected Networks Rather than Discrete Organelles?

When seen in an electron micrograph such as that in Figure 10-2, mitochondria typically appear as oval, sausage-shaped structures measuring one or more μm in length and 0.5–1.0 μm across. However, they can be seen in various shapes and sizes, depending on the cell type. This appearance has fostered the widely accepted view that mitochondria are discrete entities and, as such, are large and often very numerous organelles. In fact, a mitochondrion with these dimensions is similar in size to an entire bacterial cell and is the largest organelle in most animal cells other than the nucleus (see Figure 1A-1). (In plant cells, the chloroplasts and some of the vacuoles are also typically larger than the mitochondria.)

Calculations based on cross-sectional views of mitochondria in electron micrographs indicate that the number of mitochondria per cell is highly variable, ranging from one or a few per cell in many protists, fungi, and algae (and in some mammalian cells as well) up to a few thousand per cell in some tissues of higher plants and animals. Mammalian liver cells, for example, are thought to contain about 500–1000 mitochondria each, though only a small fraction of these are seen in a typical thin section prepared for electron microscopy, such as that shown in Figure 10-2.

The notion that the mitochondrial profiles seen in electron micrographs represent discrete organelles of known size and abundance has been challenged by the work of Hans-Peter Hoffman and Charlotte Avers. After examining a complete series of thin sections through an entire yeast cell, these investigators concluded that the oval profiles observed in individual micrographs all represent slices through a single large, extensively branched mitochondrion. Such results suggest that the number of mitochondria present in a cell may be considerably smaller than generally believed—and that the size of a mitochondrion may be much larger than can be calculated from individual cross-sectional profiles seen in thin-section electron micrographs.

Further support for the concept of mitochondria as interconnected networks (rather than many separate organelles) comes from studies in which intact living cells were examined by phase-contrast microscopy or by fluorescence microscopy using mitochondria-specific fluorescent dyes. Such investigations revealed that living cells contain large branched mitochondria in a dynamic state of flux, with segments of one mitochondrion frequently pinching off and fusing with another mitochondrion.

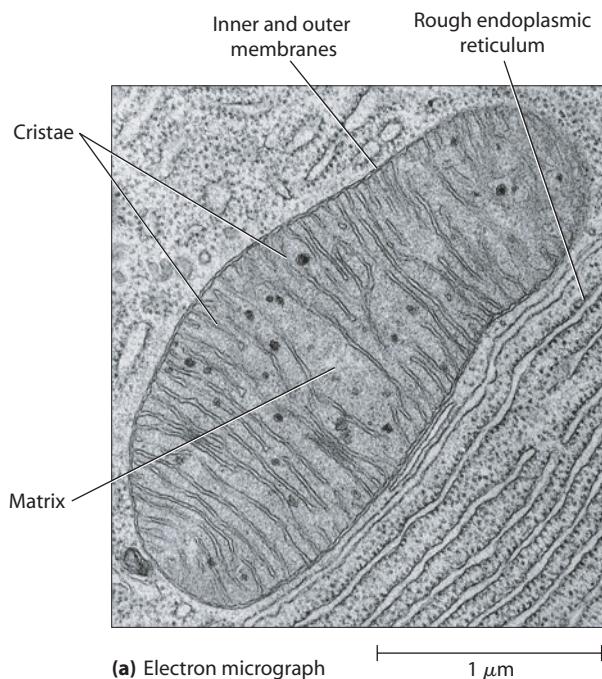

Most of the discussion and illustrations in this chapter will presume the conventional view of mitochondria as discrete entities, but keep in mind that what we regard as individual mitochondria may well be parts of a large, dynamic network instead, at least in some types of cells.

The Outer and Inner Membranes Define Two Separate Compartments and Three Regions

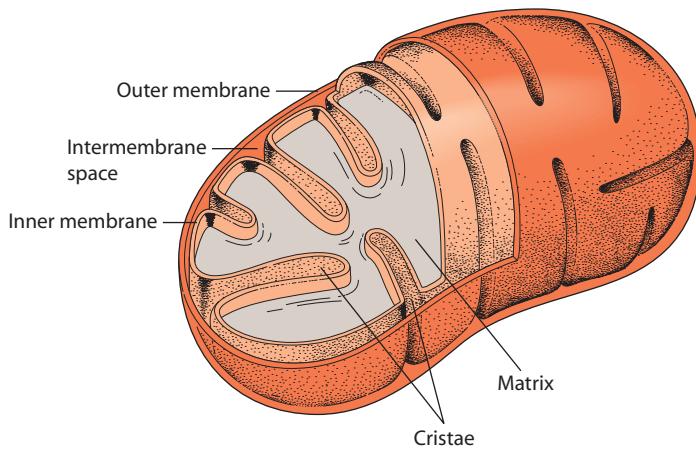

Figure 10-3 shows both an electron micrograph and an illustration of a typical mitochondrion—or perhaps a small segment of a much larger network. In either case, a distinctive feature is the presence of two membranes, called the outer and inner membranes. The **outer membrane** is not a significant permeability barrier for ions and small molecules because it contains transmembrane channel proteins called **porins** that permit the passage of solutes with molecular weights up to about 5000. Similar proteins are found in the outer membrane of gram-negative bacteria. Because porins allow the free movement of small molecules and ions across the outer membrane, the **intermembrane space** between the inner and outer membranes of the mitochondrion is continuous with the cytosol with respect to small solutes. However, enzymes targeted to the intermembrane space are effectively confined there because enzymes and other soluble proteins are too large to pass through the porin channels.

In contrast to the outer membrane, the **inner membrane** of the mitochondrion presents a permeability barrier to most solutes, thereby partitioning the mitochondrion into two separate compartments—the *intermembrane space* and the interior of the organelle (the *mitochondrial matrix*). The inner and outer membranes, shown in **Figure 10-4**, are each about 7 nm in thickness and are typically separated by an intermembrane space of about 7 nm. However, in certain spots the membranes are in contact, and it is in these regions that proteins destined for the mitochondrial matrix pass through the two membranes (see Figure 22-19).

At the perimeter of the mitochondrion, the portion of the inner membrane adjacent to the intermembrane space is known as the *inner boundary membrane*. In addition, the inner membrane of most mitochondria has many distinctive infoldings called **cristae** (singular: **crista**) that greatly increase its surface area. In a typical liver mitochondrion, for example, the area of the inner membrane (including the cristae) is about five times greater than that of the outer membrane. Because of its large surface area, the inner membrane can accommodate large numbers of

(b) Schematic diagram

FIGURE 10-3 Mitochondrial Structure. (a) A mitochondrion of a bat pancreas cell as seen by electron microscopy (TEM). The cristae are formed by infoldings of the inner membrane. (b) A mitochondrion is illustrated schematically in this cutaway view that shows the traditional “baffle” model of cristae structure. As noted in the text, however, this model is currently being reconsidered. Recent analysis using EM tomography suggests that the connections between the intracristal spaces and the intermembrane space are more limited tubular openings known as crista junctions.

[VIDEOS www.thecellplace.com](http://www.thecellplace.com) *Mitochondria in 3-D*

the protein complexes needed for electron transport and ATP synthesis, thereby enhancing the mitochondrion’s capacity for ATP generation. The inner membrane is about 75% protein by weight, which is a higher proportion of protein than in any other cellular membrane. These

inner membrane proteins include the transmembrane portions of proteins involved in solute transport, electron transport, and ATP synthesis. The cristae also provide numerous localized regions, the *intracristal spaces*, where protons can accumulate between the folded inner membranes during the electron transport process that we will discuss later in the chapter.

It was long thought that cristae were wide, flattened structures with broad connections to the inner boundary membrane, giving rise to the “baffle” model of cristae structure shown in Figure 10-3b. This view has been challenged recently due to microscopic evidence from EM (electron microscope) tomography, a microscopic technique that, like a CAT (computer-aided tomography) scan, provides detailed three-dimensional representations of cellular structures by combining successive serial images from thick (1 μm) sections. It is now believed that

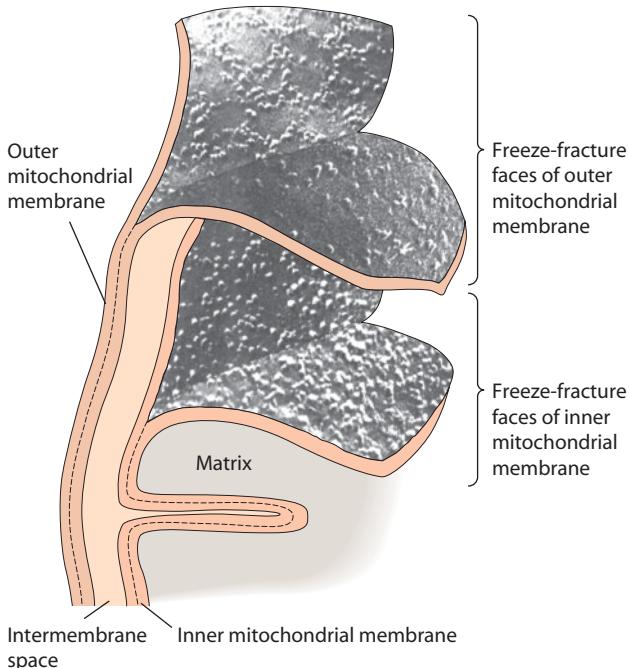

FIGURE 10-4 Structure of the Inner and Outer Mitochondrial Membranes. When the inner and outer mitochondrial membranes are subjected to freeze fracturing, each of the membranes splits along its hydrophobic interior, separating each membrane into two fracture faces. Segments of electron micrographs of the two fracture faces for both inner and outer membranes are superimposed here on a schematic diagram of the freeze-fractured membranes to illustrate the density of protein particles in each membrane.

cristae in many tissues may be tubular structures that associate in layers to form lamellar cristae of irregular size and shape. In some respects their morphology is similar to the grana stacks of thylakoids that define a third compartment in chloroplasts. Cristae appear to have only limited connections to the inner boundary membrane through small tubular openings known as *crista junctions*. The small size of these openings is thought to limit diffusion of materials between the intracristal space and the intermembrane space, effectively creating a third, nearly enclosed region in the mitochondrion.

The relative prominence of cristae within the mitochondrion frequently reflects the relative metabolic activity of the cell or tissue in which the organelle is located. Heart, kidney, and muscle cells have high respiratory activities, and thus their mitochondria have correspondingly large numbers of prominent cristae. The flight muscles of birds are especially high in respiratory activity and have mitochondria that are exceptionally well endowed with cristae. Plant cells, by contrast, have lower rates of respiratory activity than most animal cells do and have correspondingly fewer cristae within their mitochondria.

The interior of the mitochondrion is filled with a semi-fluid **matrix**. Within the matrix are many of the enzymes involved in mitochondrial function as well as DNA molecules and ribosomes. In most mammals, the mitochondrial genome consists of a circular DNA molecule of about 15,000–20,000 base pairs that code for ribosomal RNAs, transfer RNAs, and about a dozen polypeptide subunits of inner-membrane proteins. Besides the proteins encoded by the mitochondrial genome, mitochondria contain numerous nuclear-encoded proteins that are synthesized on cytoplasmic ribosomes and then imported into mitochondria (see Chapter 22).

Mitochondrial Functions Occur in or on Specific Membranes and Compartments

Specific functions and pathways have been localized within the mitochondrion by disruption of the organelle and fractionation of the various components. **Table 10-1** lists some of the main functions localized to each compartment of the mitochondrion.

Most of the mitochondrial enzymes involved in pyruvate oxidation, in the TCA cycle, and in the catabolism of fatty acids and amino acids are matrix enzymes. In fact, when mitochondria are disrupted very gently, six of the eight enzymes of the TCA cycle are released as a single large multiprotein complex, suggesting that the product of one enzyme can pass directly to the next enzyme without having to diffuse through the matrix.

On the other hand, most of the intermediates in the electron transport system are integral components of the inner membrane, where they are organized into large complexes. Protruding from the inner membrane into the matrix are knoblike spheres called **F₁ complexes** that are involved in ATP synthesis (**Figure 10-5**). Each

Table 10-1 Localization of Metabolic Functions Within the Mitochondrion

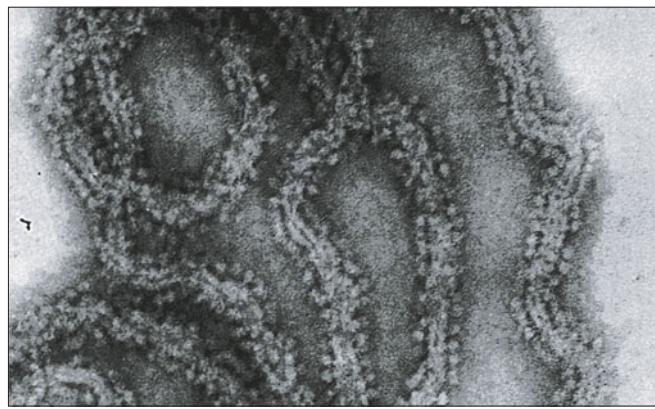

Membrane or Compartment	Metabolic Functions

Inner membrane	Electron transport Oxidative phosphorylation Pyruvate import Fatty acyl CoA import Metabolite transport
Matrix	Pyruvate oxidation TCA cycle β oxidation of fats DNA replication RNA synthesis (transcription) Protein synthesis (translation)

complex is an assembly of several different polypeptides. Individual F₁ complexes can be seen in Figure 10-5a, an electron micrograph taken at high magnification using a technique called *negative staining*, which results in a light image against a dark background. F₁ complexes are about 9 nm in diameter and are especially abundant along the cristae (Figure 10-5b).

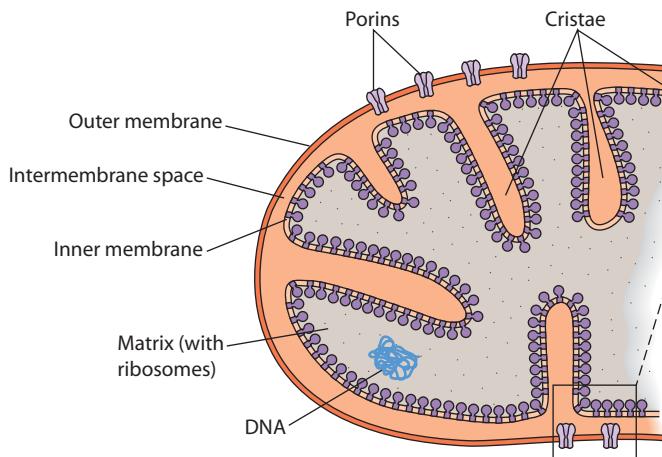

Each F₁ complex is attached by a short protein stalk to an **F₀ complex**, an assembly of hydrophobic polypeptides that are embedded within the mitochondrial inner membrane (Figure 10-5c) or in the plasma membrane of bacteria. (Note that the subscript in F₀ is the letter “o” rather than a zero. Historically, this is because the F₀ complex was the site of sensitivity to the antibiotic oligomycin.) The combination of an F₁ complex linked to an F₀ complex is called an **F₀F₁ complex** and is regarded as an *ATP synthase* because that is its normal role in energy metabolism. The F₀F₁ complex is in fact responsible for most of the ATP generation that occurs in the mitochondrion and in bacterial cells—and, as we will see in Chapter 11, in chloroplasts as well. In each case, ATP generation by F₀F₁ complexes is driven by an electrochemical gradient of protons across the membrane in which the F₀F₁ complexes are anchored, a topic we will explore in detail later in this chapter.

In Bacteria, Respiratory Functions Are Localized to the Plasma Membrane and the Cytoplasm

Bacteria do not have mitochondria, yet most bacterial cells are capable of aerobic respiration. Where in the bacterial cell are the various components of respiratory metabolism localized? Essentially, the cytoplasm and plasma membrane of a bacterial cell perform the same functions as the mitochondrial matrix and inner membrane, respectively. Therefore, in bacteria, most of the enzymes of the TCA cycle are found in the cytoplasm, whereas the electron

transport proteins are located in the plasma membrane. The F_oF₁ complex is also localized to the plasma membrane in bacteria, with the F_o component embedded in the membrane and the F₁ component protruding from the membrane into the cytoplasm.

The Tricarboxylic Acid Cycle: Oxidation in the Round

Having considered localization of respiratory functions in mitochondria and in bacterial cells, we will now return to the eukaryotic context and follow a molecule of pyruvate across the inner membrane of the mitochondrion to see what fate awaits it inside.

In the presence of oxygen, pyruvate is oxidized fully to carbon dioxide, and the energy released in the process is used to drive ATP synthesis. Pyruvate oxidation involves a cyclic pathway that is a central feature of energy metabolism in almost all aerobic chemotrophs. An important intermediate in this cyclic series of reactions is citrate, which has three carboxylic acid groups and is therefore a tricarboxylic acid. For this reason, this pathway is usually called the **tricarboxylic acid (TCA) cycle**. It is also commonly referred to as the *Krebs cycle* in honor of Hans

Krebs, whose laboratory played a key role in elucidating this metabolic sequence in the 1930s.

The TCA cycle metabolizes acetyl coenzyme A (usually abbreviated as acetyl CoA), a compound produced from pyruvate decarboxylation. Acetyl CoA consists of a two-carbon acetate group from pyruvate linked to a carrier called *coenzyme A*. (Coenzyme A was discovered by Fritz Lipmann, who shared a Nobel Prize with Krebs in 1953 for their work on aerobic respiration.) Acetyl CoA arises either by oxidative decarboxylation of pyruvate or by the stepwise oxidative breakdown of fatty acids (see Figure 10-1). Regardless of its origin, acetyl CoA transfers its acetate group to a four-carbon acceptor called oxaloacetate, thereby generating citrate. Citrate is then subjected to two successive decarboxylations and several oxidations, regenerating the oxaloacetate that will accept two more carbons from another molecule of acetyl CoA in the next round of the cycle.

Figure 10-6 shows an overview of the TCA cycle. Each round of TCA cycle activity involves the entry of two carbons, the release of two carbons as carbon dioxide, and the regeneration of oxaloacetate. Oxidation occurs at five steps: four in the cycle itself and one in the reaction that converts pyruvate to acetyl CoA. In each case, electrons

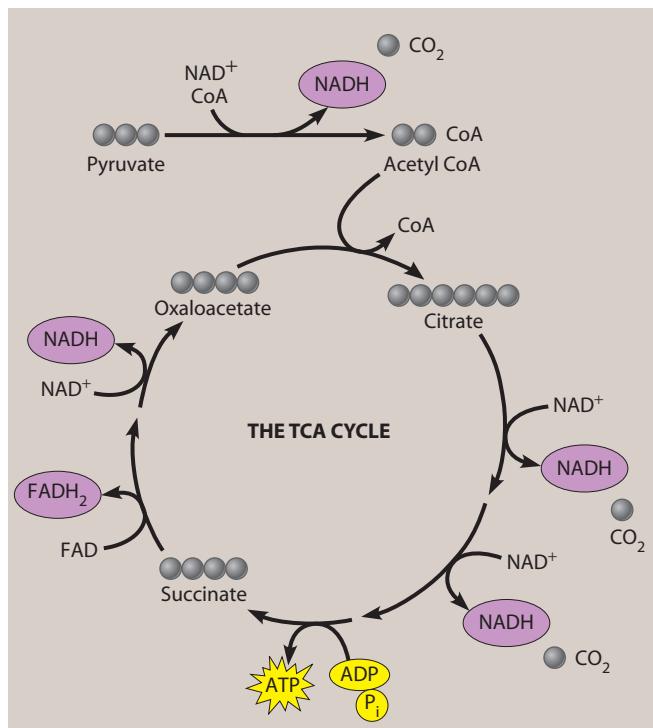

FIGURE 10-6 Overview of the TCA Cycle. Pyruvate from glycolysis is oxidatively decarboxylated to acetyl CoA, generating NADH and CO_2 . Acetyl CoA enters the TCA cycle by combining with oxaloacetate to form citrate. Two molecules of CO_2 are released and 2 NADH are formed as citrate is converted to succinate by two oxidative decarboxylation steps plus an ATP-generating step. Succinate is then oxidized and converted to oxaloacetate, generating FADH_2 and NADH. Overall, for each pyruvate metabolized to 3 CO_2 , there are 4 NADH, 1 FADH_2 , and 1 ATP generated.

are accepted by coenzyme molecules. Substrates for the TCA cycle are therefore acetyl CoA, oxidized coenzymes, ADP, and P_i , and the products are carbon dioxide, reduced coenzymes, and a molecule of ATP.

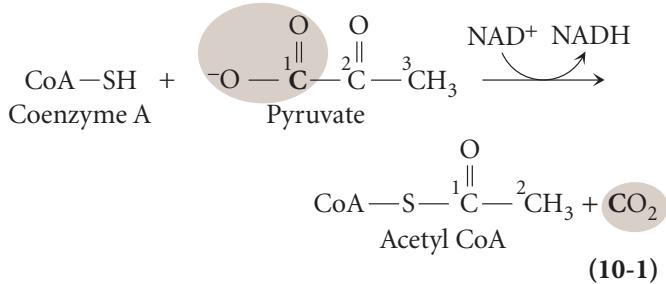

With this brief overview in mind, let's look at the TCA cycle in more detail, focusing on what happens to the carbon molecules that enter as acetyl CoA and how the energy released by each of the oxidations is conserved as reduced coenzymes.

Pyruvate Is Converted to Acetyl Coenzyme A by Oxidative Decarboxylation

As we just noted, carbon enters the TCA cycle in the form of acetyl CoA, but from Chapter 9 we know that the glycolytic pathway ends with pyruvate, which is formed in the cytoplasm. The pyruvate molecule, being relatively small, passes through porins in the mitochondrial outer membrane into the intermembrane space. At the inner mitochondrial membrane, a specific pyruvate symporter transports pyruvate across the membrane into the matrix along with a proton.

Once inside the mitochondrial matrix, pyruvate is converted to acetyl CoA by the *pyruvate dehydrogenase complex* (PDH), which consists of three different enzymes, five coen-

zymes, and two regulatory proteins. These components work together to catalyze the *oxidative decarboxylation* of pyruvate:

This reaction is a *decarboxylation* because one of the carbon atoms of pyruvate (carbon atom 1) is liberated as carbon dioxide (grey shading). As a result, carbon atoms 2 and 3 of pyruvate become, respectively, carbon atoms 1 and 2 of acetate. In addition, this reaction is an *oxidation* because two electrons (and a proton as well) are removed from the substrates and transferred to the coenzyme NAD^+ , reducing it to NADH. The electrons carried by NADH represent potential energy that is tapped when the NADH is later reoxidized by the electron transport system.

The oxidation of pyruvate occurs on carbon atom 2, which is oxidized from an α -keto to a carboxylic acid group. This oxidation is possible due to the simultaneous elimination of carbon atom 1 as carbon dioxide. The oxidation is highly exergonic ($\Delta G^\circ = -7.5 \text{ kcal/mol}$), with the free energy used to energize, or activate, the acetate molecule by linking it to the sulphydryl group of **coenzyme A** (CoA), forming **acetyl CoA**.

As shown in **Figure 10-7**, CoA is a complicated molecule containing the B vitamin *pantothenic acid*. Like the nicotinamide of NAD^+ , pantothenic acid is classified as a vitamin because humans and other vertebrates need it as a part of an essential coenzyme but cannot synthesize it themselves. The free sulphydryl, or *thiol*, group at the end of the CoA molecule can form a thioester bond with organic acids such as acetate. The thiol group is important enough that we will abbreviate coenzyme A not just as CoA, but as CoA-SH. Compared with an ester bond, a thioester bond is a higher-energy bond because significantly more free energy is released upon its hydrolysis. Just as NAD^+ is adapted for transfer of electrons, so coenzyme A is well suited as a carrier of acetate (hence the "A" in CoA). Thus, the acetyl group that is transferred to coenzyme A from pyruvate is in a higher-energy, or activated, form.

The TCA Cycle Begins with the Entry of Acetate as Acetyl CoA

The TCA cycle (**Figure 10-8**) begins with the entry of acetate in the form of acetyl CoA. With each round of TCA cycle activity, two carbon atoms enter in organic form (as acetate), and two carbon atoms leave in inorganic form (as carbon dioxide). In the first reaction (TCA-1), the two-carbon acetate group of acetyl CoA is added onto the four-carbon compound oxaloacetate to form citrate, a

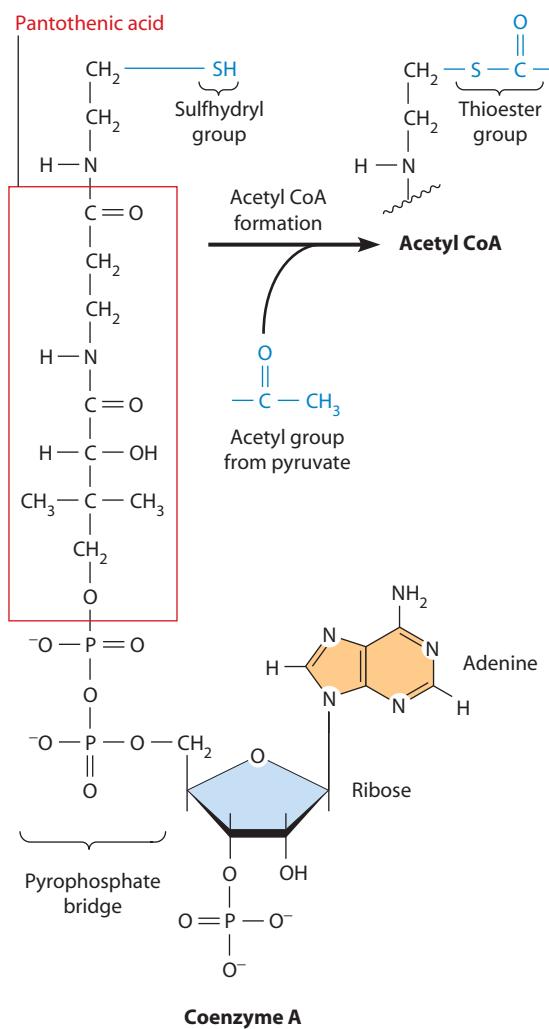

FIGURE 10-7 Structure of Coenzyme A and Acetyl CoA Formation. The portion of the coenzyme enclosed in the red box is pantothenic acid, a B vitamin. Formation of a thioester bond between CoA and an acetyl group generates acetyl coenzyme A. The acetyl group is formed by the oxidative decarboxylation of pyruvate (Reaction PDH in Figure 10-8). It is transferred to CoA from one of the enzymes of the pyruvate dehydrogenase complex.

six-carbon molecule. This condensation is driven by the free energy of hydrolysis of the thioester bond and is catalyzed by the enzyme *citrate synthase*. Note that citrate is a tricarboxylic acid—the class of compounds giving the TCA cycle its name. (The two incoming carbon atoms are shown highlighted in pink in Figure 10-8 to help you keep track of them in subsequent reactions.) In the next reaction (TCA-2), citrate is converted to the related compound isocitrate, using the enzyme *aconitase*. Isocitrate has a hydroxyl group that can be quite easily oxidized. This hydroxyl group of isocitrate is now the target of the first oxidation, or dehydrogenation, of the cycle (TCA-3).

Two Oxidative Decarboxylations Then Form NADH and Release CO₂

Next, we will see that four of the eight steps in the TCA cycle are oxidations. This is evident in Figure 10-8 because

four steps (TCA-3, TCA-4, TCA-6, and TCA-8) involve coenzymes that enter in the oxidized form and leave in the reduced form. The first two of these reactions, TCA-3 and TCA-4, are also decarboxylation steps. One molecule of carbon dioxide is eliminated in each step, reducing the number of carbons from six to five to four.

The isocitrate generated from citrate in step TCA-2 is oxidized by the enzyme *isocitrate dehydrogenase* to a six-carbon compound called *oxaloacetate* (not shown), with NAD⁺ as the electron acceptor. Oxaloacetate is unstable and immediately undergoes decarboxylation to the five-carbon compound α -ketoglutarate. This reaction (TCA-3) is the first of the two oxidative decarboxylation steps of the cycle.

The second oxidative decarboxylation event occurs in the next reaction (TCA-4), and also uses NAD⁺ as the electron acceptor. This reaction is similar to the oxidative decarboxylation of pyruvate shown previously. Both α -ketoglutarate and pyruvate are α -keto acids, so it should not be surprising that the mechanism of oxidation is the same for both, complete with decarboxylation and linkage of the oxidized product to coenzyme A as a thioester. Thus, α -ketoglutarate is oxidized to succinyl CoA, in a reaction catalyzed by the enzyme *α -ketoglutarate dehydrogenase*.

Direct Generation of GTP (or ATP) Occurs at One Step in the TCA Cycle

At this point, the carbon balance of the cycle is already satisfied: two carbon atoms entered as acetyl CoA, and two carbon atoms have now been released as carbon dioxide. (But notice carefully from Figure 10-8 that the two carbon atoms released in a given cycle *are not the same two* that entered in Reaction TCA-1 of that cycle). We have also encountered two of the four oxidation reactions of the TCA cycle and have generated two molecules of NADH. In addition, we recognize succinyl CoA as an activated compound that, like acetyl CoA, has a high-energy thioester bond.

The energy of this thioester bond is used to generate a molecule of either ATP (in bacterial cells and plant mitochondria) or GTP (in animal mitochondria). GTP and ATP are energetically equivalent because their terminal phosphoanhydride bonds have identical free energies of hydrolysis. Thus, the net result of succinyl CoA hydrolysis is the generation of one molecule of ATP, whether directly or via GTP, as depicted in Figure 10-8.

The Final Oxidative Reactions of the TCA Cycle Generate FADH₂ and NADH

Of the remaining three steps in the TCA cycle, two are oxidations. In Reaction TCA-6, the succinate formed in the previous step is oxidized to fumarate. This reaction is unique in that both electrons come from adjacent carbon atoms, generating a C=C double bond. Other oxidations we have encountered thus far involve the removal of electrons either from adjacent carbon and oxygen atoms

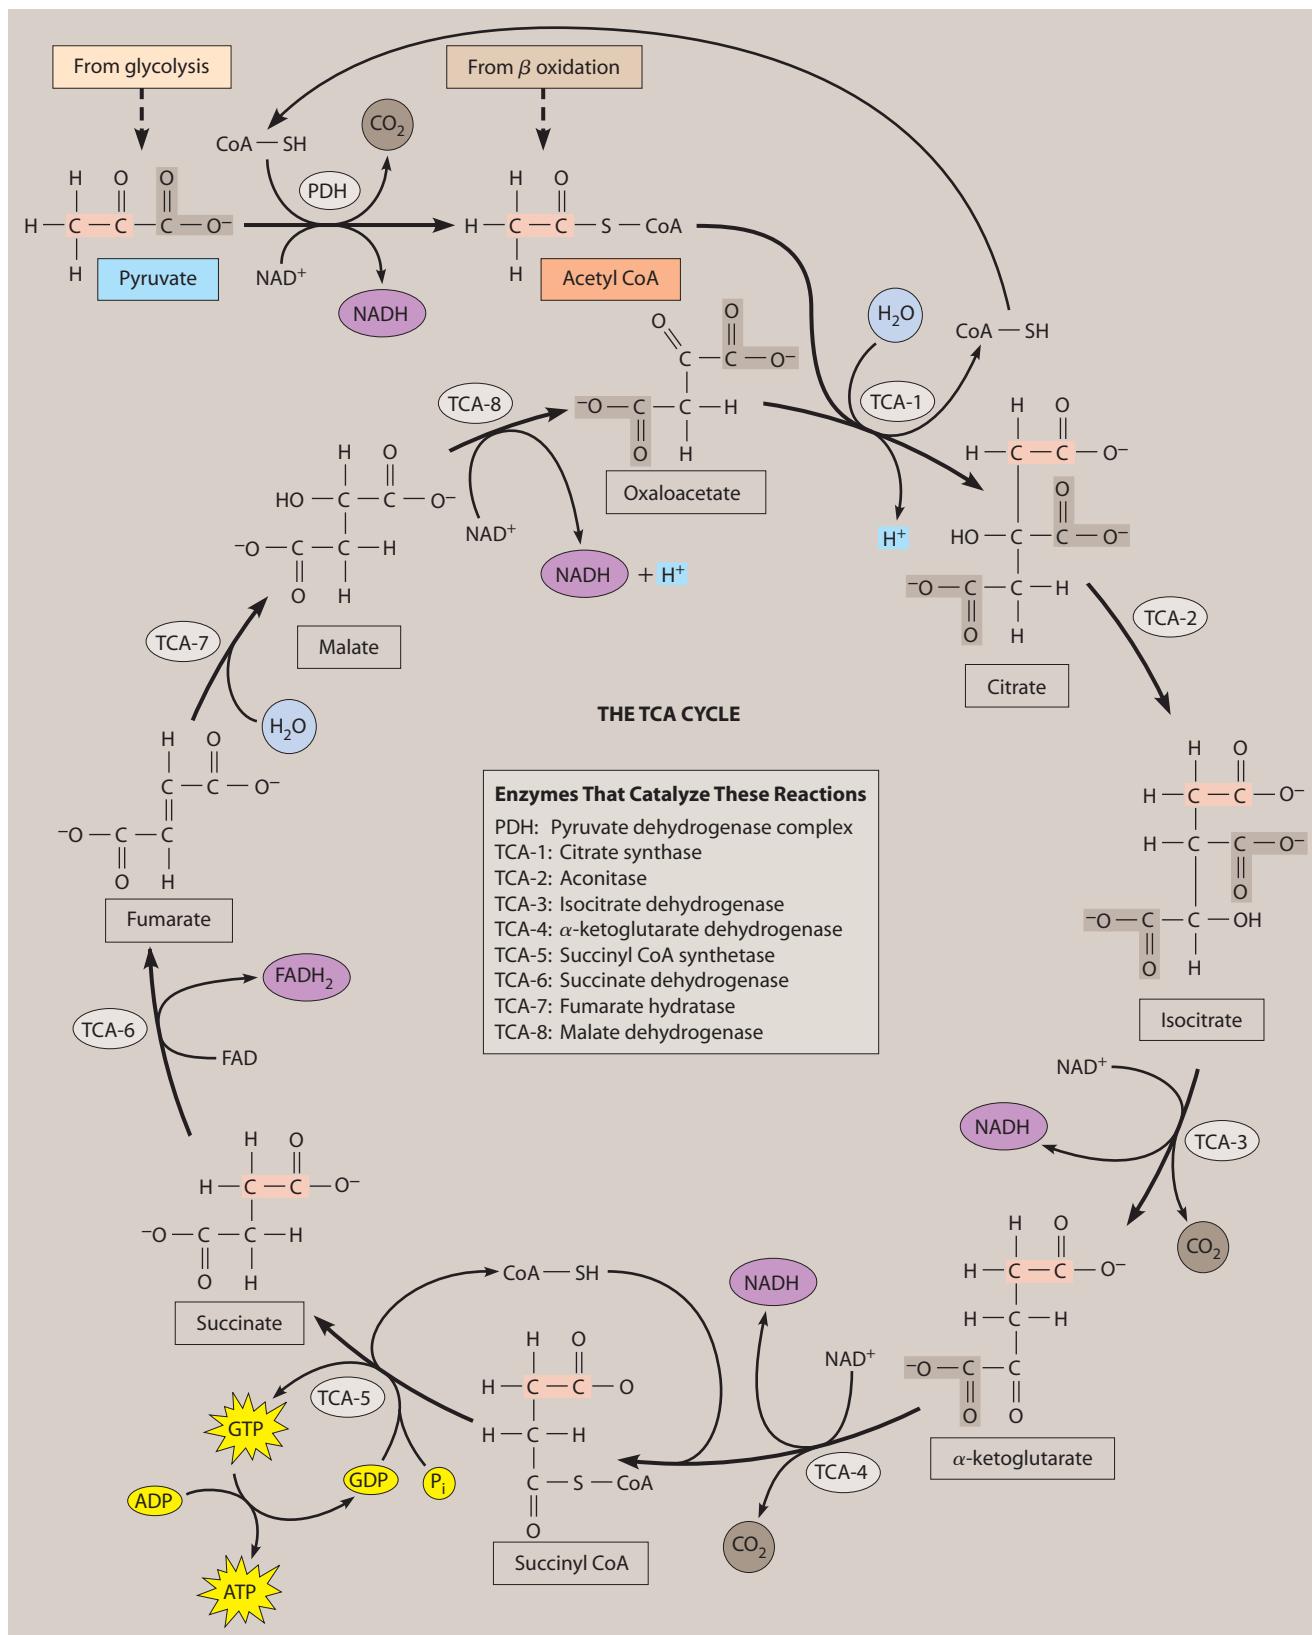

FIGURE 10-8 The Tricarboxylic Acid (TCA) Cycle. The two carbon atoms of pyruvate that enter the cycle via acetyl CoA are shown in pink in citrate and subsequent molecules until they are randomized by the symmetry of the fumarate molecule. The carbon atom of pyruvate that is lost as CO_2 is shown in gray, as are the two carboxyl groups of oxaloacetate that give rise to CO_2 in Reactions TCA-3 and TCA-4. Five of the reactions are oxidations, with NAD^+ as the electron acceptor in four reactions (PDH, TCA-3, TCA-4, and TCA-8) and FAD as the electron acceptor in one case (TCA-6). The reduced form of the coenzyme is shown in purple in each case. Note that when CO_2 is released, no H^+ is given off during NAD^+ reduction, thereby maintaining the charge balance of these reactions. The generation of GTP shown in Reaction TCA-5 is characteristic of animal mitochondria. In bacterial cells and plant mitochondria, ATP is formed directly.

(TCA-3) or from a carbon atom and a sulfur atom of separate molecules (PDH, TCA-4), generating either a C=O double bond or a C—S bond, respectively. The oxidation of a carbon–carbon bond releases less energy than does the oxidation of a carbon–oxygen bond—not enough energy to transfer electrons exergonically to NAD⁺. Accordingly, the electron acceptor for this dehydrogenation is not NAD⁺ but a lower-energy coenzyme, **flavin adenine dinucleotide** (FAD). Like NAD⁺ and coenzyme A, FAD contains a B vitamin as part of its structure—riboflavin, in this case (**Figure 10-9**). FAD accepts two protons and two electrons, so the reduced form is written as FADH₂. As we will see later, the maximum ATP yield upon coenzyme oxidation is about three for NADH but only about two FADH₂.

In the next step of the cycle, the double bond of fumarate is hydrated, producing malate (Reaction TCA-7, catalyzed by the enzyme *fumarate hydratase*). Because fumarate is a symmetric molecule, the hydroxyl group of water has an equal chance of adding to either of the internal carbon atoms. As a result, the carbon atoms of Figure 10-8 that were color-coded pink (to keep track of the most recent acetate group to enter the cycle) are randomized at this step and are therefore not color-coded from this point on. In Reaction TCA-8, the hydroxyl group of malate becomes the target of the final oxidation in the cycle. As electrons are removed from adjacent carbon and

oxygen atoms to form a C=O double bond, NAD⁺ serves as the electron acceptor, producing NADH as malate is converted to oxaloacetate.

Summing Up: The Products of the TCA Cycle Are CO₂, ATP, NADH, and FADH₂

With the regeneration of oxaloacetate, one turn of the cycle is complete. We can summarize what has been accomplished by noting the following properties of the TCA cycle:

1. Two carbons enter the cycle as acetyl CoA, which is joined to the four-carbon acceptor molecule oxaloacetate to form citrate, a six-carbon compound.
2. Decarboxylation occurs at two steps in the cycle so that the input of two carbons as acetyl CoA is balanced by the loss of two carbons as carbon dioxide.
3. Oxidation occurs at four steps, with NAD⁺ as the electron acceptor in three cases and FAD as the electron acceptor in one case.
4. ATP is generated at one point, with GTP as an intermediate in animal cells.
5. One turn of the cycle is completed upon regeneration of oxaloacetate, the original four-carbon acceptor.

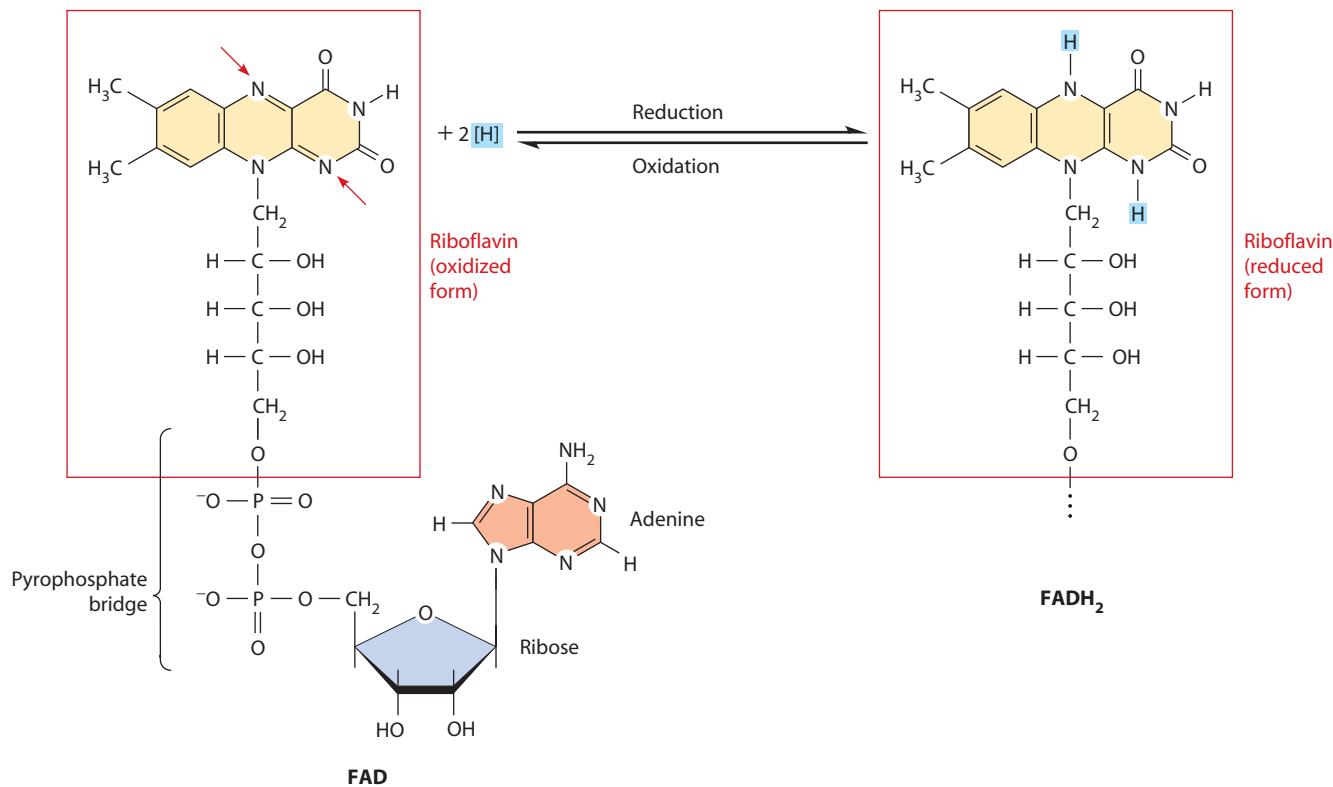

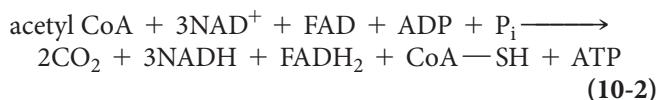

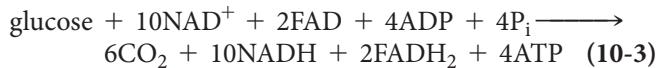

FIGURE 10-9 Structure of FAD and Its Oxidation and Reduction. The portion of the coenzyme enclosed in the red box is riboflavin, a B vitamin. The arrows point to the two nitrogen atoms of riboflavin that acquire one proton and one electron each when FAD is reduced to FADH₂. The half of the molecule that includes riboflavin and one phosphate group represents the structure of flavin mononucleotide (FMN), a closely related coenzyme.

By summing the eight component reactions of the TCA cycle as shown in Figure 10-8, we arrive at an overall reaction. (In this and subsequent reactions, protons and water molecules are not explicitly shown if they would be present only for charge or chemical balancing.) This reaction is written as

Because the cycle must, in effect, occur twice to metabolize both of the acetyl CoA molecules derived from a single molecule of glucose, the summary reaction on a per-glucose basis can be obtained by doubling Reaction 10-2. If we then add to this reaction the summary reactions for glycolysis through pyruvate (Reaction 9-16) and for the oxidative decarboxylation of pyruvate to acetyl CoA (Reaction 10-1, also multiplied by 2), we arrive at the following overall reaction for the entire sequence from glucose through the TCA cycle:

As you consider this summary reaction, two points may strike you: how modest the ATP yield is thus far and how many coenzyme molecules are reduced during the oxidation of glucose. However, despite the low ATP yield, we must also recognize the reduced coenzymes NADH and FADH₂ as high-energy compounds. As we will see later in this chapter, the transfer of electrons from these coenzymes to oxygen is highly exergonic. Thus, the reoxidation of the 12 reduced coenzyme molecules shown on the right side of Reaction 10-3 provides the energy needed to drive the synthesis of most of the 38 ATP molecules produced during the complete oxidation of glucose.

For the release of that energy, we must look to the remaining stages of respiratory metabolism—electron transport and oxidative phosphorylation. Before doing so, however, we will consider several additional features of the TCA cycle: its regulation, its central position in energy metabolism, and its role in other metabolic pathways.

Several TCA Cycle Enzymes Are Subject to Allosteric Regulation

Like all metabolic pathways, the TCA cycle must be carefully regulated to ensure that its level of activity reflects cellular needs for its products. The main regulatory sites are shown in **Figure 10-10**. Most of the control involves **allosteric regulation** of four key enzymes by specific *effector molecules* that bind reversibly to them. As you may recall from Chapter 6, effector molecules can be either inhibitors or activators, which are indicated in Figure 10-10 as red minus signs and green plus signs, respectively. In addition to allosteric regulation, the

pyruvate dehydrogenase complex (PDH) is reversibly inactivated by phosphorylation and activated by dephosphorylation of one of its protein components.

To appreciate the logic of TCA cycle regulation, remember that it uses acetyl CoA, NAD⁺, FAD, and ADP as substrates and generates as its products NADH, FADH₂, CO₂, and ATP (see Reactions 10-3 and 10-4). Three of these products—NADH, ATP, and acetyl CoA—are important allosteric effectors of one or more enzymes, as shown in Figure 10-10. In addition, NAD⁺, ADP, and AMP each activate at least one of the regulatory enzymes. In this way, the cycle is highly sensitive to the redox and energy status of the cell, as assessed by both the NADH/NAD⁺ ratio and the relative concentrations of ATP, ADP, and AMP.

All four of the NADH-generating dehydrogenases shown in Figure 10-10 are inhibited by NADH. An increase in the NADH concentration of the mitochondrion therefore decreases the activities of these dehydrogenases, leading to a reduction in TCA cycle activity. In addition, PDH is inhibited by ATP, which is more abundant when energy is plentiful, and both PDH and isocitrate dehydrogenase are activated by AMP and ADP, which are more abundant when energy is needed.

The overall availability of acetyl CoA is determined primarily by the activity of the PDH complex (see Reaction 10-1), which is allosterically inhibited by NADH, ATP, and acetyl CoA and is activated by NAD⁺, AMP, and free CoA (Figure 10-10). In addition, this enzyme complex is inactivated by phosphorylation of one of its protein components when the [ATP]/[ADP] ratio in the mitochondrion is high and is activated by removal of the phosphate group when the [ATP]/[ADP] ratio is low. These phosphorylation and dephosphorylation reactions are catalyzed by *PDH kinase* and *PDH phosphatase*, respectively. Not surprisingly, ATP is an activator of the kinase and an inhibitor of the phosphatase.

Due to these multiple control mechanisms, the generation of acetyl CoA is sensitive to the [acetyl CoA]/[CoA] and [NADH]/[NAD⁺] ratios within the mitochondrion and to the mitochondrial ATP status as well. In addition to these regulatory effects on reactions of the TCA cycle, feedback control from the cycle to the glycolytic pathway is provided by the inhibitory effects of citrate and acetyl CoA on phosphofructokinase and pyruvate kinase, respectively (see Figures 9-12 and 10-10).

The TCA Cycle Also Plays a Central Role in the Catabolism of Fats and Proteins

It is essential to understand the central role of the TCA cycle in all of aerobic energy metabolism. Thus far, we have regarded glucose as the main substrate for cellular respiration. In addition to glucose (and other carbohydrates), we must also note the roles of alternative fuel molecules in cellular energy metabolism and the TCA cycle, especially fats and proteins, which constitute roughly half of a diet based on the most recent dietary guidelines

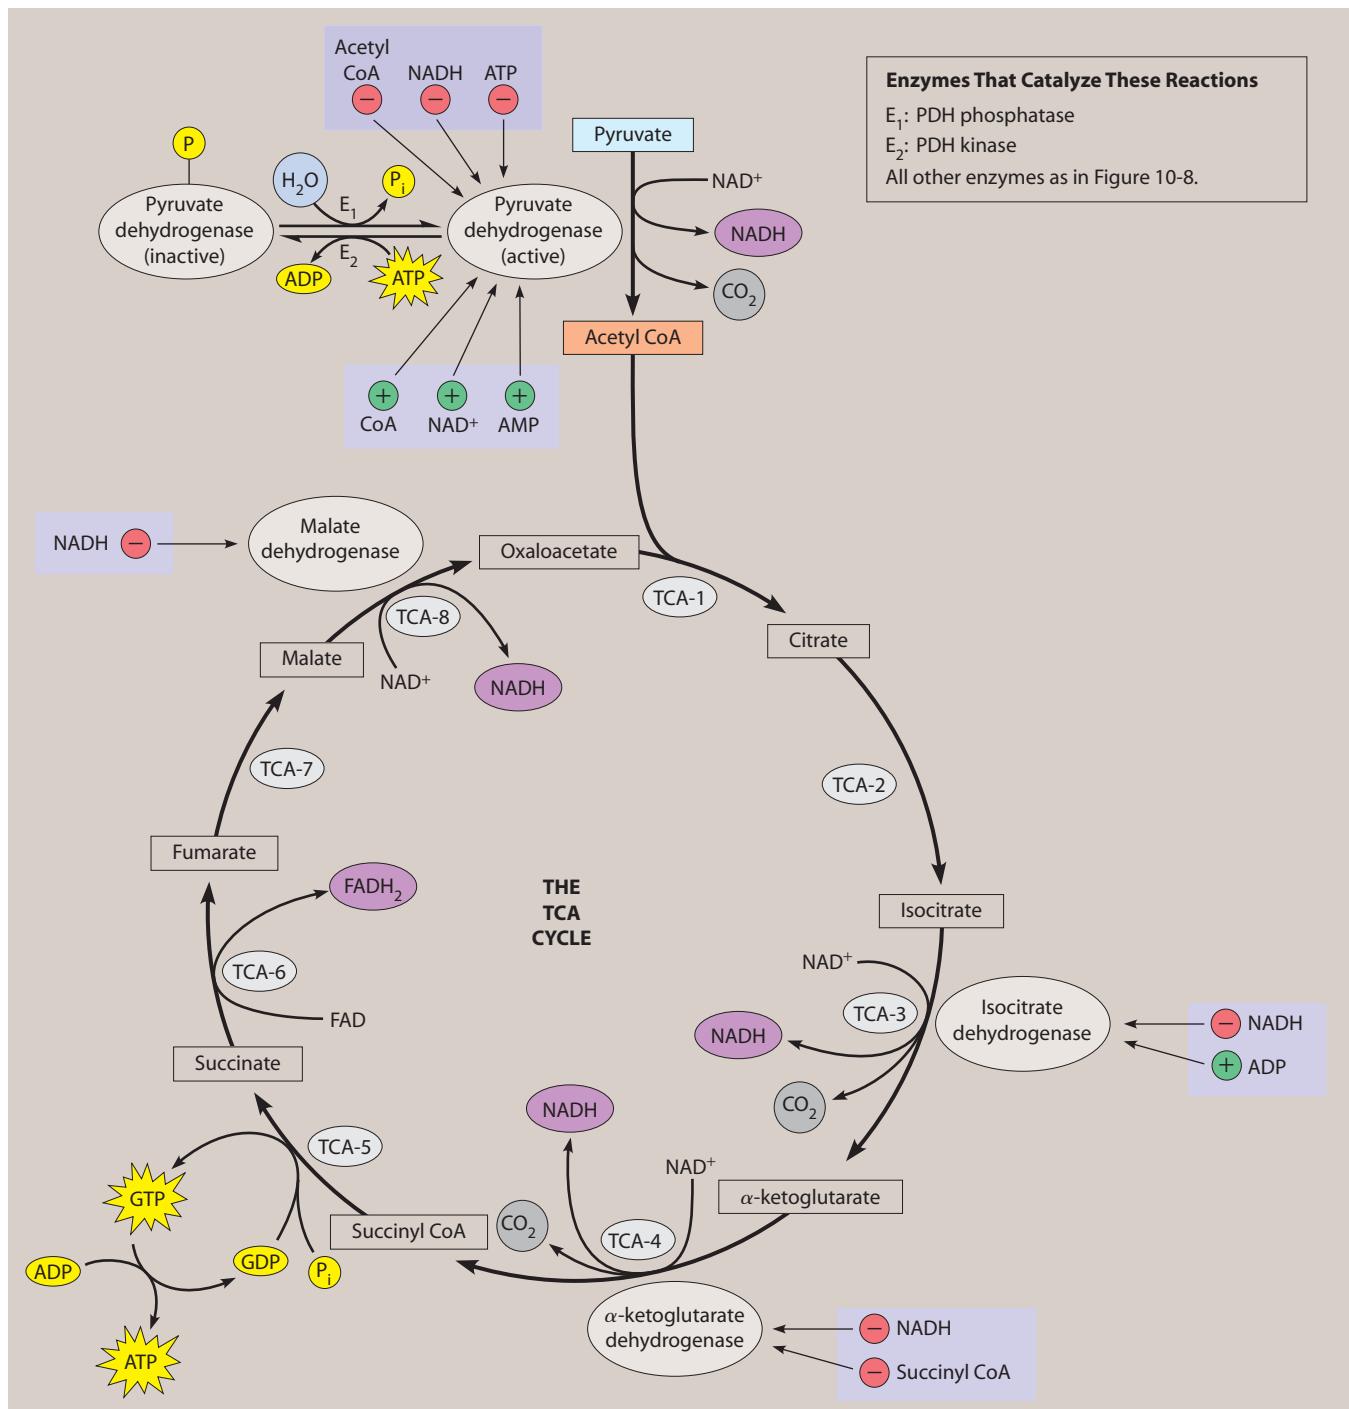

FIGURE 10-10 Regulation of the TCA Cycle. The pyruvate dehydrogenase reaction and the TCA cycle are shown here in outline form, with full names given for regulatory enzymes. Major regulatory effects are indicated as either activation (+) or inhibition (-). Allosteric regulators include CoA, NAD⁺, AMP, and ADP as activators and acetyl CoA, NADH, ATP, and succinyl CoA as inhibitors. In addition to its allosteric effect on pyruvate dehydrogenase activity, ATP activates PDH kinase (E₂), the enzyme that phosphorylates one component of the PDH complex, thereby converting it to an inactive form. The enzyme PDH phosphatase (E₁) removes the phosphate group, returning the enzyme to its active form.

(carbohydrates = 50%, fats = 30%, proteins = 20%). Far from being a minor pathway for the catabolism of a single sugar, the TCA cycle represents the main conduit of aerobic energy metabolism in a broad spectrum of organisms ranging from microbes to higher plants and animals.

Fat As a Source of Energy. When we first encountered fats in Chapter 3, we noted their role in energy storage and observed that they are highly reduced compounds that liberate more energy per gram upon oxidation than do carbohydrates. For this reason, fats are an important

long-term energy storage form for many organisms. Fat reserves are especially important in hibernating animals and migrating birds. In plant seeds, fats are a common form of energy and carbon storage. Fats are well suited for this storage function because they allow a maximum number of calories to be stored compactly.

Most fat is stored as deposits of **triacylglycerols**, which are neutral triesters of *glycerol* and long-chain *fatty acids* that we encountered earlier (see Figure 3-27b). Catabolism of triacylglycerols begins with their hydrolysis to glycerol and free fatty acids. The glycerol is channeled into the glycolytic pathway by oxidative conversion to dihydroxyacetone phosphate, as shown in Figure 9-9. The fatty acids are linked to coenzyme A to form fatty acyl CoAs, which are then degraded by **β oxidation**, a catabolic process that generates acetyl CoA and the reduced coenzymes NADH and FADH₂.

In bacteria, β oxidation occurs in the cytoplasm, and in eukaryotes it occurs both in the mitochondria and in peroxisomes. In plants and other eukaryotes that do not depend upon fatty acids as an energy source, β oxidation occurs in the peroxisome and can function as a way to recycle membrane fatty acids. Here we will focus on the process of β oxidation as it occurs in the mitochondrion of animals using saturated fatty acids with an even number of carbons as an energy source.

In animals, most fatty acids derived from dietary fats, like the pyruvate derived from carbohydrates, are oxidatively converted into acetyl CoA in the mitochondrion, which then can be further catabolized by the TCA cycle. The fatty acids are degraded in a series of repetitive cycles, each of which removes two carbons from the fatty acid until it is completely degraded. This process of fatty acid catabolism to acetyl CoA is called β oxidation because the oxidative events in each cycle occur on the carbon atom in the β position of the fatty acid (i.e., the second carbon in from the carboxylic acid group). Each cycle involves the same four steps—oxidation, hydration, reoxidation, and thiolysis (Figure 10-11)—and results in the production of one molecule each of FADH₂, NADH, and acetyl CoA as the fatty acid is shortened by two carbons in each cycle.

β oxidation of a fatty acid begins with an energy-requiring activation step in the cytosol. The energy of hydrolysis of ATP drives the attachment of a CoA molecule to the fatty acid (Reaction FA-1 in Figure 10-11). This forms a *fatty acyl CoA*, which is transported into the mitochondrion by a specific translocase located in the inner membrane. The next four enzymatic steps are repeated in a series of cycles until the fatty acid is completely degraded, losing two carbons per cycle as acetyl CoA. The first three of these steps closely resemble the oxidation, hydration, and reoxidation steps that convert succinate to oxaloacetate in the TCA cycle (TCA-6, 7, and 8).

First, an integral membrane protein acting as a *dehydrogenase* oxidizes the fatty acyl CoA, forming a double bond between the α and β carbons (FA-2). The

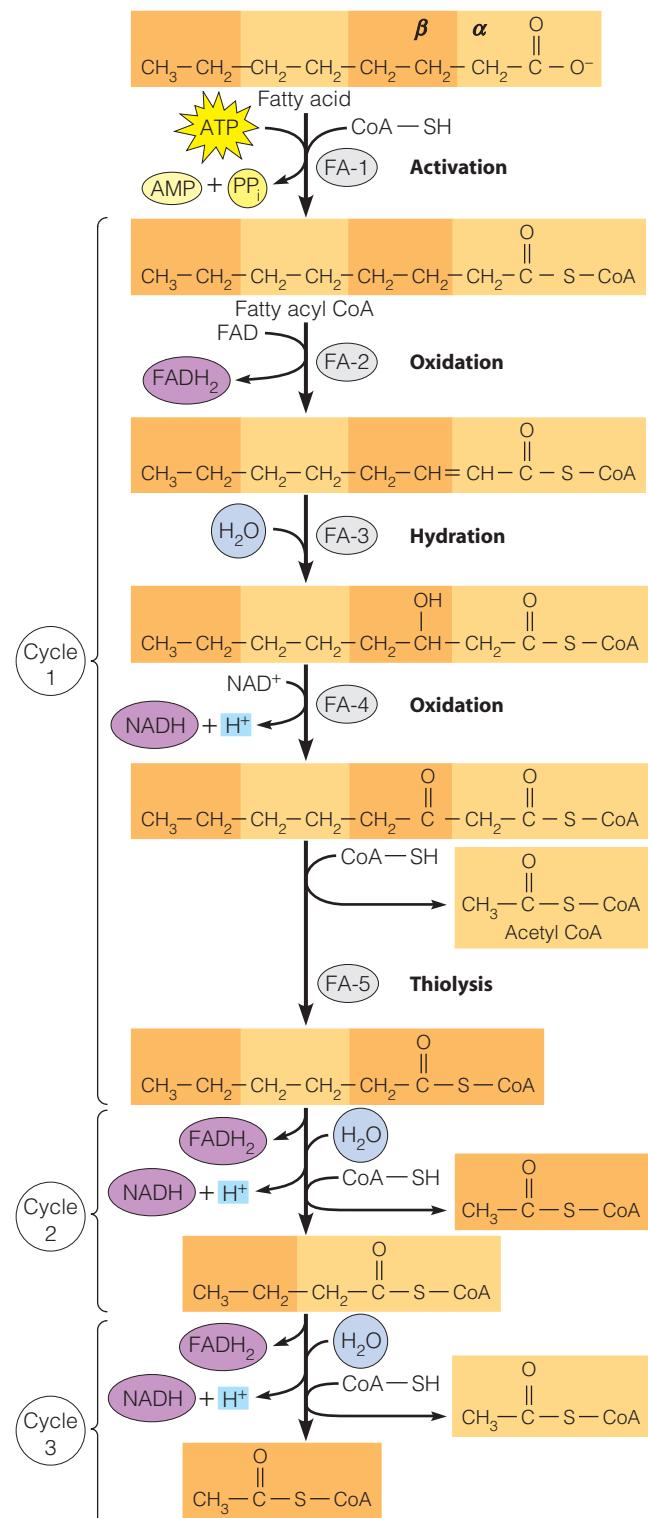

FIGURE 10-11 The β -Oxidation Pathway. Following an ATP-dependent activation step that links a fatty acid to CoA, the fatty acyl CoA derivative is transported into the mitochondrion (or peroxisome) and degraded in a series of repetitive cycles of oxidation, hydration, reoxidation, and thiolysis. Each cycle generates one FADH₂ and one NADH in the oxidation steps and releases acetyl CoA in the thiolysis step, shortening the fatty acid by two carbons. The example above is for the eight-carbon fatty acid octanoate, which requires three cycles of β oxidation. (Reaction numbers and chemical details are shown for the first cycle only.)

two electrons and two protons removed during formation of the unsaturated derivative are transferred to FAD, forming FADH_2 . In the next step, water is added across the double bond by a *hydratase* so that the α carbon receives a H atom and the β carbon receives a hydroxyl group (FA-3). Then another *dehydrogenase* oxidizes the β carbon (hence the name β oxidation), converting the hydroxyl group to a keto group (FA-4). The two electrons and one proton removed in this oxidation are used to reduce NAD^+ to NADH. In the fourth step of the cycle, the bond between the α and β carbons is broken by a *thiolase*, and a two-carbon fragment is transferred to the S atom of a second molecule of CoA (FA-5). This results in the production of acetyl CoA and a fatty acyl CoA that is two carbons shorter than the fatty acyl CoA that entered the four-step cycle.

These four steps are repeated using the shortened fatty acyl CoA as a substrate until the original fatty acid is completely degraded. Most dietary fatty acids have an even number of carbons and are completely degraded to acetyl CoA, although unsaturated fatty acids require one or two additional enzymes. For unusual fatty acids having an odd number of carbons, the final cycle produces propionyl CoA, which is one carbon longer than acetyl CoA. In a three-step side pathway, a carbon from bicarbonate is added to propionyl CoA to generate succinyl CoA, which then enters the TCA cycle.

While glucose is the preferred energy source of most cells, fats provide energy when glucose is limiting (as during starvation), under conditions of very low carbohydrate intake, or following extremely demanding exercise (such as running a marathon). In humans, excessive fat breakdown can deplete free CoA and lead to a condition known as *ketosis*. During ketosis, fats cannot be oxidized completely to CO_2 , and partial oxidation products known as ketone bodies (acetone, acetoacetate, and β -hydroxybutyrate) are formed. In large quantities, they can lower the pH of the blood, resulting in *ketoacidosis*, a condition often seen in uncontrolled diabetes. While ketone bodies can be a source of energy for heart and brain cells, there is currently considerable controversy over whether ketosis is a health risk or simply a side effect of a low-carbohydrate diet.

Protein As a Source of Energy and Amino Acids. Although proteins act as enzymes, transport proteins, hormones, and receptors in the cell, they can also be catabolized to generate ATP if necessary, especially during fasting or starvation conditions when carbohydrates and lipid stores are depleted. In plants, catabolism of proteins to free amino acids provides building blocks for protein synthesis during the germination of protein-storing seeds. In addition, all cells eventually undergo turnover of proteins and protein-containing structures, and the resulting amino acids can either be used to synthesize new proteins or be degraded oxidatively to yield energy.

Protein catabolism begins with hydrolysis of the peptide bonds that link amino acids together in the polypeptide chain. The process is called **proteolysis**, and the enzymes responsible for it are called **proteases**. The products of proteolytic digestion are small peptides and free amino acids. Further digestion of peptides is catalyzed by peptidases, which either hydrolyze internal peptide bonds (*endopeptidases*) or remove successive amino acids from the end of the peptide (*exopeptidases*).

Free amino acids, whether ingested as such or obtained by the digestion of proteins, can be catabolized for energy. Generally, these alternative substrates are converted to intermediates of mainstream catabolism in as few steps as possible. Despite their number and chemical diversity, all of the pathways for amino acid catabolism eventually lead to pyruvate, acetyl CoA, or a few key intermediates in the TCA cycle, notably α -ketoglutarate, oxaloacetate, fumarate, and succinyl CoA. The mitochondrion also participates in the *urea cycle*, a pathway prominent in the liver in which excess amino groups from degraded amino acids are converted to *urea* for excretion.

Of the 20 amino acids found in proteins, three of them give rise to pyruvate or TCA cycle intermediates directly: alanine, aspartate, and glutamate can be directly converted to pyruvate, oxaloacetate, and α -ketoglutarate, respectively (Figure 10-12). All the other amino acids require more complicated pathways, but ultimately all of them have end products that are TCA cycle intermediates.

The TCA Cycle Serves as a Source of Precursors for Anabolic Pathways

In addition to the catabolic function of the TCA cycle, there is a considerable flow of four-, five-, and six-carbon intermediates into and out of the cycle in most cells. These side reactions can replenish the supply of intermediates in the cycle if needed or use intermediates in the cycle for the synthesis of other compounds in anabolic pathways. Because the TCA cycle is a central link between catabolic and anabolic pathways, it is often called an **amphibolic pathway** (from the Greek prefix *amphi-*, meaning “both”).

Besides its central role in catabolism, the TCA cycle is involved in various anabolic processes. For example, the three reactions shown in Figure 10-12 convert α -keto intermediates of the TCA cycle into the amino acids alanine, aspartate, and glutamate. These amino acids are constituents of proteins, so the TCA cycle is indirectly involved in protein synthesis by providing several of the amino acids required for the process. Other metabolic precursors provided by the TCA cycle include succinyl CoA and citrate. Succinyl CoA is the starting point for the biosynthesis of heme, whereas citrate can be transported out of the mitochondrion and used as a source of acetyl CoA for the stepwise synthesis of fatty acids in the cytosol.

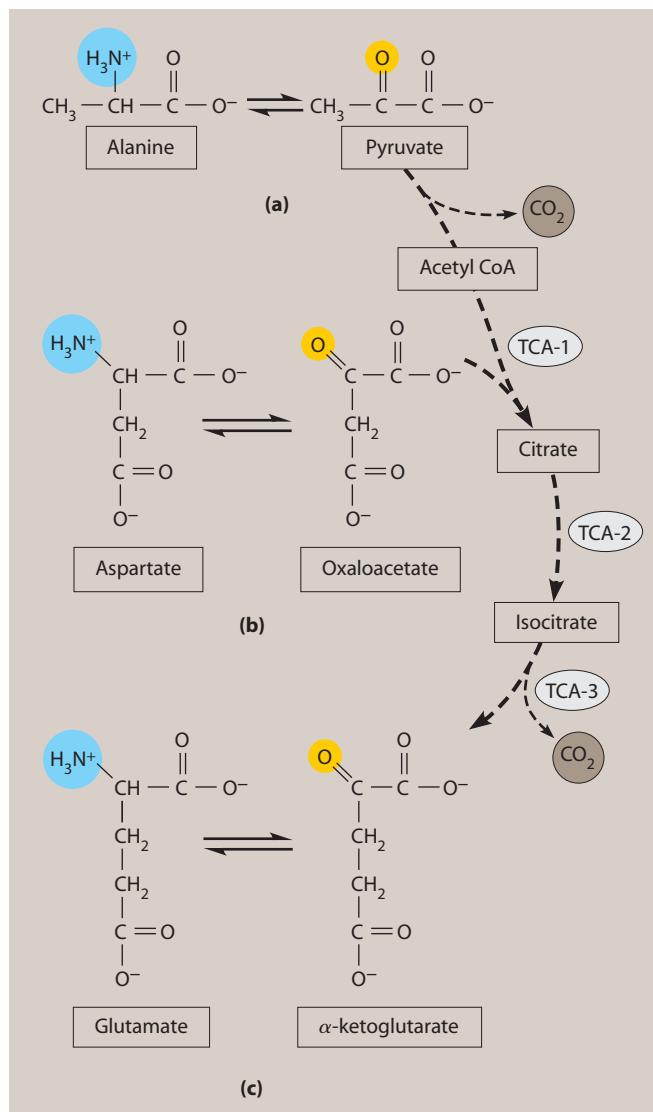

FIGURE 10-12 Interconversion of Several Amino Acids and Their Corresponding Keto Acids in the TCA Cycle. The amino acids (a) alanine, (b) aspartate, and (c) glutamate can be converted into the corresponding α -keto acids: pyruvate, oxaloacetate, and α -ketoglutarate, respectively. Each of these keto acids is an intermediate in the TCA cycle, a portion of which is shown to provide the metabolic context for these reactions. In each case, the amino group is shown in blue and the keto group in yellow. These reactions are readily reversible and can occur in either catabolism (oxidizing amino acids to CO_2 and H_2O) or anabolism (producing amino acids for protein synthesis).

The Glyoxylate Cycle Converts Acetyl CoA to Carbohydrates

The *glyoxylate cycle* has several intermediates in common with the TCA cycle but performs a specialized anabolic function in some germinating seeds and fungal spores, as described in **Box 10A**. This cycle occurs in a special type of peroxisome called the *glyoxysome*, which is common in fat-storing plant seeds that must convert this fat to sucrose. The glyoxylate cycle has several of the same reactions (and enzymes) as the TCA cycle but

lacks the two oxidative decarboxylation reactions where CO_2 is released in the TCA cycle. Instead, two acetate molecules (which enter the pathway as acetyl CoA) are used to generate succinate, a four-carbon compound (see Figure 10A-2). The succinate is then converted to phosphoenolpyruvate, from which sugars can be synthesized by gluconeogenesis.

Organisms possessing this pathway can synthesize sugars from two-carbon compounds such as acetate. The glyoxylate cycle also makes possible the conversion of stored fat to carbohydrate, with acetyl CoA as the intermediate. This capability is vital to seed germination in those plant species that store significant amounts of carbon reserves in their seeds as fats. Mammals, on the other hand, lack a functional glyoxylate cycle and therefore cannot convert fats into carbohydrates.

Electron Transport: Electron Flow from Coenzymes to Oxygen

Having considered the first three stages of aerobic respiration—glycolysis, pyruvate oxidation, and the TCA cycle—let's pause briefly to ask what has been achieved thus far. As Reaction 10-3 indicates, chemotrophic energy metabolism through the TCA cycle accounts for the synthesis of four ATP molecules per glucose, two from glycolysis, and two from the TCA cycle. Complete oxidation of glucose to CO_2 could yield 686 kcal/mol, but we have recovered less than 10% of that amount (only 4 ATP \times approximately 10 kcal/mol each, based on the $\Delta G'$ value for ATP synthesis in a typical cell). Where is the rest of the free energy? And when will we get to the substantially greater ATP yield that is characteristic of respiration?

The answer is straightforward: The free energy is right there in Reaction 10-3, represented by the reduced coenzyme molecules NADH and FADH₂. As we will see shortly, large amounts of free energy are released when these reduced coenzymes are reoxidized by transfer of their electrons to molecular oxygen. In fact, about 90% of the potential free energy present in a glucose molecule is conserved in the 12 molecules of NADH and FADH₂ that are formed when a molecule of glucose is oxidized to CO_2 .

The Electron Transport System Conveys Electrons from Reduced Coenzymes to Oxygen

The process of coenzyme reoxidation by the transfer of electrons to oxygen is called **electron transport**. Electron transport is the fourth stage of respiratory metabolism (see Figure 10-1). The accompanying process of ATP synthesis (stage 5) will be discussed later in this chapter. Keep in mind, however, that electron transport and ATP synthesis are not isolated processes. They are both integral parts of cellular respiration, functionally linked to each other by the electrochemical proton gradient that is the result of electron transport as well as the source of the energy that drives ATP synthesis.

The Glyoxylate Cycle, Glyoxysomes, and Seed Germination

Plant species that store carbon and energy reserves in their seeds as fats face a special metabolic challenge when their seeds germinate: They must convert the stored fat to sucrose, the immediate source of carbon and energy for most cells in the seedling. Many plant species are in this category, including such well-known oil-bearing species as soybeans, peanuts, sunflowers, castor beans, and maize. The fat consists mainly of triacylglycerols and is stored in the cell as *lipid bodies*. The electron micrograph in **Figure 10A-1** shows the prominence of lipid bodies in the cotyledon (embryonic leaf) of a cucumber seedling.

The advantage of storing fat rather than carbohydrate is that one gram of triacylglycerol contains more than twice as much energy as one gram of carbohydrate. This difference enables fat-storing species to pack the greatest amount of carbon and calories into the least amount of space. However, it also means that such species must be able to convert the stored fat into sugar when the seeds germinate.

While many organisms readily convert sugars and other carbohydrate to stored fat (as people do), most eukaryotic organisms, including us, cannot carry out the conversion of fat to sugar. For the seedlings of fat-storing plant species, however, the conversion of storage triacylglycerols to sucrose is essential because sucrose is the form in which carbon and energy are transported to the growing shoot and root tips of the developing seedling.

The metabolic pathways that make this conversion possible are β oxidation and the **glyoxylate cycle**. The function of β oxidation is to degrade the stored fat to acetyl CoA. The acetyl CoA then enters the glyoxylate cycle (**Figure 10A-2**), a five-step cyclic pathway that is named for one of its intermediates, the two-carbon

keto acid called *glyoxylate*. The glyoxylate cycle is related to the TCA cycle and uses three of the same reactions. A critical difference, however, is the presence of two glyoxysome-specific enzymes, *isocitrate lyase* and *malate synthase*. Using these enzymes, the glyoxylate cycle bypasses the two decarboxylation reactions of the TCA cycle. Also, the glyoxylate cycle takes in not one but two molecules of acetyl CoA per turn of the cycle, generating succinate, a four-carbon compound. Thus, the glyoxylate cycle is anabolic (carbon enters as two 2-carbon molecules and leaves as a four-carbon molecule), whereas the TCA cycle is catabolic (carbon enters as a two-carbon molecule and leaves as two CO₂ molecules).

In the seedlings of fat-storing species, the enzymes of β oxidation and the glyoxylate cycle are localized in organelles called **glyoxysomes**, which are found in the seedlings of fat-storing species of plants (Figure 10A-1) and in spores of some fungi. The intimate association of glyoxysomes with lipid bodies presumably facilitates the transfer of fatty acids from the lipid bodies.

Figure 10A-2 shows the relevant metabolism in an intracellular context. Stored triacylglycerols are hydrolyzed in the lipid bodies, releasing fatty acids. The fatty acids are transported into the glyoxysome and are degraded by β oxidation to acetyl CoA, which is converted to succinate by the enzymes of the glyoxylate cycle. The succinate moves to the mitochondrion, where it is converted to malate by reactions that are a part of the TCA cycle. (Notice that mitochondria are adjacent to glyoxysomes in the cucumber cotyledon in Figure 10A-1.) Malate goes to the cytosol and is oxidized to oxaloacetate, which is decarboxylated to form phosphoenolpyruvate (PEP). PEP serves as the starting point for gluconeogenesis in the cytosol, ultimately yielding sucrose,

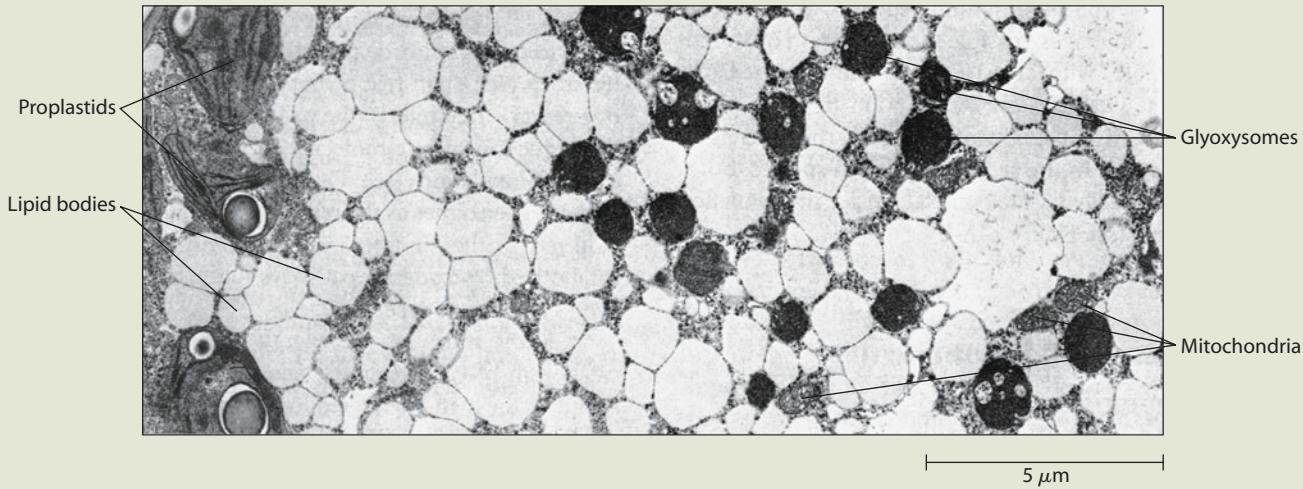

FIGURE 10A-1 The Association of Glyoxysomes and Lipid Bodies in Fat-Storing Seedlings. Shown here is a cell from the cotyledon of a cucumber seedling during early postgerminative development. The glyoxysomes and mitochondria involved in fat mobilization and gluconeogenesis are intimately associated with the lipid bodies in which the fat is stored. The fat is present primarily as triacylglycerols (also called triglycerides). Evidence that the cotyledon is not yet photosynthetically active and is therefore still heterotrophic in its nutritional mode can be seen in the presence of proplastids instead of mature chloroplasts (TEM).

the major carbohydrate transported to growing tissues in plants.

The route from stored triacylglycerols to sucrose is obviously quite complex, involving enzymes located in lipid bodies, glyoxysomes, mitochondria, and the cytosol, but it is the metabolic lifeline on

which the seedlings of all fat-storing plant species depend. It complements much of the metabolism we've been learning about in Chapters 9 and 10, including gluconeogenesis, the TCA cycle, β oxidation—and now the glyoxylate cycle as well.

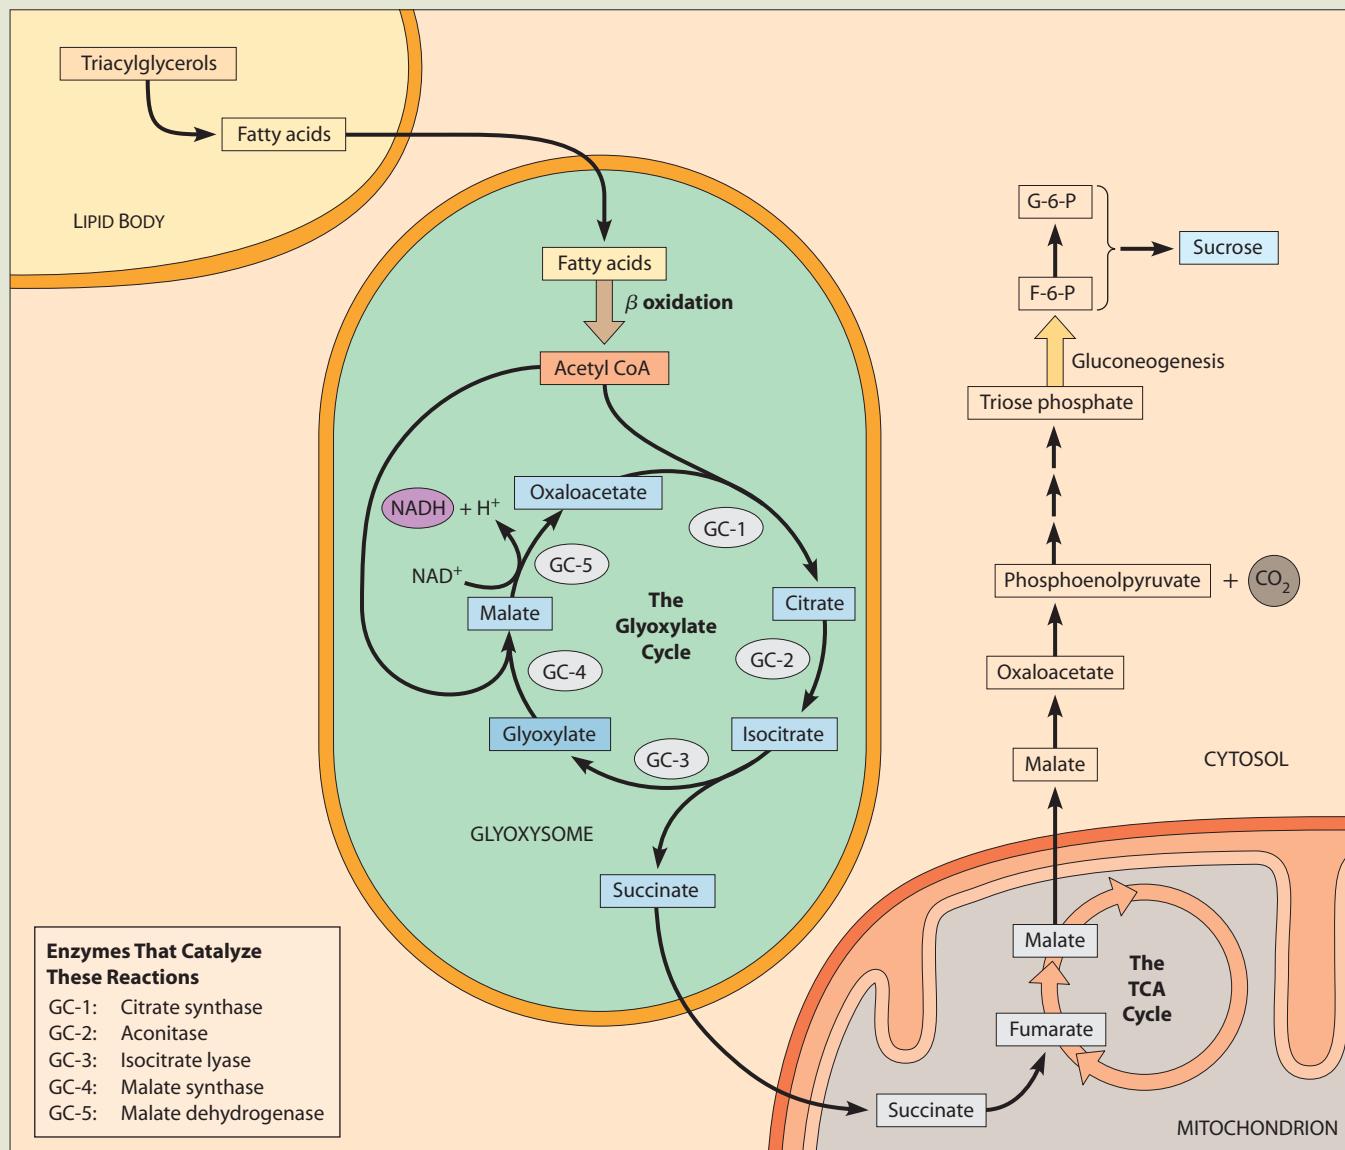

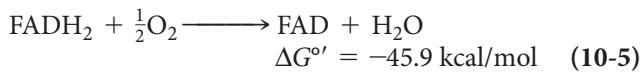

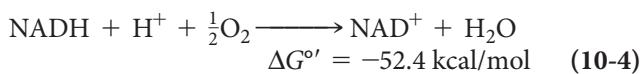

FIGURE 10A-2 The Glyoxylate Cycle and Gluconeogenesis in Fat-Storing Seedlings. Seedlings of fat-storing plant species can convert stored fat into sugar. Fatty acids derived from the hydrolysis of storage triacylglycerols are oxidized to acetyl CoA by the process of β oxidation. Acetyl CoA is then converted into succinate by the glyoxylate cycle, a five-reaction anabolic sequence named for glyoxylate, the molecule that is generated and consumed by Reactions GC-3 and GC-4, respectively. All the enzymes of β oxidation and the glyoxylate cycle are located in the glyoxysome. Conversion of succinate to malate occurs within the mitochondrion, whereas the further metabolism of malate via phosphoenolpyruvate to hexoses and hence to sucrose takes place in the cytosol. In seedlings of fat-storing plant species such as soybean, peanut, maize, and castor bean, acetyl CoA is derived from β oxidation of fatty acids. In bacteria and eukaryotic microorganisms capable of growing on two-carbon substrates such as ethanol or acetate, acetyl CoA is generated from acetyl phosphate, which is formed by ATP-dependent phosphorylation of free acetate.

Electron Transport and Coenzyme Oxidation. Electron transport involves the highly exergonic oxidation of NADH and FADH₂ with O₂ as the *terminal electron acceptor*, so we can write summary reactions as follows:

Electron transport therefore accounts not only for the reoxidation of coenzymes and the consumption of oxygen but also for the formation of water, which is the reduced form of oxygen and, along with CO₂, one of the two end products of aerobic energy metabolism.

The Electron Transport System. The most important aspect of Reactions 10-4 and 10-5 is the large amount of free energy released upon oxidation of NADH and FADH₂ by the transfer of electrons to oxygen. The highly negative ΔG° values for these reactions make it clear that the oxidation of a coenzyme is an extraordinarily exergonic process, enough to synthesize several molecules of ATP. Electron transfer is accomplished as a multistep process that involves an ordered series of reversibly oxidizable electron carriers functioning together in what is called the **electron transport system (ETS)**. The ETS contains a number of integral membrane proteins that are found in the inner mitochondrial membrane of eukaryotes (or the plasma membrane of bacteria).

Our discussion of the electron transport system will focus on three questions: (1) What are the major electron carriers in the ETS? (2) What is the sequence of these carriers in the system? (3) How are these carriers organized in the membrane to ensure that the flow of electrons from reduced coenzymes to oxygen is coupled to the pumping of protons across the membrane, thereby producing the electrochemical proton gradient on which ATP synthesis depends?

The Electron Transport System Consists of Five Kinds of Carriers

The carriers that make up the ETS include *flavoproteins*, *iron-sulfur proteins*, *cytochromes*, *copper-containing cytochromes*, and a quinone known as *coenzyme Q*. The flavoproteins and coenzyme Q transport protons along with electrons. Except for coenzyme Q, all the carriers are proteins with specific prosthetic groups capable of being reversibly oxidized and reduced. Almost all the events of electron transport occur within membranes, so it is not surprising that most of these carriers are hydrophobic molecules. In fact, most of these intermediates occur in the membrane as parts of large assemblies of proteins called *respiratory complexes*. We will first look briefly at the chemistry of these electron carriers and then see how they are organized into respiratory complexes and ordered

into a sequence of carriers that transfer electrons from reduced coenzymes to oxygen.

Flavoproteins. Several membrane-bound **flavoproteins** participate in electron transport, using either *flavin adenine dinucleotide (FAD)* or *flavin mononucleotide (FMN)* as the prosthetic group. FMN is essentially the flavin-containing half of the FAD molecule shown in Figure 10-9. An example of a flavoprotein is *NADH dehydrogenase*, which is part of the protein complex that accepts pairs of electrons from NADH. Another example, already familiar to us from the TCA cycle, is the enzyme succinate dehydrogenase, which has FAD as its prosthetic group and is part of the membrane-bound respiratory complex that accepts pairs of electrons from succinate via FAD. An important characteristic of the flavoproteins (and of the coenzyme NADH) is that they transfer both electrons and protons as they are reversibly oxidized and reduced.

Iron-Sulfur Proteins. **Iron-sulfur proteins**, also called *nonheme iron proteins*, are a family of proteins, each with an *iron-sulfur (Fe-S)* center that consists of iron and sulfur atoms complexed with cysteine groups of the protein. At least a dozen different Fe-S centers are known to be involved in the mitochondrial transport system. The iron atoms of these centers are the actual electron carriers. Each iron atom alternates between the oxidized (Fe³⁺) and the reduced (Fe²⁺) states during electron transport, which, in this case, involves transfer of only one electron at a time and no protons.

Cytochromes. Like the iron-sulfur proteins, **cytochromes** also contain iron but as part of a porphyrin prosthetic group called *heme*, which you probably recognize as a component of hemoglobin (see Figures 10-13 and 3-4). There are at least five different kinds of cytochromes in the electron transport system, designated as cytochromes *b*, *c*, *c*₁, *a*, and *a*₃. The iron atom of the heme prosthetic group, like that of the iron-sulfur center, serves as the electron carrier for the cytochromes. Thus, cytochromes are also one-electron carriers that do not transfer protons. While cytochromes *b*, *c*₁, *a*, and *a*₃ are integral membrane proteins, cytochrome *c* is a peripheral membrane protein that is loosely associated with the outer surface of the membrane. Moreover, cytochrome *c* is not a part of a large complex and can therefore diffuse much more rapidly, a key property in its role in transferring electrons between protein complexes.

Copper-Containing Cytochromes. In addition to their iron atoms, cytochromes *a* and *a*₃ also contain a single copper atom bound to the heme group of the cytochrome, where it associates with an iron atom to form a **bimetallic iron-copper (Fe-Cu) center**. Like iron atoms, copper ions can be reversibly converted from the oxidized (Cu²⁺) to the reduced (Cu⁺) form by accepting or donating single electrons. The iron-copper center plays a critical role in keeping an O₂ molecule bound to the cytochrome oxidase

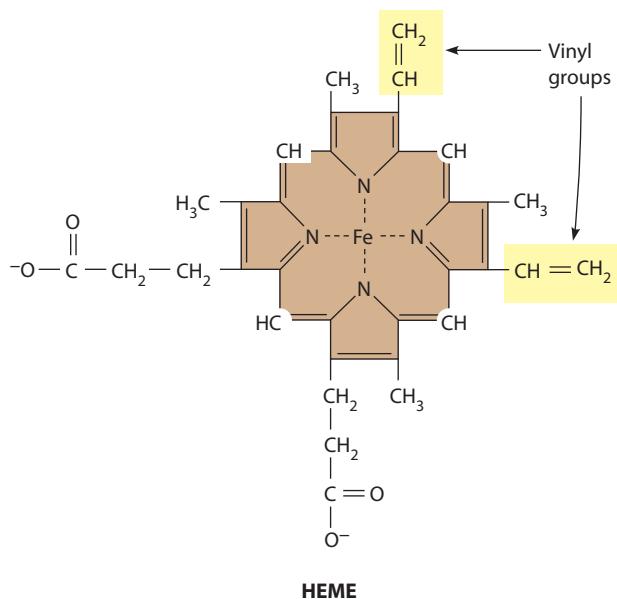

FIGURE 10-13 The Structure of Heme. Heme, also called iron-protoporphyrin IX, is the prosthetic group in cytochromes *b*, *c*, and *c₁*. A similar molecule, called heme A, is present in cytochromes *a₁* and *a₃*. The heme of cytochromes *c* and *c₁* is covalently attached to the protein by thioether bonds between the sulfhydryl groups of two cysteines in the protein and the vinyl ($-\text{CH}=\text{CH}_2$) groups of the heme (highlighted in yellow). In other cytochromes, the heme prosthetic group is linked noncovalently to the protein.

complex until the O_2 molecule has picked up the requisite four electrons and four protons, at which point the oxygen atoms are released as two molecules of water. (A nutritional note: If you have ever wondered why you require the elements iron and copper in your diet, their roles in electron transport are a major part of the reason.)

Coenzyme Q. The only nonprotein component of the ETS is **coenzyme Q (CoQ)**, a quinone with the structure shown in **Figure 10-14**. Because of its ubiquitous occurrence in nature, coenzyme Q is also known as *ubiquinone*. Figure 10-14 also illustrates the reversible reduction, in two successive one-electron (plus one-proton) steps, from the quinone form (CoQ) via the *semiquinone* form (CoQH) to the *dihydroquinone* form (CoQH₂).

Unlike the proteins of the ETS, most of the coenzyme Q is freely mobile in the nonpolar interior of the inner mitochondrial membrane (or of the plasma membrane, in the case of bacteria). CoQ molecules are the most abundant electron carriers in the membrane and occupy a central position in the ETS, serving as a collection point for electrons from the reduced prosthetic groups of FMN- and FAD-linked dehydrogenases in the membrane. Although most of the CoQ is mobile, recent work suggests that a portion of it is tightly bound to specific respiratory complexes and may participate in the mechanism of proton pumping.

Note that coenzyme Q accepts electrons as well as protons when it is reduced and that it releases both electrons

and protons when it is oxidized. This property is vital to the role of coenzyme Q in the active transport, or pumping, of protons across the inner mitochondrial membrane. When CoQ is reduced to CoQH₂, it always accepts protons from one side of the membrane then diffuses across the membrane to the outer surface, where it is oxidized to CoQ, with the protons ejected to the other side of the membrane. This motion provides a proton pump coupled to electron transport, which is thought to be one of the mechanisms whereby mitochondria, chloroplasts, and bacteria establish and maintain the electrochemical proton gradients that are used to store the energy of electron transport.

The Electron Carriers Function in a Sequence Determined by Their Reduction Potentials

Now that we are acquainted with the kinds of electron carriers that make up the ETS, our next question concerns the sequence in which these carriers operate. To answer that question, we need to understand the **standard reduction potential**, E_0' , which is a measure, in volts (V), of the affinity a compound has for electrons. It describes how easily a compound will gain electrons and become reduced.

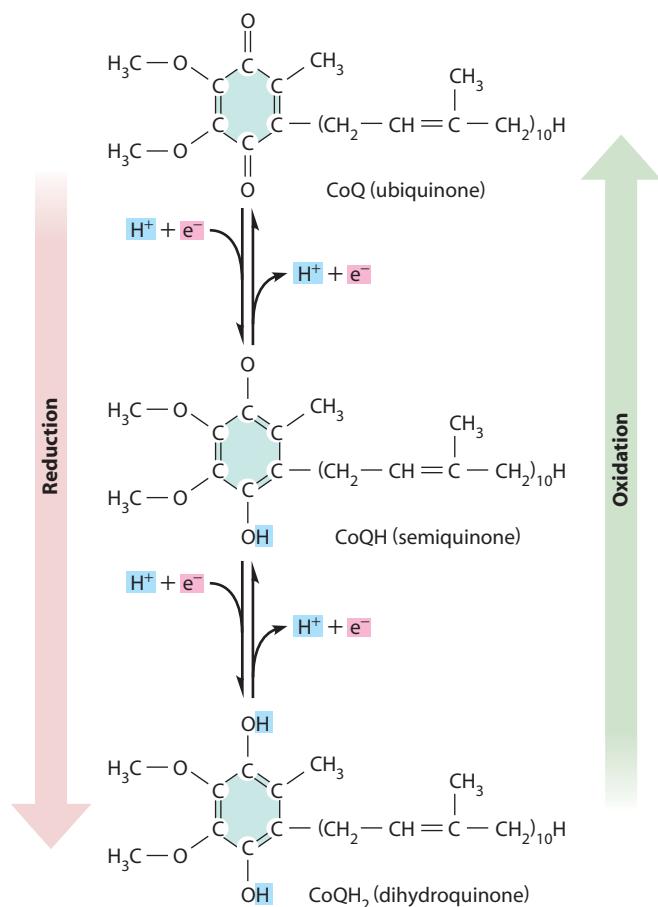

FIGURE 10-14 Oxidized and Reduced Forms of Coenzyme Q. Coenzyme Q (also called ubiquinone) accepts both electrons and protons as it is reversibly reduced in two successive one-electron steps to form first CoQH (the semiquinone form) and then CoQH₂ (the dihydroquinone form).

Reduction potentials are determined experimentally for a **redox (reduction-oxidation) pair**, which consists of two molecules or ions that are interconvertible by the loss or gain of electrons. For example, NAD⁺ and NADH constitute a redox pair, as do Fe³⁺ and Fe²⁺ or $\frac{1}{2}$ O₂ and H₂O, as shown in Reactions 10-6 to 10-8:

Relative E'_0 values allow us to compare redox pairs and to predict the direction electrons will tend to flow when several redox pairs are present in the same system, as is clearly the case for the electron transport system.

As described above, the reduction potential is a measure of the affinity that the oxidized form of a redox pair has for electrons. For a redox pair to have a positive E'_0 means that the oxidized form has a high affinity for electrons and is therefore a good electron *acceptor*. For example, the E'_0 value for the O₂/H₂O couple is highly positive, meaning that O₂ is a good electron acceptor. On the other hand, the NAD⁺/NADH couple has a highly negative E'_0 value, meaning that NAD⁺ is a poor electron acceptor. Alternatively, a negative E'_0 value can be thought of as a measure of how good an electron *donor* the reduced form of a redox pair is. Thus, the highly negative E'_0 value for the NADH pair means that NADH is a good electron donor.

Understanding Standard Reduction Potentials. To standardize calculations and comparisons of reduction potentials for various redox pairs, we clearly need values determined under specified conditions, much as we did for standard free energy in Chapter 5. For this purpose, we will use the standard reduction potential (E'_0), which is the reduction potential for a redox pair under standard conditions (25°C, 1 M concentration, 1 atmosphere pressure, and pH 7.0). The standard reduction potentials of redox pairs relevant to energy metabolism are given in **Table 10-2**.

By convention, the 2H⁺/H₂ redox pair is used as a reference and is assigned the value 0.00 V (Table 10-2, boldface line). For a redox pair to have a positive standard reduction potential means that, under standard conditions, the oxidized form of the pair has a higher affinity for electrons than H⁺ and will accept electrons from H₂. Conversely, a negative reduction potential means that the oxidized form of the pair has less affinity for electrons than H⁺, and its reduced form will donate electrons to H⁺ to form H₂.

The redox pairs of Table 10-2 are arranged in order, with the most negative E'_0 values (i.e., the best electron donors and hence the strongest reducing agents) at the top. Any redox pair shown in Table 10-2 can undergo a redox reaction with any other pair. The direction of such a reaction under standard conditions can be predicted by inspection because, under standard conditions, *the reduced form of any redox pair will spontaneously reduce the oxidized form of any pair below it on the table*. Thus, NADH can reduce pyruvate to lactate but cannot reduce α-ketoglutarate to isocitrate.

The tendency of the reduced form of one pair to reduce the oxidized form of another pair can be quantified by determining $\Delta E'_0$, the difference in the E'_0 values between the two pairs:

$$\Delta E'_0 = E'_{0, \text{acceptor}} - E'_{0, \text{donor}} \quad (10-9)$$

For example, $\Delta E'_0$ for the transfer of electrons from NADH to O₂ (Reaction 10-4) is calculated as follows, with NADH as the donor and O₂ as the acceptor:

$$\begin{aligned} \Delta E'_0 &= E'_{0, \text{acceptor}} - E'_{0, \text{donor}} \\ &= +0.816 - (-0.32) = +1.136 \text{ V} \end{aligned} \quad (10-10)$$

The Relationship Between ΔG° and $\Delta E'_0$. As you may already have guessed, $\Delta E'_0$ is a measure of thermodynamic spontaneity for the redox reaction between any two redox pairs under standard conditions. The spontaneity of a redox reaction under standard conditions can therefore be

Table 10-2 Standard Reduction Potentials for Redox Pairs of Biological Relevance*

Redox Pair (oxidized form → reduced form)	No. of Electrons	E'_0 (V)
Acetate → pyruvate	2	-0.70
Succinate → α-ketoglutarate	2	-0.67
Acetate → acetaldehyde	2	-0.60
3-phosphoglycerate → glyceraldehyde-3-P	2	-0.55
α-ketoglutarate → isocitrate	2	-0.38
NAD ⁺ → NADH	2	-0.32
FMN → FMNH ₂	2	-0.30
1,3-bisphosphoglycerate → glyceraldehyde-3-P	2	-0.29
Acetaldehyde → ethanol	2	-0.20
Pyruvate → lactate	2	-0.19
FAD → FADH ₂	2	-0.18
Oxaloacetate → malate	2	-0.17
Fumarate → succinate	2	-0.03
2H⁺ → H₂	2	0.00**
CoQ → CoQH ₂	2	+0.04
Cytochrome <i>b</i> (Fe ³⁺ → Fe ²⁺)	1	+0.07
Cytochrome <i>c</i> (Fe ³⁺ → Fe ²⁺)	1	+0.25
Cytochrome <i>a</i> (Fe ³⁺ → Fe ²⁺)	1	+0.29
Cytochrome <i>a₃</i> (Fe ³⁺ → Fe ²⁺)	1	+0.55
Fe ³⁺ → Fe ²⁺ (inorganic iron)	1	+0.77
$\frac{1}{2}\text{O}_2 \rightarrow \text{H}_2\text{O}$	2	+0.816

*Each $\Delta E'_0$ value is for the following half-reaction, where *n* is the number of electrons transferred:

**By definition, this redox pair is the reference point for determining values of all other redox pairs. It requires that [H⁺] = 1.0 M and therefore specifies pH 0.0. At pH 7.0, the value for the 2H⁺/H₂ pair is -0.42 V.

expressed as either $\Delta G^\circ'$ or $\Delta E_0'$. The sign convention for $\Delta E_0'$ is the opposite of that for $\Delta G^\circ'$, so an exergonic reaction is one with a negative $\Delta G^\circ'$ and a positive $\Delta E_0'$. For any oxidation-reduction reaction, $\Delta G^\circ'$ is related to $\Delta E_0'$ by the equation

$$\Delta G^\circ' = -nF \Delta E_0' \quad (10-11)$$

where n is the number of electrons transferred, and F is the Faraday constant (23,062 cal/mol · V). For example, the reaction of NADH with oxygen (Reaction 10-4) involves the transfer of two electrons, so $\Delta G^\circ'$ for the reaction can be calculated as

$$\begin{aligned} \Delta G^\circ' &= -2F \Delta E_0' = -2(23,062)(+1.136) \\ &= -52,400 \text{ cal/mol} = -52.4 \text{ kcal mol} \end{aligned} \quad (10-12)$$

The $\Delta G_0'$ for this reaction is highly negative, so the transfer of electrons from NADH to O_2 is thermodynamically spontaneous under standard conditions. This difference in reduction potentials between the $NAD^+/NADH$ and O_2/H_2O redox pairs drives the ETS and, as we will soon see, creates a proton gradient whose electrochemical potential will drive ATP synthesis.

Ordering of the Electron Carriers. We now have the information needed to put the pieces of the ETS together. As we already know, the respiratory ETS consists of several FMN- and FAD-linked dehydrogenases, iron-sulfur proteins with a total of 12 or more Fe-S centers, five cytochromes (including two with Fe-Cu centers), and a pool of coenzyme Q molecules. Shown in **Figure 10-15** are the major ETS components from free NADH

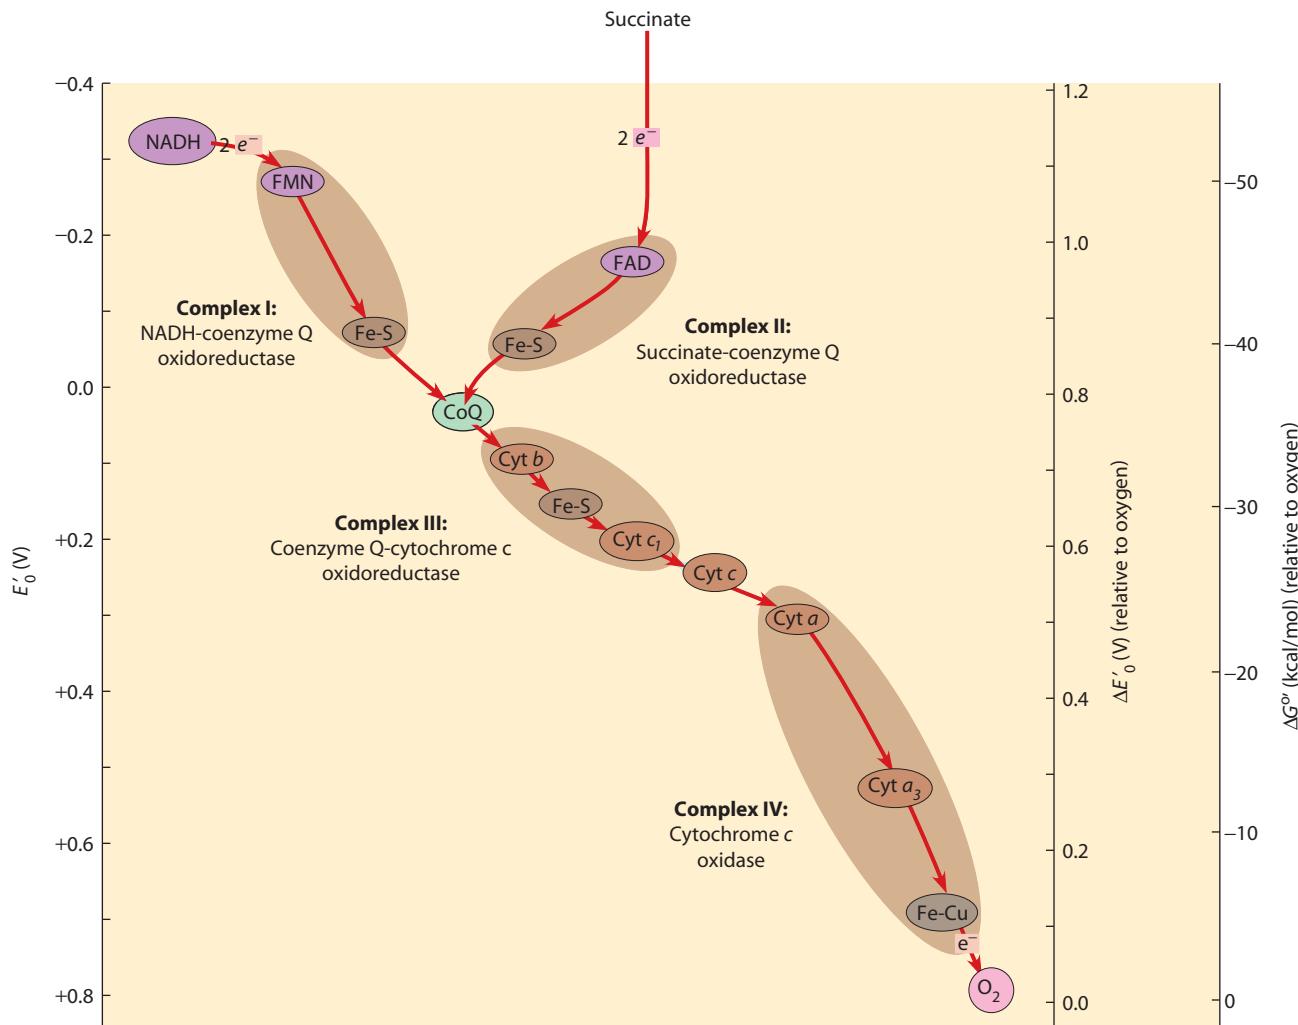

FIGURE 10-15 Major Components of the Respiratory Complexes and Their Energetics. Major intermediates in the transport of electrons from NADH (-0.32 V) and $FADH_2$ (-0.18 V) to oxygen ($+0.816$ V) are positioned vertically according to their energy levels, as measured by their standard reduction potentials (E_0' , left axis). The four respiratory complexes are shown as large brown ovals, with the major electron carriers in each complex enclosed within inset ovals. Coenzyme Q and cytochrome c are small, mobile intermediates that transfer electrons between the several complexes. The red lines trace the exergonic flow of electrons through the system. On the right axes are the $\Delta E_0'$ and $\Delta G^\circ'$ values relative to oxygen (i.e., the changes in the standard reduction potential and the standard free energy for the transfer of two electrons to O_2).

($E'_0 = -0.32$ V) and the FADH_2 of succinate dehydrogenase ($E'_0 = -0.18$ V) to oxygen ($E'_0 = +0.816$ V), arranged according to their standard reduction potentials (E'_0 values as obtained from Table 10-2).

In terms of energy, the key point of Figure 10-15 is that *the position of each carrier is determined by its standard reduction potential*. The electron transport system, in other words, consists of a series of chemically diverse electron carriers, with their order of participation in electron transfer determined by their relative reduction potentials. This means, in turn, that electron transfer from NADH or FADH_2 at the top of the figure to O_2 at the bottom is spontaneous and exergonic, with some of the transfers between successive carriers characterized by quite large differences in E'_0 values and hence by large changes in free energy.

Most of the Carriers Are Organized into Four Large Respiratory Complexes

Although there are many electron carriers involved in the ETS, most are not present in the membrane as separate entities. Instead, the behavior of these carriers in mitochondrial extraction experiments indicates that they are organized into *multiprotein complexes*. For example, when mitochondrial membranes are extracted under gentle conditions, only cytochrome *c* is readily removed. The other electron carriers remain bound to the inner membrane and are not released unless the membrane is exposed to detergents or concentrated salt solutions. Such treatments then extract the remaining electron carriers from the membrane not as individual molecules but as four large complexes.

Based on these and similar findings, most of the electron carriers in the ETS are thought to be organized within the inner mitochondrial membrane into four different kinds of **respiratory complexes**. These complexes are identified in Figure 10-15 by the brown ovals

and Roman numerals, which indicate the ordering of the various electron carriers based on their E'_0 values as well as their organization within the membrane.

Properties of the Respiratory Complexes. Each respiratory complex consists of a distinctive assembly of polypeptides and prosthetic groups, and each complex has a unique role to play in the electron transport process.

Table 10-3 summarizes some properties of these complexes.

Complex I transfers electrons from NADH to coenzyme Q and is called the *NADH-coenzyme Q oxidoreductase complex* (or *NADH dehydrogenase complex*). **Complex II** transfers to CoQ the electrons derived from succinate in Reaction TCA-6. This complex is called the *succinate-coenzyme Q oxidoreductase complex*, although it is often also referred to by its more common name, *succinate dehydrogenase*. **Complex III** is called the *coenzyme Q-cytochrome c oxidoreductase complex* because it accepts electrons from coenzyme Q and passes them to cytochrome *c*. This complex is also referred to as the *cytochrome b/c₁ complex* because those two cytochromes are its most prominent components. **Complex IV** transfers electrons from cytochrome *c* to oxygen and is called *cytochrome c oxidase*.

Figure 10-16 places the three complexes needed for NADH oxidation (complexes I, III, and IV) in their proper eukaryotic context, the inner mitochondrial membrane. (Complex II is not included in the figure because it is not involved in NADH oxidation.) Also shown in the figure is the outward pumping of protons across the membrane that accompanies electron transport within the membrane. Each of these complexes represents one site of proton pumping. *For each pair of electrons transported through complexes I, III, and IV, 10 protons are pumped from the matrix into the intermembrane space.*

Some researchers have noted that, under certain conditions, additional protons can be pumped out of the matrix

Table 10-3 Properties of the Mitochondrial Respiratory Complexes

Respiratory Complex		Number of Polypeptides*	Prosthetic Groups	Electron Flow		Protons Translocated (per electron pair)
Number	Name			Accepted from	Passed to	
I	NADH-coenzyme Q oxidoreductase (NADH dehydrogenase)	43 (7)	1 FMN 6–9 Fe-S centers	NADH	Coenzyme Q	4
II	Succinate-coenzyme Q oxidoreductase (succinate dehydrogenase)	4 (0)	1 FAD 3 Fe-S centers	Succinate (via enzyme-bound FAD)	Coenzyme Q	0
III	Coenzyme Q-cytochrome c oxidoreductase (cytochrome b/c ₁ complex)	11 (1)	2 cytochrome <i>b</i> 1 cytochrome <i>c</i> ₁ 1 Fe-S center	Coenzyme Q	Cytochrome <i>c</i>	4**
IV	Cytochrome <i>c</i> oxidase	13 (3)	1 cytochrome <i>a</i> 1 cytochrome <i>a</i> ₃ 2 Cu centers (as Fe-Cu centers with cytochrome <i>a</i> ₃)	Cytochrome <i>c</i>	Oxygen (O_2)	2

*The number of polypeptides encoded by the mitochondrial genome is indicated in parentheses for each complex.

**The value for complex III includes two protons translocated by coenzyme Q.

(a) Complex I receives 2 electrons from NADH and passes them to CoQ via FMN and an Fe-S protein. During this process, 4 H⁺ are pumped out of the matrix by complex I.

(b) Complex III passes electrons from CoQH₂ to cytochrome c via cytochromes b and c₁ and an Fe-S protein. CoQH₂ carries 2 H⁺ across the inner membrane and 2 more H⁺ are pumped out of the matrix.

(c) Complex IV receives electrons from cytochrome c and, via cytochrome a and a₃, passes them to molecular oxygen, which is reduced to water as 2 more H⁺ are pumped from the matrix by complex IV.

(d) ATP synthase uses the energy from the proton gradient generated during electron transport to synthesize ATP from ADP and P_i.

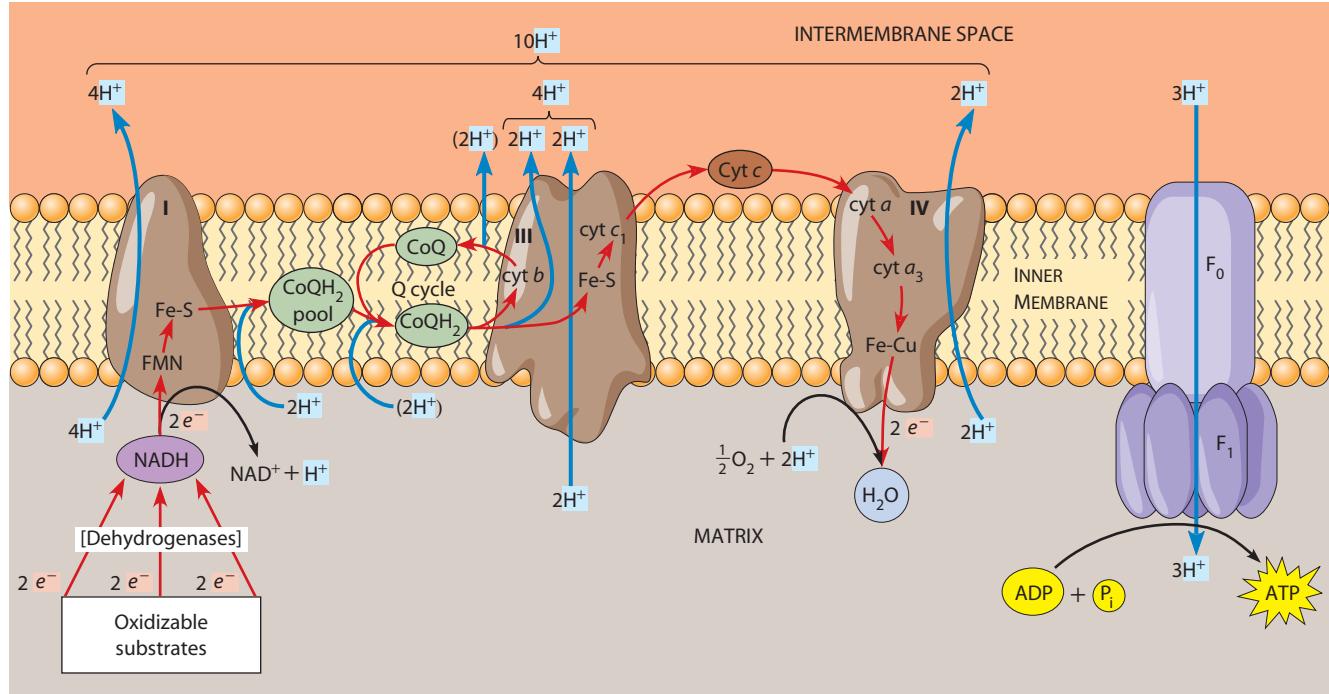

FIGURE 10-16 The Flow of Electrons Through Respiratory Complexes I, III, and IV Causes Directional Proton Pumping. (a–c) Electrons derived from oxidizable substrates in the mitochondrial matrix flow exergonically from NADH to oxygen via respiratory complexes I, III, and IV. (d) During the transport of two electrons, 10 H⁺ are pumped across the inner membrane, and 3 ATP are synthesized by the F₀F₁ ATP synthase. Two extra H⁺ (shown in parentheses in Figure 10-16) are pumped when the Q cycle operates.

without requiring additional electrons to be transported. This can be explained by the operation of a mitochondrial **Q cycle**, first proposed by Peter Mitchell in 1975. In this model, for every electron transferred from CoQH₂ to the Fe-S protein of complex III, one electron from CoQH₂ is used in the Q cycle to reduce a second molecule of CoQ via cytochrome b. As this CoQ is reduced to CoQH₂, two additional protons (shown in parentheses in Figure 10-16) are taken up from the matrix and then released into the intermembrane space as CoQH₂ is reoxidized.

The Role of Cytochrome c Oxidase. Of the several respiratory complexes involved in aerobic respiration in humans, cytochrome c oxidase (complex IV) is the **terminal oxidase**, transferring electrons directly to oxygen. This complex is therefore the critical link between aerobic respiration and the oxygen that makes it all possible. Cyanide and azide ions are highly toxic to nearly all aerobic cells because they bind tightly to the Fe-Cu center of cytochrome c oxidase, thereby blocking electron transport. Transport of four electrons from cytochrome c to O₂ plus the addition of four protons results in the production of two

molecules of H₂O. However, studies have shown that complexes I and III also can transfer electrons directly to O₂, resulting in its incomplete reduction. This can generate toxic *superoxide anion* (O₂[−]) or *hydrogen peroxide* (H₂O₂), compounds that can contribute to cellular aging under both normal and pathological conditions.

The Respiratory Complexes Move Freely Within the Inner Membrane

Unlike some integral proteins of the plasma membrane, the protein complexes of the mitochondrial inner membrane are mobile, free to diffuse within the plane of the membrane. This diffusion can be demonstrated experimentally. In one study, for example, inner mitochondrial membranes were placed in an electric field and the distribution of protein complexes was assessed subsequently by freeze-fracture analysis. Particles corresponding to protein complexes were found to accumulate at one end of the membrane. When the electrical field was turned off, the particles returned to a random distribution within seconds, clearly demonstrating their freedom to diffuse in a fluid lipid bilayer.

The results of this and similar studies make it clear that the respiratory complexes are not lined up in the membrane in the orderly fashion often seen in textbook diagrams but exist in the membrane as mobile complexes. In fact, the inner mitochondrial membrane has a high ratio of unsaturated to saturated phospholipids and virtually no cholesterol, so its fluidity is very high, and the mobility of the respiratory complexes is correspondingly high.

Recent work suggests that these multiprotein respiratory complexes themselves are organized into supercomplexes, known as **respirasomes**, containing several individual respiratory complexes associated in defined ratios. The association of several of the TCA cycle dehydrogenases with these respirasomes suggests that they function to minimize diffusion distances, facilitating electron flow between the respiratory complexes. Respirasomes have been found in systems as diverse as bacteria, yeast, plants, and humans and may have other regulatory functions as well.

As Figure 10-15 indicates, NADH, coenzyme Q, and cytochrome *c* are key intermediates in the electron transfer process. NADH links the ETS to the dehydrogenation (oxidation) reactions of the TCA cycle and to most other oxidation reactions in the matrix of the mitochondrion. Coenzyme Q and cytochrome *c* transfer electrons between the respiratory complexes. Coenzyme Q accepts electrons from both complexes I and II, and is, in fact, the “funnel” that collects electrons from virtually every oxidation reaction in the cell. Coenzyme Q and cytochrome *c* are both relatively small molecules that can diffuse rapidly, either within the membrane (coenzyme Q) or on the membrane surface (cytochrome *c*). They are also quite numerous—about 10 molecules of cytochrome *c* and 50 molecules of coenzyme Q for every complex I. Because of their abundance and mobility, these carriers are able to transfer electrons between the major complexes frequently enough to account for the observed rates of electron transfer in actively respiring mitochondria.

The Electrochemical Proton Gradient: Key to Energy Coupling

So far, we have learned that coenzymes are reduced during the oxidative events of glycolysis, pyruvate oxidation, and the TCA cycle, the first three stages of aerobic respiration (see Figure 10-1). We have also learned that reduced coenzymes are reoxidized by the exergonic transfer of electrons to oxygen via a system of reversibly oxidizable intermediates located within the inner mitochondrial membrane (stage ④). Now we will consider how the free energy released during electron transport is used to generate an electrochemical proton gradient and how the energy of the gradient is then used to drive ATP synthesis in stage ⑤.

Because this means of ATP synthesis involves phosphorylation events that are linked to oxygen-dependent electron transport, the process is called **oxidative phosphorylation**, thereby distinguishing it from *substrate-level phosphorylation*, which occurs as an integral part of a

specific reaction in a metabolic pathway. (Reactions Gly-7 and Gly-10 of the glycolytic pathway and Reaction TCA-5 of the TCA cycle are examples of substrate-level phosphorylation; see Figures 9-7 and 10-8.)

Electron Transport and ATP Synthesis Are Coupled Events

Mechanistically, oxidative phosphorylation is more complex than substrate-level phosphorylation. It has, in fact, been a confusing and highly controversial topic for much of its 60-year history, prompting Efraim Racker, a respected researcher in the field, to comment at one point, “Anyone who is not confused about oxidative phosphorylation just doesn’t understand the situation.” Now, however, we know that the crucial link between electron transport and ATP production is an **electrochemical proton gradient** that is established by the directional pumping of protons across the membrane in which electron transport is occurring.

Under normal cellular conditions, ATP synthesis is *coupled* to electron transport, meaning not only that ATP synthesis depends on electron flow but also that electron flow is possible only when ATP can be synthesized. However, treating isolated mitochondria with certain chemicals—known as *uncouplers*—abolishes the interdependence of these two processes. In other words, uncouplers allow continued electron transport (and O₂ consumption) even in the absence of ATP synthesis. In contrast, addition of respiratory complex inhibitors that stop electron flow also stops ATP synthesis. Therefore ATP synthesis is strictly dependent on electron transport, but electron transport is not necessarily dependent on ATP synthesis. In brown adipose (fat) tissue in the bodies of newborn mammals, a similar uncoupling mechanism operates, using exergonic electron transport to generate heat rather than ATP.

Respiratory Control of Electron Transport. Because electron transport is coupled to ATP synthesis, the availability of ADP regulates the rate of oxidative phosphorylation and therefore of electron transport. This is called **respiratory control**, and its physiological significance is easy to appreciate: Electron transport and ATP generation will be favored when the ADP concentration is high (i.e., when the ATP concentration is low) and inhibited when the ADP concentration is low (when the ATP concentration is high). Oxidative phosphorylation is therefore regulated by cellular ATP needs, such that electron flow from organic fuel molecules to oxygen is adjusted to the energy needs of the cell. This regulatory mechanism becomes apparent during exercise, when the accumulation of ADP in muscle tissue causes an increase in electron transport rates, followed by a dramatic rise in the need for oxygen.

The Chemiosmotic Model: The “Missing Link” Is a Proton Gradient. How can ATP synthesis, a dehydration reaction, be tightly coupled to electron transport, which involves the sequential oxidation and reduction of various protein complexes in a lipid bilayer? Scientists puzzled over

this question, but the answer eluded their best efforts for several decades. Most were convinced that some as yet undiscovered high-energy intermediate must be involved in oxidative phosphorylation just as in substrate-level phosphorylation. (Recall the ATP-generating steps of the glycolytic pathway and the TCA cycle in Reactions Gly-7 and Gly-10 in Figure 9-7 and Reaction TCA-5 in Figure 10-8.)

But while others continued their feverish search for high-energy intermediates, the British biochemist Peter Mitchell made the revolutionary suggestion that such intermediates might not exist at all. In 1961, Mitchell proposed an alternative explanation, which he called the **chemiosmotic coupling model**. According to this model, the exergonic transfer of electrons through the respiratory complexes is accompanied by the unidirectional pumping of protons across the membrane in which the transport system is localized. The electrochemical proton gradient that is generated in this way represents potential energy that then provides the driving force for ATP synthesis. In other words, the “missing link” between electron transport and ATP synthesis was not a high-energy chemical intermediate but an electrochemical proton gradient. This mechanism is illustrated in Figure 10-16, which depicts both the outward pumping of protons that accompanies electron transport through complexes I, III, and IV and the proton-driven synthesis of ATP by the F_oF_1 complex.

As you might expect, Mitchell’s theory met with considerable initial skepticism and resistance. Not only was it a radical departure from conventional wisdom on coupling, but Mitchell proposed it in the virtual absence of experimental data. Over the years, however, a large body of evidence has been amassed in its support, and in 1978 Mitchell was awarded a Nobel Prize for his pioneering work. Today the chemiosmotic coupling model is a well-verified concept that provides a unifying framework for understanding energy transformations not just in mitochondrial membranes but in chloroplast and bacterial membranes as well.

The essential feature of the chemiosmotic model is that the *link between electron transport and ATP formation is an electrochemical potential across a membrane*. It is, in fact, this feature that gives the model its name: The “chemi” part of the term refers to the chemical processes of oxidation and electron transfer and the “osmotic” part comes from the Greek word *osmos*, meaning “to push”—to push protons across the membrane, in this case. The chemiosmotic model has turned out to be exceptionally useful not only because of the very plausible explanation it provides for coupled ATP generation but also because of its pervasive influence on the way we now think about energy conservation in biological systems.

Coenzyme Oxidation Pumps Enough Protons to Form 3 ATP per NADH and 2 ATP per FADH₂

Before considering the experimental evidence that has confirmed the chemiosmotic model, notice that Figure 10-16

provides us with estimates of the numbers of protons pumped outward by the three respiratory complexes involved in NADH oxidation, as well as the number of protons required to drive the synthesis of ATP by the F_oF_1 complex. The word *estimate* is important here because investigators still disagree on some of these numbers. This disagreement arises partly due to a structural feature that varies in different ATP synthase complexes. As we will see shortly, the number of protons required to produce 3 ATP is directly related to the number of *c* subunits in the F_o portion of the F_oF_1 ATP synthase, and this number can differ among organisms.

As we have already seen, most of the dehydrogenases in the mitochondrial matrix transfer electrons from oxidizable substrates to NAD⁺, generating NADH. NADH, in turn, transfers electrons to the FMN component of complex I, thereby initiating the electron transport system. As Figure 10-16 shows, transfer of two electrons from NADH down the respiratory chain to oxygen is accompanied by the transmembrane pumping of 4 protons by complex I, 4 protons by CoQ plus complex III, and 2 protons by complex IV. This gives a total of 10 protons per NADH (12 protons per NADH if the Q cycle is operating).

The number of protons required to drive the synthesis of one molecule of ATP by the F_oF_1 ATP synthase is thought to be 3 or 4, with 3 generally regarded as more likely. If we assume that 10 protons are pumped per NADH oxidized and that 3 protons are required per ATP molecule, then we can conclude that oxidative phosphorylation yields about 3 molecules of ATP synthesized per molecule of NADH oxidized. This agrees well with evidence dating back to the 1940s that a fixed relationship usually exists between the number of molecules of ATP generated and the number of oxygen atoms consumed in respiration as a pair of electrons passes along the sequence of carriers from reduced coenzyme to oxygen. Racker and his colleagues, for example, showed that synthetic phospholipid vesicles containing complex I, complex III, or complex IV could generate one molecule of ATP per pair of electrons that passed through the complex. These results are consistent with our current understanding that each of these three complexes serves as a proton pump, thereby contributing to the proton gradient that drives ATP synthesis.

For purposes of our discussion, we will assume the ATP yields to be 3 for NADH and 2 for FADH₂, recognizing that the values on which these yields are based are still imprecisely known. These are reasonable numbers, considering that the $\Delta G^\circ'$ for the oxidation of NADH by molecular oxygen is -52.4 kcal/mol. This is enough of a free energy change to produce 3 ATP (requiring about 10 kcal/mole each under cellular conditions), even assuming an efficiency of only 50%.

The Chemiosmotic Model Is Affirmed by an Impressive Array of Evidence

Since its initial formulation in 1961, the chemiosmotic model has come to be universally accepted as the link

between electron transport and ATP synthesis. To understand why, we will first consider several of the most important lines of experimental evidence that support this model. In the process, we will also learn more about the mechanism of chemiosmotic coupling.

1. Electron Transport Causes Protons to Be Pumped Out of the Mitochondrial Matrix

NADH or Succinate as an Electron Source. Shortly after proposing the chemiosmotic model, Mitchell and his colleague Jennifer Moyle demonstrated experimentally that the flow of electrons through the ETS is accompanied by the movement of protons across the inner mitochondrial membrane. They first suspended mitochondria in a medium in which electron transfer could not occur because oxygen was lacking. The proton concentration (i.e., the pH) of the medium was then monitored as electron transfer was stimulated by the addition of oxygen. Under these conditions, the pH of the medium declined rapidly with either NADH or succinate as the electron source (**Figure 10-17**). Because a decline in pH reflects an increase in proton concentration, Mitchell and Moyle concluded that electron transfer within the mitochondrial inner membrane is accompanied by **unidirectional pumping of protons** from the mitochondrial matrix into the external medium.

The mechanism whereby the transfer of electrons from one carrier to another is coupled to the directional transport of protons is still not well understood. There may, in fact, be more than one such mechanism. A possible mechanism is the one discussed earlier for coenzyme Q, which moves two protons across the mitochondrial membrane as it carries two electrons from respiratory complex I to complex III (Figure 10-16).

In the case of proton-pumping complexes I and IV, current evidence suggests that a second pumping mechanism may involve allosteric changes in protein conformation. In one conformational state, a polypeptide in the complex could bind a proton at the inner surface of the membrane. Transfer of one or more electrons through the complex might then cause the polypeptide to assume an alternative conformation and release the proton at the outer surface of the membrane. Thus, the pumping of protons may be achieved either by the physical movement of a carrier molecule such as coenzyme Q or by a conformational change in a polypeptide within a respiratory complex.

2. Components of the Electron Transport System Are Asymmetrically Oriented Within the Inner Mitochondrial Membrane

The unidirectional pumping demonstrated by Mitchell and Moyle requires that the electron carriers making up the ETS be asymmetrically oriented within the membrane. If not, protons would presumably be pumped randomly in both directions. Studies with a variety of antibodies, enzymes, and labeling agents designed to interact with various membrane components have shown clearly that some constituents of the respiratory complexes face the matrix side of the inner membrane, others are exposed on the opposite side, and

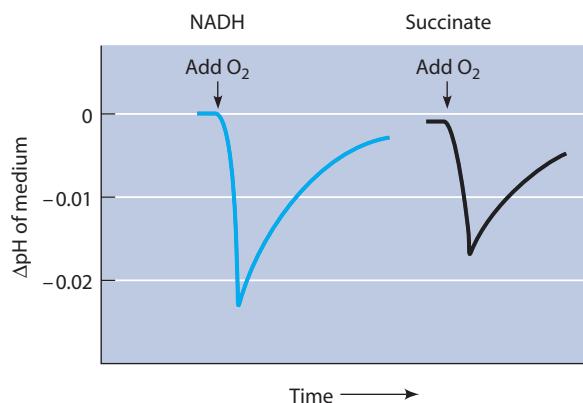

FIGURE 10-17 Experimental Evidence That Electron Transport Generates a Proton Gradient.

Isolated mitochondria were incubated with either NADH or succinate as an electron source. The mitochondria were deprived of oxygen, and the pH of the medium was then monitored as electron transport was stimulated by the addition of a known quantity of oxygen. The rapid decline in pH reflects an increase in proton concentration, indicating that protons were pumped out of the mitochondrial matrix when oxygen was available. The pH change was reproducibly greater with NADH than with succinate, which is consistent with the greater ATP yield that accompanies the oxidation of NADH.

some are transmembrane proteins. These findings confirm the prediction that ETS components are asymmetrically distributed across the inner mitochondrial membrane, as shown schematically in Figure 10-16.

3. Membrane Vesicles Containing Complexes I, III, or IV Establish Proton Gradients

Further support for the chemiosmotic model has come from experiments involving the reconstitution of membrane vesicles from mixtures of isolated components. Since each of respiratory complexes I, III, and IV has a coupling site for ATP synthesis (see Figure 10-16), the chemiosmotic model predicts that each of these complexes should be capable of pumping protons across the inner mitochondrial membrane. This prediction has been confirmed experimentally by reconstituting artificial phospholipid vesicles containing complex I, III, or IV. When provided with appropriate oxidizable substrates, each of these three complexes is able to pump protons across the membrane of the vesicle. As noted before, these vesicles are also capable of ATP synthesis.

4. Oxidative Phosphorylation Requires a Membrane-Enclosed Compartment

An obvious prediction of the chemiosmotic model is that oxidative phosphorylation occurs only within a compartment enclosed by an intact mitochondrial membrane. Otherwise, the proton gradient that drives ATP synthesis could not be maintained. This prediction has been verified by experimental demonstration that electron transfer carried out by isolated complexes cannot be coupled to ATP synthesis unless the complexes are incorporated into membranes that form enclosed, intact vesicles.

5. Uncoupling Agents Abolish Both the Proton Gradient and ATP Synthesis. Additional evidence for the role played by proton gradients in ATP formation has come from studies using agents such as dinitrophenol (DNP) that are known to uncouple ATP synthesis from electron transport. For example, Mitchell showed in 1963 that membranes become freely permeable to protons in the presence of DNP. Dinitrophenol, in other words, abolished both ATP synthesis and the capability of a membrane to maintain a proton gradient. This finding is clearly consistent with the concept of ATP synthesis driven by an electrochemical proton gradient.

6. The Proton Gradient Has Enough Energy to Drive ATP Synthesis. For the chemiosmotic model to be viable, the proton gradient generated by electron transport must store enough energy to drive ATP synthesis. We can address this point with a few thermodynamic calculations. The electrochemical proton gradient across the inner membrane of a metabolically active mitochondrion involves both a membrane potential (the “electro” component of the gradient) and a concentration gradient (the “chemical” component). As you may recall from Chapter 8, the equation used to quantify this electrochemical gradient has two terms, one for the membrane potential, V_m , and the other for the concentration gradient, which in the case of protons is a pH gradient (see Table 8-3, page 218).

A mitochondrion actively involved in aerobic respiration typically has a membrane potential of about 0.16 V (positive on the side that faces the intermembrane space) and a pH gradient of about 1.0 pH unit (higher on the matrix side). This electrochemical gradient exerts a **proton motive force (pmf)** that tends to drive protons back down their concentration gradient—back into the matrix of the mitochondrion, that is. The pmf can be calculated by summing the contributions of the membrane potential and the pH gradient using the following equation:

$$\text{pmf} = V_m + 2.303 RT \Delta \text{pH}/F \quad (10-13)$$

where pmf is the proton motive force in volts, V_m is the membrane potential in volts, ΔpH is the difference in pH across the membrane ($\Delta \text{pH} = \text{pH}_{\text{matrix}} - \text{pH}_{\text{cytosol}}$), R is the gas constant (1.987 cal/mol · K), T is the temperature in kelvins, and F is the Faraday constant (23,062 cal/mol · V).

For a mitochondrion at 37°C with a V_m of 0.16 V and a pH gradient of 1.0 unit, the pmf can be calculated as follows:

$$\begin{aligned} \text{pmf} &= 0.16 + \left(\frac{2.303(1.987)(37 + 273)(1.0)}{23,062} \right) \\ &= 0.16 + 0.06 = 0.22 \text{ V} \end{aligned} \quad (10-14)$$

Notice that the membrane potential accounts for more than 70% of the mitochondrial pmf.

Like the redox potential, pmf is an electrical force in volts and can be used to calculate $\Delta G^\circ'$, the standard free

energy change for the movement of protons across the membrane, using the following equation:

$$\Delta G^\circ' = -nF(\text{pmf}) = -(23.062)(0.22) = -5.1 \text{ kcal/mol} \quad (10-15)$$

Thus, a proton motive force of 0.22 V across the inner mitochondrial membrane corresponds to a free energy change of about -5.1 kcal/mole of protons. This is the amount of energy that will be released as protons return to the matrix.

Is this enough to drive ATP synthesis? Not surprisingly, the answer is yes, though it depends on how many protons are required to drive the synthesis of one ATP molecule by the F_0F_1 complex. Mitchell's original model assumed two protons per ATP, which would provide about 10.2 kcal/mol, barely enough to drive ATP formation, assuming the $\Delta G'$ for phosphorylation of ADP to be about 10 to 14 kcal/mol under mitochondrial conditions. Differences of opinion still exist concerning the number of protons per ATP, but the real number is probably closer to three or four. That number would provide about 15 to 20 kcal of energy per ATP, enough to ensure that the reaction is driven strongly in the direction of ATP formation.

7. Artificial Proton Gradients Are Able to Drive ATP Synthesis in the Absence of Electron Transport. Direct evidence that a proton gradient can in fact drive ATP synthesis has been obtained by exposing mitochondria or inner membrane vesicles to artificial pH gradients. When mitochondria are suspended in a solution in which the external proton concentration is suddenly increased by the addition of acid, ATP is generated in response to the artificially created proton gradient. Because such artificial pH gradients induce ATP formation even in the absence of oxidizable substrates that would otherwise pass electrons to the ETS, it is evident that ATP synthesis can be induced by a proton gradient even in the absence of electron transport.

ATP Synthesis: Putting It All Together

We are now ready to take up the fifth, and final, stage of aerobic respiration: ATP synthesis. We have thus far seen that: (1) some of the energy of glucose is transferred to reduced coenzymes during the oxidation reactions of glycolysis and the TCA cycle; and (2) how this energy is used to generate an electrochemical proton gradient across the inner membrane of the mitochondrion. Now we can ask how the pmf of that gradient is harnessed to drive ATP synthesis. For that, we return to the F_1 complexes that can be seen along the inner surfaces of cristae (see Figure 10-5a) and ask about the evidence that these particles are capable of synthesizing ATP.

F_1 Particles Have ATP Synthase Activity

Key evidence concerning the role of F_1 particles came from studies conducted by Racker and his colleagues to test the prediction of the chemiosmotic hypothesis: that a reversible,

proton-translocating ATPase is present in membranes that are capable of coupled ATP synthesis. Beginning with intact mitochondria (**Figure 10-18a**), the investigators were able to disrupt the mitochondria in such a way that fragments of the inner membrane formed small vesicles, which they called *submitochondrial particles* (**Figure 10-18b**). These submitochondrial particles were capable of carrying out electron transport and ATP synthesis. By subjecting these particles to mechanical agitation or protease treatment, they were able to dislodge the F₁ structures from the membranous vesicles (**Figure 10-18c**).

When the F₁ particles and the membranous vesicles were separated from each other by centrifugation, the membranous fraction could still carry out electron transport but could no longer synthesize ATP; the two functions had become uncoupled (**Figure 10-18d**). The isolated F₁ particles, on the other hand, were not capable of either electron transport or ATP synthesis but had ATPase activity (**Figure 10-18e**), a property consistent with the F-type ATPase that we now know the mitochondrial F₀F₁ complex to be (see Table 8-2, page 210). The ATP-generating capability of the membranous fraction was restored by adding

the F₁ particles back to the membranes, suggesting that the spherical projections seen on the inner surface of the inner mitochondrial membrane are an important part of the ATP-generating complex of the membrane. These F₁ particles were therefore referred to as *coupling factors* (the “F” in F₁) and are now known to be the structures responsible for the ATP-synthesizing activity of the inner mitochondrial membrane or the bacterial plasma membrane.

The F₀F₁ Complex: Proton Translocation Through F₀ Drives ATP Synthesis by F₁

Although the F₁ portion of the F₀F₁ ATP synthase complex is not directly membrane bound, it is attached to the F₀ complex that is embedded in the inner mitochondrial membrane (see Figure 10-5c). We now know that the F₀ complex serves as the **proton translocator**, the channel through which protons flow across the mitochondrial inner membrane (or the bacterial plasma membrane as in the case of the *E. coli* complex discussed below). Thus, the F₀F₁ complex is the complete, functional **ATP synthase**. The F₀ component provides a channel for the

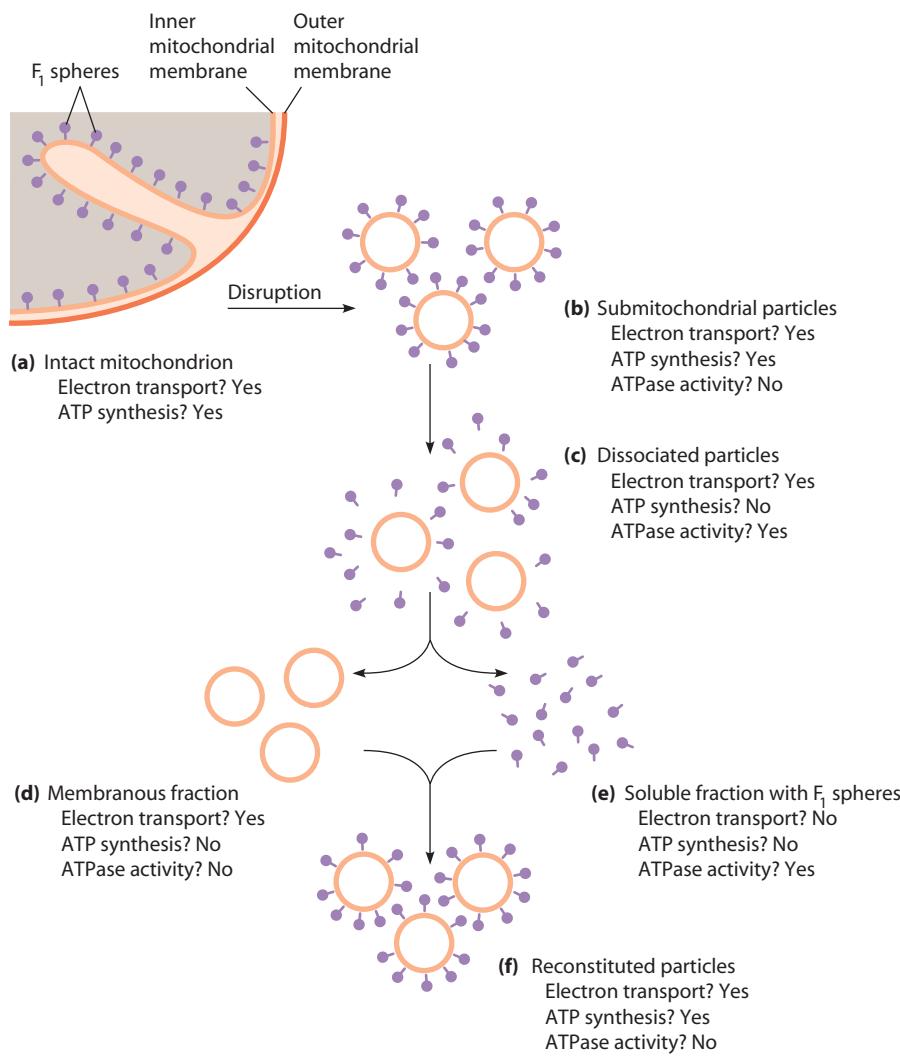

FIGURE 10-18 Dissociation and Reconstitution of the Mitochondrial ATP-Synthesizing System. (a) Intact mitochondria were disrupted so that fragments of the inner membrane formed (b) submitochondrial particles, capable of both electron transport and ATP synthesis. (c) When these particles were dissociated by mechanical agitation or enzyme treatment, the components could be separated into (d) a membranous fraction devoid of ATP-synthesizing capacity and (e) a soluble fraction with F₁ spheres having ATPase activity. (f) Mixing the two fractions reconstituted the structure and restored ATP synthase activity.

Table 10-4 Polypeptide Composition of the *E. coli* F_oF₁ ATP Synthase (ATPase)*

Structure	Polypeptide	Molecular Weight	Number Present	Function
F _o	<i>a</i>	30,000	1	Proton channel
	<i>b</i>	17,000	2	Peripheral stator stalk connecting F _o and F ₁
	<i>c</i>	8,000	10	Rotating ring that turns γ subunit of F ₁
F ₁	α	52,000	3	Promotes activity of β subunit
	β	55,000	3	Catalytic site for ATP synthesis
	δ	19,000	1	Anchors $\alpha_3\beta_3$ ring to stator stalk of F _o
	γ	31,000	1	Rotates to transmit energy from F _o to F ₁
	ϵ	15,000	1	Anchors γ subunit to c_{10} ring of F _o

*Mitochondrial F_oF₁ complexes are similar to the bacterial complex but with somewhat different polypeptide compositions for F_o and F₁.

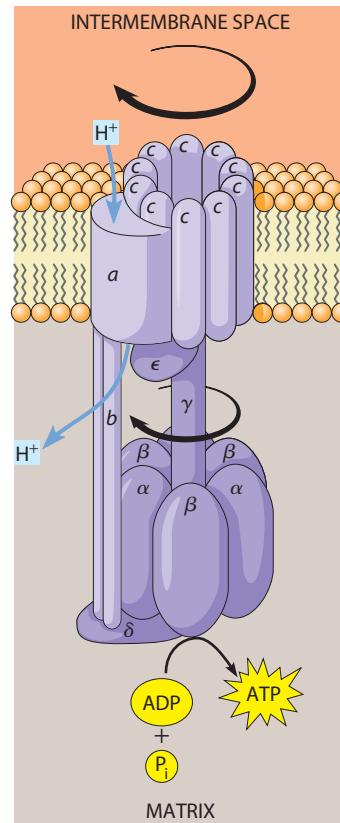

exergonic flow of protons through the membrane, and the F₁ component carries out the actual synthesis of ATP, driven by the energy of the proton gradient.

Table 10-4 presents the polypeptide composition of the bacterial F_oF₁ complex from *Escherichia coli*, and **Figure 10-19** illustrates the four major structural components in this functional complex. Each of the F_o and F₁ complexes contains both a static component that remains stationary and a mobile component that moves during proton translocation. Together, these components of the

F_oF₁ complex form one of the wonders of the molecular world—a miniature motor in which proton flow turns a microscopic gear that drives ATP synthesis.

The F_o complex is embedded in the bacterial membrane (or the inner mitochondrial membrane in eukaryotic cells) and consists of 1 *a* subunit, 2 *b* subunits, and 10 *c* subunits. The *a* and *b* subunits comprise the static component that is immobilized in the membrane. The ten *c* subunits form a ring that acts as a miniature gear that can rotate in the membrane relative to the *a* and *b*

(a) The F_o static component consists of one *a* and two *b* subunits. The *a* subunit forms the proton channel and is immobilized in the membrane. The *b* subunits form the peripheral stalk and are attached both to the *a* subunit and to F₁.

(b) The F_o mobile component consists of a ring of 10 *c* subunits. Only one *c* subunit can form an ionic bond with the *a* subunit at a time. For each proton translocated, the ring rotates one-tenth of a turn as the adjacent *c* subunit in the ring bonds with the *a* subunit.

(c) The F₁ static component consists of the *delta* subunit plus a catalytic ring formed by a hexagon of alternating α and β subunits. The $\alpha_3\beta_3$ ring is the site of ATP synthesis and is immobilized by the δ subunit, which connects it to the b_2 peripheral stalk of F_o.

(d) The F₁ mobile component consists of the *epsilon* and γ subunits, which form the central stalk that is firmly attached to the c_{10} ring of F_o. As proton translocation turns the c_{10} ring, the γ subunit rotates inside the $\alpha_3\beta_3$ catalytic ring of F₁.

FIGURE 10-19 F_o and F₁ Components of the *E. coli* F_oF₁ ATP Synthase. This illustration shows the subunit composition of the static and mobile components of the F_o (a) and (b) and F₁ (c) and (d) complexes that comprise the functional F_oF₁ ATP synthase in *E. coli*. As 10 H⁺ move through the F_o proton translocator, the ring of 10 *c* subunits in F_o rotates once, resulting in the synthesis of 3 ATP by the $\alpha_3\beta_3$ catalytic ring of F₁.

VIDEOS www.thecellplace.com Rotation of ATP synthase

subunits. The α subunit functions as the proton channel, and the β subunits form the *stator stalk* that connects the surfaces of the F_o and F_1 complexes.

The F_1 complex protrudes into the bacterial cytoplasm (or into the mitochondrial matrix in eukaryotic cells) and consists of 3 α subunits, 3 β subunits, plus 1 delta (δ), 1 gamma (γ), and 1 epsilon (ϵ) subunit. ATP is synthesized by a catalytic ring of three $\alpha\beta$ complexes that form a hexagon of alternating subunits. The δ subunit of F_1 anchors the $\alpha_3\beta_3$ catalytic ring to the b_2 stator stalk of F_o , immobilizing the catalytic ring. The mobile component of F_1 consists of the γ and ϵ subunits, which are attached to (and move with) the ring of c subunits in F_o . As protons move through the F_o proton channel, the c_{10} ring rotates, spinning the γ subunit within the $\alpha_3\beta_3$ catalytic ring. This

results in ATP synthesis by the catalytic ring, using an intriguing mechanism that is described further in the next section.

ATP Synthesis by F_oF_1 Involves Physical Rotation of the Gamma Subunit

Once the link between electron transport within the membrane and proton pumping across the membrane had been established, the next piece of the puzzle was almost as daunting: How does the exergonic flux of protons through F_o drive the otherwise endergonic synthesis of ATP by the three β subunits of F_1 ? A novel answer to this question was suggested in 1979 by Paul Boyer, who proposed the **binding change model** shown in **Figure 10-20**.

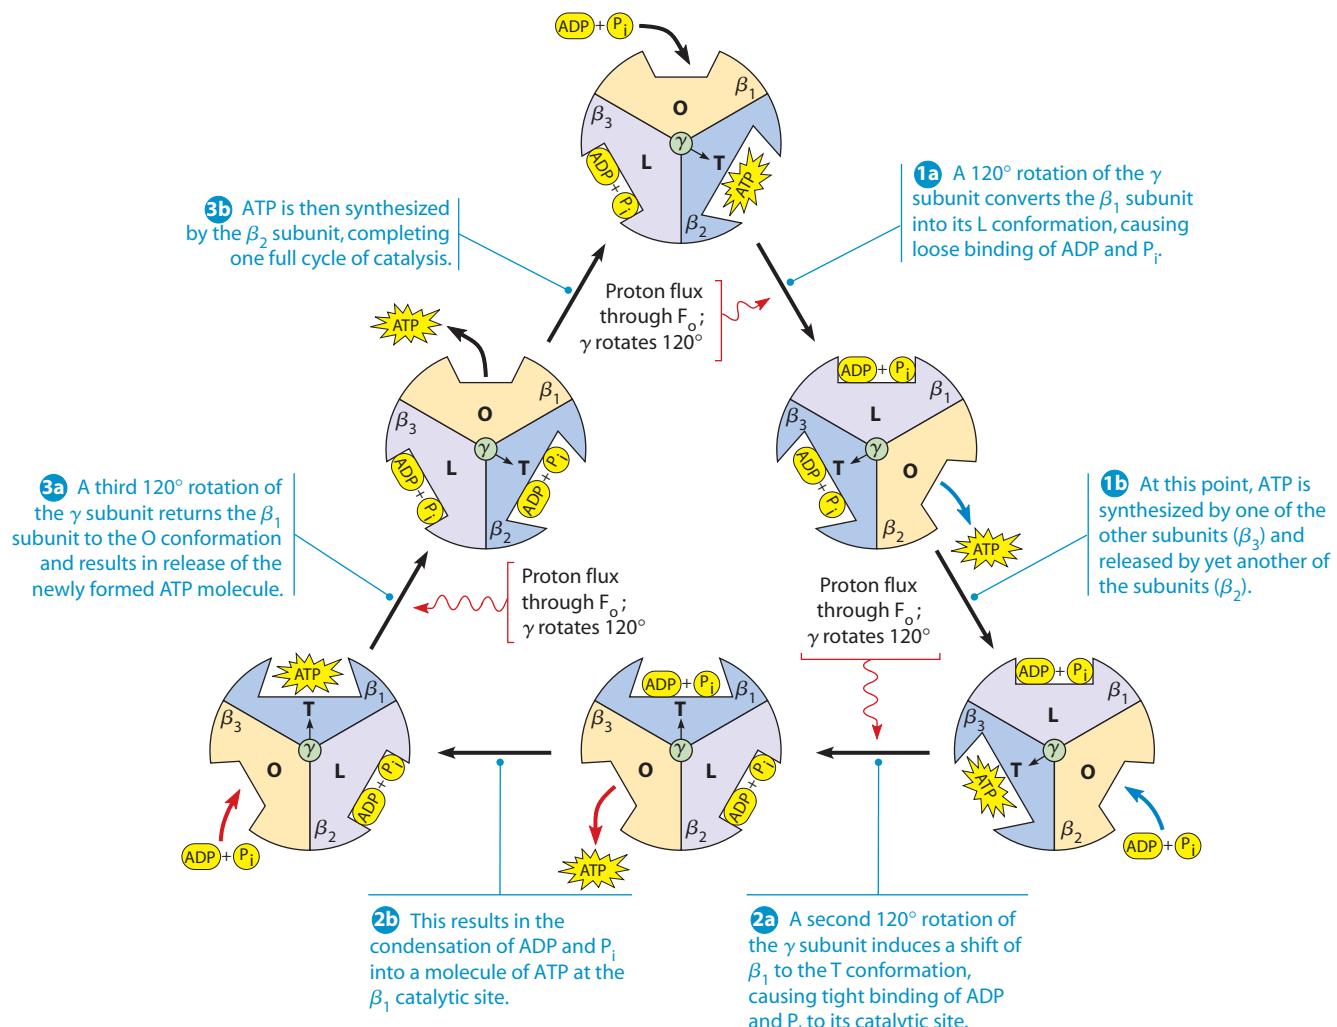

FIGURE 10-20 The Binding Change Model for ATP synthesis by the β Subunits of the F_oF_1 Complex.

According to this model, each of the β subunits of the F_1 complex is in a different conformation at any instant. Each undergoes a sequence of conformational changes from the O (open) conformation through the L (loose) conformation to the T (tight) conformation. These conformational changes are driven by the rotation of the γ subunit. The process of ATP synthesis begins with one of the β subunits (arbitrarily identified as β_1) in its O conformation and involves the six steps shown, involving three 120° rotations and synthesis of 3 ATP per full 360° rotation. Notice that the same sequence of events occurs at each of the other sites, but it is offset temporally.

[VIDEOS](http://www.thecellplace.com) www.thecellplace.com ATP synthase 3-D structure

Boyer's model envisioned the catalytic site on each of the three β subunits of the F_1 complex as progressing through three distinctly different conformations with quite different affinities for the substrates (ADP and P_i) and the product (ATP). Boyer identified these as the L (for loose) conformation, which binds ADP and P_i loosely; the T (for tight) conformation, which binds ADP and P_i tightly and catalyzes their condensation into ATP; and the O (for open) conformation, which has a very low affinity for substrates or product and is unoccupied most of the time. Boyer proposed that, at any point in time, each of the three active sites is in a different conformation and that the hexagonal ring of α and β subunits actually rotates with respect to the central stalk containing the γ subunit. This rotation was proposed to be driven by the flux of protons through the F_o complex. (As mentioned earlier, we now know that it is the γ subunit that rotates within the stationary $\alpha_3\beta_3$ catalytic ring, but the concept of relative motion was quite accurate.)

Though not widely accepted at first, Boyer's model was substantially confirmed in 1994 by John Walker and co-workers, who used X-ray crystallography to provide the first detailed atomic model of the F_1 complex. Their model identified structures in the active sites of the β subunits that corresponded to Boyer's O, L, and T conformations, and they confirmed that each of the three active sites is in a different conformation at any given time. Even more remarkably, the γ subunit within the stalk that connects the F_1 and F_o complexes (see Figure 10-19) was shown to extend into the center of the F_1 structure in an asymmetric manner, such that its contact with and effect upon each of the β subunits is different at any given instant.

The Binding Change Model in Action. The sequence of events shown in Figure 10-20 is a current model of how the exergonic flux of protons through the F_o complex drives the synthesis of ATP by the catalytic sites on the three β subunits of the F_1 complex. As protons flow through a channel in the α subunit of F_o , they drive the rotation of the ring of c subunits in the F_o structure—and therefore also the rotation of the γ subunit of the stalk, which is attached to the c ring. The asymmetry of the γ subunit not only results in characteristically different interactions with the three β subunits at any point in time but also causes each β subunit to pass successively through the O, L, and T conformations as the γ subunit rotates 360 degrees.

The way that proton flow through F_o causes the c_{10} ring to rotate is truly a marvel of protein structure and function. Each of the 10 c subunits has an aspartate residue capable of forming an ionic bond with an arginine residue on the immobile α subunit. Only one aspartate from one c subunit can bind to the arginine at a time—and only if the aspartate is unprotonated (charged). As a proton is taken up from the external side of the membrane, it protonates and neutralizes the aspartate residue, disrupting the ionic bond. This causes a conformational change that rotates the ring

one-tenth of a turn, causing the aspartate residue in the adjacent residue to lose a proton and form an ionic bond with the arginine in the α subunit. Thus, as 10 protons pass through the membrane via the α subunit, the c_{10} ring (and the attached $F_1 \gamma$ subunit) makes one complete rotation.

Meanwhile, in the $\alpha_3\beta_3$ catalytic ring, the β_1 subunit starts out in the O conformation, with the substrates ADP and P_i free to enter the catalytic site (see Figure 10-20). The catalytic site has little affinity for them in this conformation. As protons flow through the F_o subunit in the membrane, the c ring and the attached γ subunit rotate 120° degrees (step 1b). This induces a shift in the β_1 site from the O to the L conformation and results in the loose binding of ADP and P_i to the catalytic site.

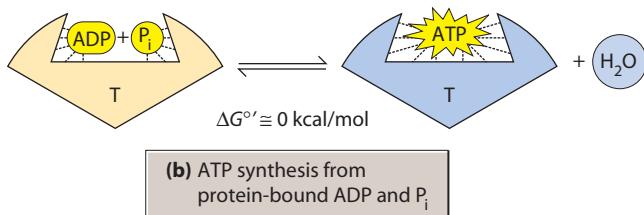

Following the synthesis of an ATP molecule by the β_3 subunit (step 1b), the γ subunit rotates another 120° (step 2a), inducing a shift in the β_1 subunit to the T conformation. This increases the affinity for ADP and P_i , which become tightly bound to the catalytic site in an orientation that allows them to condense spontaneously to form ATP (step 2b). The γ subunit now rotates a further 120°, returning the β_1 catalytic site to the O conformation, thereby releasing the ATP from the catalytic site (step 3a). Following the generation of an ATP molecule by one of the other subunits (the β_2 subunit; step 3b), one full cycle is completed, and the β_1 subunit is available for another round of ATP synthesis. Note that the same sequence of events has occurred at the other two subunits as well. Thus, one complete revolution of the γ subunit results in the synthesis of 3 ATP molecules, one by each of the three β subunits.

Spontaneous Synthesis of ATP? Close scrutiny of Figure 10-20 reveals that each of the three steps at which ATP is formed occurs without a direct input of energy. Yet we know that the synthesis of ATP is a highly endergonic reaction. How, we might then ask, does ATP synthesis proceed spontaneously at the catalytic site of a β subunit in its T conformation? Actually, what we really know is that ATP synthesis is a highly endergonic reaction *in dilute aqueous solution*. However, the reaction *at the catalytic site of a β subunit* involves enzyme-bound intermediates in a drastically different environment—so different, in fact, that the reaction under these conditions has a ΔG° close to zero (**Figure 10-21**) and can therefore occur spontaneously, without any immediate energy input. It is thought that the immediate environment at the catalytic site may serve to minimize charge repulsion between ADP and P_i , favoring their condensation into ATP.

This doesn't mean that ATP synthesis proceeds without thermodynamic cost, though. It simply means that the input of energy is required at other points in the cycle. Prior energy input is needed to drive the transition of the catalytic site from the L to the T conformation, thereby packing the ADP and P_i together tightly and facilitating their interaction (step 2a of Figure 10-20). Subsequent energy input is required for release of the tightly bound ATP product from the catalytic site (step 3a). This energy

(a) ATP synthesis in dilute aqueous solution

(b) ATP synthesis from protein-bound ADP and P_i

FIGURE 10-21 Comparative Energetics of ATP Synthesis. The energy requirement for ATP synthesis differs greatly, depending on the environment. (a) In dilute aqueous solution, ATP synthesis from soluble ADP and P_i is highly endergonic, with a ΔG° of +7.3 kcal/mol. (b) At the catalytic site of a β subunit in its T conformation, however, the environment is drastically different and the reaction has a ΔG° close to 0 (i.e., the K_{eq} is close to 1) and can therefore proceed spontaneously with no immediate energy requirement.

comes from the proton gradient generated by electron transport and transmitted through the rotation of the c ring and γ subunit as mechanical energy. Thus, the F_oF₁ ATP synthase provides us with a marvelous example of how the cell can convert electrical work (electron transport) to concentration work (proton gradient) to mechanical work (subunit rotation) to biosynthetic work (ATP synthesis).

The Chemiosmotic Model Involves Dynamic Transmembrane Proton Traffic

The dynamics of the chemiosmotic model are summarized in **Figure 10-22**. Complexes I, III, and IV of the ETS pump protons outward across the inner membrane of the mitochondrion, where they accumulate in the intracristal space. The resulting electrochemical gradient then drives ATP generation by means of the F_oF₁ complexes associated with the inner membrane. There is, in other words, continuous, dynamic two-way proton traffic across the inner membrane. First let's count the number of protons extruded by each of the respiratory assemblies shown in Figure 10-22: 10 for complexes I + III + IV (using NADH) and 6 for complexes II + III = IV (using FADH₂). Assuming that, and that 3 protons are required to drive the synthesis of 1 ATP molecule, then the production of 3 ATP per NADH and 2 ATP per FADH₂ seems quite reasonable.

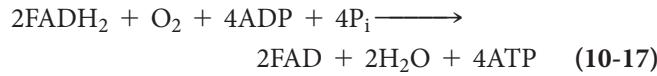

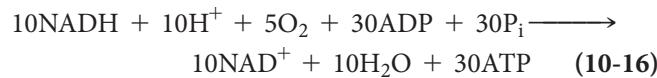

Aerobic Respiration: Summing It All Up

To summarize aerobic respiration, let's now return to Figure 10-1 and review the role of each of the components. As substrates such as carbohydrates and fats are oxidized to generate energy, coenzymes are reduced. These reduced coenzymes represent a storage form of much of the free

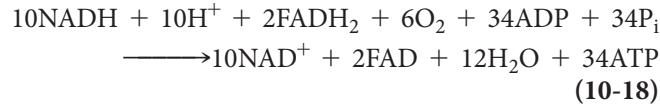

energy that was released by the original substrate molecules during oxidation. This energy can be used to drive ATP synthesis as the coenzymes are themselves reoxidized by the ETS. As electrons are transported from NADH or FADH₂ to oxygen, they pass through several respiratory complexes, where electron transport is coupled to the directional pumping of protons across the membrane. *The resulting electrochemical gradient exerts a pmf that serves as the driving force for ATP synthesis.* Under most conditions, a steady-state pmf will be maintained across the membrane. The transfer of electrons from coenzymes to oxygen is carefully and continuously adjusted so that the outward pumping of protons balances the inward proton flux necessary to synthesize ATP at the desired rate.

The Maximum ATP Yield of Aerobic Respiration Is 38 ATPs per Glucose

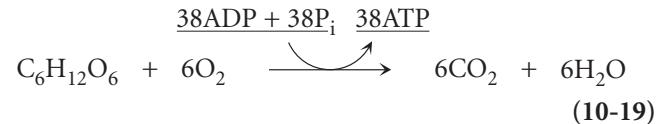

Now we can return to the question of the **maximum ATP yield** per molecule of glucose under aerobic conditions. Recall from Reaction 10-3 that the complete oxidation of glucose to carbon dioxide by glycolysis and the TCA cycle results in the generation of 4 molecules of ATP by substrate-level phosphorylation, with most of the remaining free energy of glucose oxidation stored in the 12 coenzyme molecules—10 of NADH and 2 of FADH₂. In prokaryotes and some eukaryotic cells, electrons from all the NADH molecules pass through all three ATP-generating complexes of the ETS, yielding 3 ATP molecules per molecule of coenzyme. Electrons from FADH₂, on the other hand, traverse only two of the three complexes, yielding only 2 ATP molecules per molecule of coenzyme. The maximum theoretical ATP yield obtainable upon reoxidation of the 12 coenzyme molecules formed per glucose can therefore be represented as follows:

Summing these reactions gives us an overall reaction for electron transport and ATP synthesis:

Addition of Reaction 10-18 to the summary reaction for glycolysis and the TCA cycle (Reaction 10-3) leads to the following overall expression for the maximum theoretical ATP yield obtainable by the complete aerobic respiration of glucose or other hexoses:

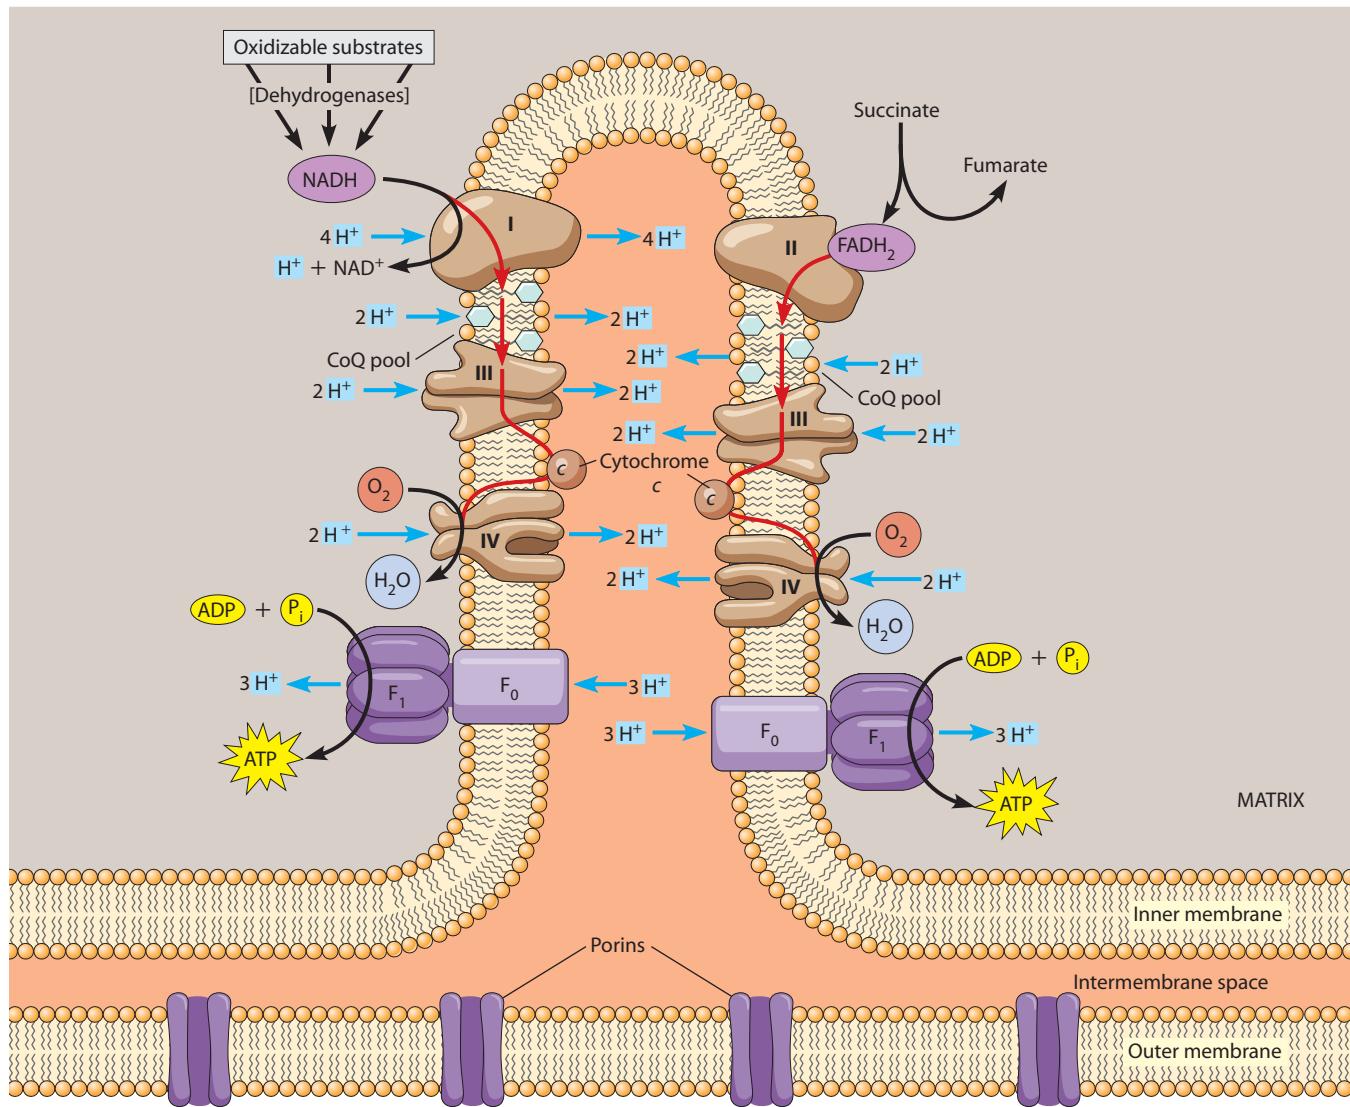

FIGURE 10-22 Dynamics of the Electrochemical Proton Gradient. Respiratory complexes I through IV are integral components of the inner mitochondrial membrane. Complexes I, III, and IV (but not complex II) couple the exergonic flow of electrons (red lines) through the complexes with the outward pumping of protons (blue) across the membrane. The proton motive force of the resulting electrochemical proton gradient drives ATP synthesis by F_1 as protons are translocated back across the membrane by the F_0 complex, which is also embedded in the inner membrane. ATP synthesis also consumes protons in the mitochondrial matrix (see Figure 9-1b), a depletion that contributes to the transmembrane proton gradient driving ATP synthesis.

This summary reaction is valid for most prokaryotic cells and for some types of eukaryotic cells. Depending on the cell type, however, the maximum ATP yield for a eukaryotic cell may be only 36 instead of 38 because of the lesser ATP yield from NADH molecules generated in the cytosol rather than in the mitochondrion (see question 1 below).

Before leaving Reaction 10-19 and the aerobic energy metabolism that it summarizes, we will consider two questions that are often asked, with the hope that the answers will further enhance your understanding of aerobic respiration.

I. Why Does the Maximum ATP Yield in Eukaryotic Cells Vary Between 36 and 38 ATPs Per Glucose?

Recall that when glucose is catabolized aerobically in a eukaryotic cell, glycolysis gives rise to two molecules of

NADH per glucose in the cytosol, while the catabolism of pyruvate generates another eight molecules of NADH in the matrix of the mitochondrion. This spatial distinction is important because the inner membrane of the mitochondrion does not have a carrier protein for NADH or NAD^+ , so NADH generated in the cytosol cannot enter the mitochondrion to deliver its electrons to complex I of the ETS. Instead, the electrons and H^+ ions are passed inward by one of several *electron shuttle systems* that differ in the number of ATP molecules formed per NADH molecule oxidized.

An **electron shuttle system** consists of one or more electron carriers that can be reversibly reduced, with transport proteins present in the membrane for both the oxidized and the reduced forms of the carrier. In liver, kidney, and heart cells, electrons from cytosolic NADH

are transferred into the mitochondrion by means of the *malate-aspartate shuttle*. After NADH reduces oxaloacetate in the cytosol to malate, the malate is transported into the mitochondrial matrix, where it reduces NAD⁺ to NADH. Thus, electrons derived from cytosolic NADH pass through all three proton-pumping complexes of the mitochondrial ETS and generate three molecules of ATP. Aspartate is transported back to the cytosol for production of more oxaloacetate to accept electrons from NADH.

In contrast, in skeletal muscle, brain, and other tissues, electrons are delivered from cytosolic NADH to the mitochondrial respiratory complexes by means of a shuttle mechanism that uses FAD rather than NAD⁺ as the mitochondrial electron acceptor. This mechanism, called the **glycerol phosphate shuttle**, is shown in **Figure 10-23**. NADH in the cytosol reduces dihydroxyacetone phosphate (DHAP) to glycerol-3-phosphate, which is transported into the mitochondrion. There, it is reoxidized to DHAP

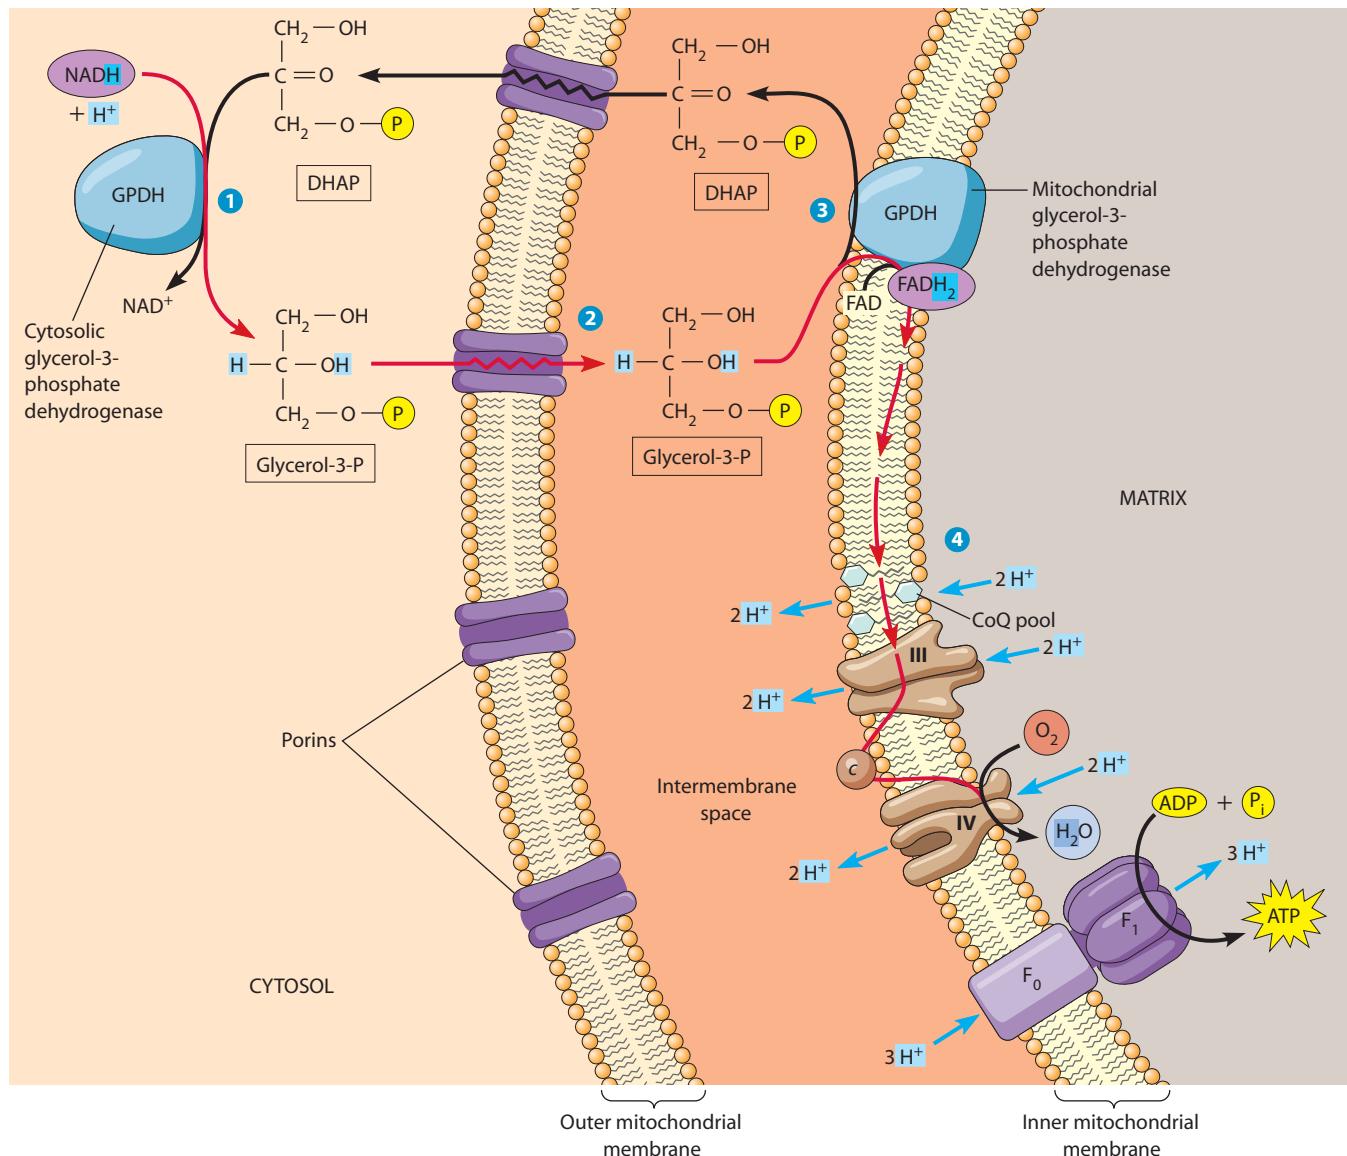

FIGURE 10-23 The Glycerol Phosphate Shuttle. The inner mitochondrial membrane is impermeable to NADH, so electrons from cytosolic NADH are moved into the mitochondrion by one of two shuttle mechanisms. Cells of skeletal muscle, brain, and other tissues use the glycerol phosphate shuttle for this purpose. The red line traces the path of electrons from cytosolic NADH to oxygen. ① The cytosolic enzyme glycerol-3-phosphate dehydrogenase (GPDH) uses electrons (and protons) from NADH to reduce dihydroxyacetone phosphate (DHAP) to glycerol-3-phosphate (glycerol-3-P), which ② can cross the outer mitochondrial membrane by diffusing through a porin channel. ③ Glycerol-3-P is then reoxidized to DHAP by an FAD-linked GPDH in the inner membrane, with concomitant reduction of FAD to FADH₂. Because NADH is a more energy-rich coenzyme than FADH₂, the inward transport of electrons is exergonic, driven by the difference in the reduction potentials of the two coenzymes. The cost of this inward transport is a decreased ATP yield because ④ electrons from the FADH₂ generated by the mitochondrial GPDH bypass complex I, thereby reducing the number of protons pumped across the inner membrane.

by an enzyme that uses FAD instead of NAD⁺ as its electron acceptor. As a result, these electrons bypass complex I of the ETS, generating only two molecules of ATP instead of three. This reduces the maximum theoretical yield by one ATP per cytosolic NADH and therefore by two ATP molecules per molecule of glucose (from 38 to 36).

2. Why Is the ATP Yield of Aerobic Respiration Referred to as the “Maximum Theoretical ATP Yield”?

This wording is a reminder that yields of 36 or 38 ATP molecules per molecule of glucose are possible only if we assume that the energy of the electrochemical proton gradient is used solely to drive ATP synthesis. Such an assumption may be useful in calculating maximum possible yields, but it is not otherwise realistic because the pmf of the proton gradient provides the driving force not only for ATP synthesis, but for other energy-requiring reactions and processes. For example, some of the energy of the proton gradient is used to drive the transport of various metabolites and ions across the membrane and to

drive the import of proteins into mitochondria. Several of these transport processes are illustrated in **Figure 10-24**.

Depending on the relative concentrations of pyruvate, fatty acids, amino acids, and TCA-cycle intermediates in the cytosol and the mitochondrial matrix, variable amounts of energy may be needed to ensure that the mitochondrion has adequate supplies of oxidizable substrates and TCA-cycle intermediates. Moreover, the inward transport of phosphate ions needed for ATP synthesis is accompanied by the concomitant outward movement of hydroxyl ions, which are neutralized by protons in the intermembrane space, thereby also diminishing the proton gradient. In some cells, the phosphate transporter can act as a symporter, transporting a phosphate ion and a proton inward simultaneously.

Aerobic Respiration Is a Highly Efficient Process

To determine the overall efficiency of ATP production by aerobic respiration, we need to ask what proportion of the energy of glucose oxidation is preserved in the 36 or 38

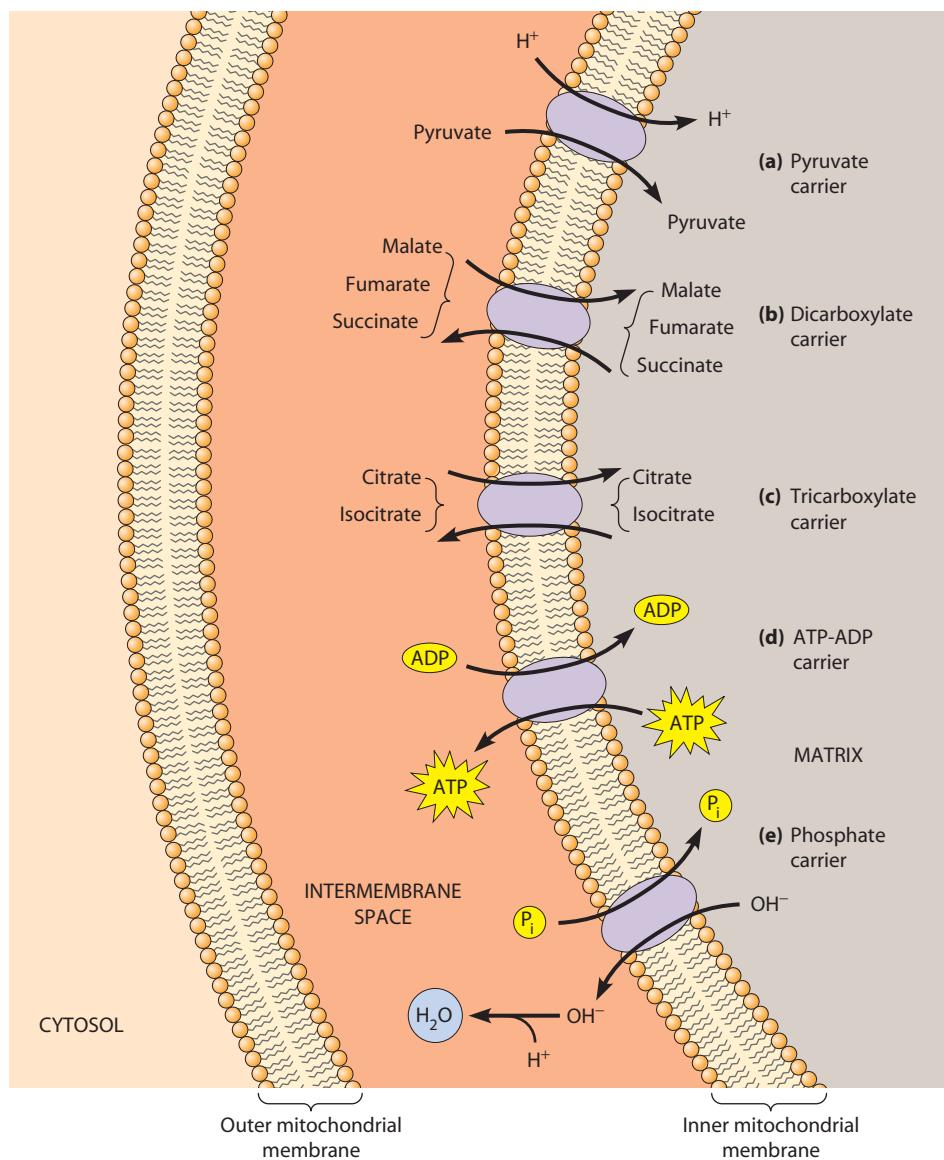

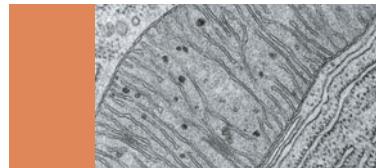

FIGURE 10-24 Major Transport Systems of the Inner Mitochondrial Membrane.

The major transport proteins localized in the inner mitochondrial membrane are shown here. (a) The pyruvate carrier cotransports pyruvate and protons inward, driven by the pmf of the electrochemical proton gradient. The (b) dicarboxylate and (c) tricarboxylate carriers exchange organic acids across the membrane, with the direction of transport depending on the relative concentrations of dicarboxylic and tricarboxylic acids on the inside and outside of the inner membrane, respectively. (d) The ATP-ADP carrier exchanges ATP outward for ADP inward, and (e) the phosphate carrier couples the inward movement of phosphate with the outward movement of hydroxyl ions, which are neutralized by protons in the intermembrane space.

molecules of ATP generated per molecule of glucose. The ΔG° value for the complete oxidation of glucose to CO_2 and H_2O is -686 kcal/mol . ATP hydrolysis has a standard ΔG° of about -7.3 kcal/mol , but the actual $\Delta G'$ under cellular conditions is typically in the range of -10 to -14 kcal/mol . Assuming a value of 10 kcal/mol as we did earlier in the chapter, the $36-38$ moles of ATP generated by aerobic respiration of 1 mole of glucose in an aerobic cell correspond to about $360-380 \text{ kcal}$ of energy conserved per mole of glucose oxidized. This is an efficiency

of about $52-55\%$, well above that obtainable with the most efficient machines we are capable of creating.

This, then, is aerobic energy metabolism. No transistors, no mechanical parts, no noise, no pollution—and all done in units of organization that require an electron microscope to visualize. Yet the process goes on continuously in living cells with a degree of efficiency, fidelity, and control that we can scarcely understand well enough to appreciate fully, let alone aspire to reproduce in our test tubes.

SUMMARY OF KEY POINTS

Cellular Respiration: Maximizing ATP Yields

- Compared with fermentation, aerobic respiration gives the cell access to much more of the free energy that is available from organic substrates such as sugars, fats, and proteins by using molecular oxygen as a terminal electron acceptor.
- The complete catabolism of glucose derived from carbohydrates begins with glycolysis in the cytosol, forming pyruvate. Pyruvate enters the mitochondrion, where it is oxidatively decarboxylated to acetyl CoA, releasing CO_2 . Acetyl CoA is then oxidized fully to CO_2 by enzymes of the TCA cycle.

The Mitochondrion: Where the Action Takes Place

- Mitochondria are the site of respiratory metabolism in eukaryotic cells and are prominent organelles, especially in cells requiring a large amount of ATP. They may form large, interconnected networks in some cell types but are typically regarded as discrete organelles.
- A mitochondrion is surrounded by two membranes. The outer membrane is freely permeable to ions and small molecules due to the presence of porins. The inner membrane is a significant permeability barrier that contains specific carriers for the inward transport of pyruvate, fatty acids, and other organic molecules into the mitochondrial matrix.
- The inner membrane has many infoldings called cristae, which greatly increase the surface area of the membrane and hence its ability to accommodate the numerous respiratory complexes, F_0F_1 complexes, and transport proteins needed for respiratory function. Spaces within the cristae provide a region where protons pumped across the membrane during electron transport are concentrated in order to drive subsequent ATP synthesis.

The Tricarboxylic Acid Cycle: Oxidation in the Round

- Pyruvate from glycolysis is oxidatively decarboxylated to acetyl CoA, generating NADH and CO_2 . Acetyl CoA enters the TCA cycle by combining with oxaloacetate to form citrate.

- As citrate is converted to succinate, two molecules of CO_2 are released, and 2 NADH are formed. This involves two oxidative decarboxylation steps plus an ATP-generating step. Succinate is then oxidized and converted to oxaloacetate, generating FADH_2 and NADH.
- Several of the TCA cycle enzymes are subject to allosteric regulation. Three of the products of pyruvate catabolism (NADH, ATP, and acetyl CoA) act as inhibitors. The substrates NAD^+ , AMP, ADP, and CoA act as activators.
- The TCA cycle is also important in the catabolism of fats and proteins for energy. Fatty acid catabolism via β oxidation occurs in the mitochondrial matrix, generating acetyl CoA, which then enters the TCA cycle. Proteins are degraded to amino acids, which are converted to intermediates of either the glycolytic pathway or the TCA cycle.
- In addition, several intermediates of the TCA cycle serve as a source of precursors for anabolic pathways such as amino acid and heme synthesis. In certain plant seeds, acetyl CoA from stored fat can be converted to carbohydrates.

Electron Transport: Electron Flow from Coenzymes to Oxygen

- Most of the energy yield from aerobic catabolism of glucose is obtained as the reduced coenzymes NADH and FADH_2 are reoxidized by an electron transport system. This system consists of several distinct respiratory complexes—large multiprotein assemblies embedded in the inner mitochondrial membrane.
- The respiratory complexes are free to move laterally within the membrane and assemble into larger supercomplexes known as respirasomes.
- Key intermediates in the electron transport system are coenzyme Q and cytochrome *c*, which transfer electrons between the complexes. In aerobic organisms, oxygen is the ultimate electron acceptor and water is the product of oxygen reduction.

The Electrochemical Proton Gradient and ATP Synthesis

- Of the four main respiratory complexes, three (complexes I, III, and IV) couple the transfer of electrons to the outward pumping of protons. This establishes an electrochemical proton gradient that is the driving force for ATP generation.
- The ATP-synthesizing system consists of a proton translocator, F_o , embedded in the membrane and an ATP synthase, F_1 , that projects from the inner membrane on the matrix side.
- ATP is synthesized by F_1 as the proton gradient powers the movement of protons through F_o . Thus, the electrochemical proton gradient and ATP are, in effect, interconvertible forms of stored energy.

MAKING CONNECTIONS

Now that we are finished with our detailed look at aerobic energy metabolism, you can appreciate how the oxygen you are breathing enables your cells to maximize the amount of energy they can obtain from glucose. Hopefully, your knowledge of cellular chemistry, membranes, enzymes, and bioenergetics from earlier chapters has helped you understand how the well-defined structural features of mitochondria enable specific enzymes and electron carriers to cooperate in the generation of ATP. As we proceed through the rest of our studies in cell biology, you will see many examples of how the energy from catabolism of energy-rich molecules is put to use for cellular functions. When you turn these pages, your cells are using ATP

Aerobic Respiration: Summing It All Up

- Complete oxidation of glucose to six molecules of CO_2 yields a total of 10 NADH, 2 FADH₂, and 4 ATP. Each NADH oxidized in the electron transport system results in synthesis of 3 ATP, and each FADH₂ oxidized gives 2 ATP.
- Therefore, the maximum ATP yield of aerobic respiration is 38 ATP per molecule of glucose. However, in some eukaryotic cells, the ATP yield is reduced to 36 as NADH generated by glycolysis in the cytosol passes its electrons to mitochondrial FADH₂ via the glycerol phosphate shuttle.

PROBLEM SET

More challenging problems are marked with a •.

10-1 Localization of Molecules and Functions Within the Mitochondrion. Indicate whether you would expect to find each of the following molecules or functions in the matrix (MA), the inner membrane (IM), the outer membrane (OM), the intermembrane space (IS), or not in the mitochondrion at all (NO).

- (a) Coenzyme A
- (b) Coenzyme Q
- (c) Nucleotide phosphorylation
- (d) Succinate dehydrogenase
- (e) Malate dehydrogenase
- (f) Fatty acid elongation
- (g) Dicarboxylate carrier
- (h) Conversion of lactate into pyruvate
- (i) ATP synthase
- (j) Accumulation of a high proton concentration
- (k) Respirasomes
- (l) Crista junctions
- (m) Fatty acyl CoA translocase

to power muscle contraction. When you listen to music, your cells are using ATP to aid in nerve impulse transmission. When you have a nasty cut that's healing, your cells are using ATP to divide and to synthesize new DNA. But before we see all the ways we will use energy in cellular processes, let's find out where the glucose we are metabolizing came from in the first place. In the next chapter we will see how photosynthetic organisms harvest energy from the sun, convert it to chemical energy, and use it to convert carbon dioxide to sugar. Again, you will see how this process involves a coordinated series of enzymes and membrane-bound electron carriers operating in a well-defined cellular structure—in this case, the chloroplast.

10-2 Localization of Molecules and Functions Within the Prokaryotic Cell. Repeat Problem 10-1, but indicate where in a prokaryotic cell you would expect to find each of the listed molecules or functions. Choices: cytoplasm (CY), plasma membrane (PM), exterior of cell (EX), or not present at all (NO).

10-3 True or False. Indicate whether each of the following statements is true (T) or false (F). If false, reword the statement to make it true.

- (a) The orderly flow of carbon through the TCA cycle is possible because each of the enzymes of the cycle is embedded in the inner mitochondrial membrane in such a manner that their order in the membrane is the same as their sequence in the cycle.
- (b) Thermodynamically, acetyl CoA should be capable of driving the phosphorylation of ADP (or GDP), just as succinyl CoA does, assuming availability of the appropriate enzyme.
- (c) Respiration is impossible without oxygen as an electron acceptor for the reoxidation of coenzymes.
- (d) We can predict that the flow of electrons through the electron transport system is exergonic because the $NAD^+/NADH$ redox pair has a highly negative $\Delta E'_0$ and the O_2/H_2O redox pair has a highly positive $\Delta E'_0$.

- (e) Unlike , the coenzyme FAD tends to be tightly associated with the dehydrogenase enzymes that use it as an electron acceptor.
- (f) Because β oxidation degrades fatty acids in two-carbon acetyl CoA units, it is not possible to degrade fatty acids with an odd number of carbons.

10-4 Mitochondrial Transport. For aerobic respiration, a variety of substances must be in a state of flux across the inner mitochondrial membrane. Assuming a brain cell in which glucose is the sole energy source, indicate for each of the following substances whether you would expect a net flux across the membrane and, if so, how many molecules will move in which direction per molecule of glucose catabolized.

- | | |
|--------------------------|---------------------|
| (a) Pyruvate | (g) NADH |
| (b) Oxygen | (h) FADH_2 |
| (c) ATP | (i) Oxaloacetate |
| (d) ADP | (j) Water |
| (e) Acetyl CoA | (k) Electrons |
| (f) Glycerol-3-phosphate | (l) Protons |

10-5 Completing the Pathway. In each of the following cases, complete the pathway by indicating the structures and order of the intermediates.

- (a) The conversion of citrate to α -ketoglutarate by Reactions TCA-2 and TCA-3 involves as intermediates not only isocitrate but also molecules identified (but not shown in Figure 10-8) as aconitate and oxalosuccinate. Illustrate the pathway from citrate to α -ketoglutarate by showing the structures and order of all three intermediates.
- (b) Synthesis of the amino acid glutamate can be effected from pyruvate and alanine by a metabolic sequence that illustrates the amphibolic role of the TCA cycle. Devise such a pathway, assuming the availability of whatever additional enzymes may be needed.
- (c) If pyruvate-2- ^{14}C (pyruvate with the middle carbon atom radioactively labeled) is provided to actively respiring mitochondria, most of the radioactivity will be incorporated into citrate. Trace the route whereby radioactively labeled carbon atoms are incorporated into citrate, and indicate where in the citrate molecule the label will first appear.

10-6 The Calculating Cell Biologist. Use Table 10-2, page 272 as the basis for the calculations needed to answer the following questions.

- (a) Without doing any calculations initially, predict whether isocitrate can pass electrons exergonically to NAD^+ under standard conditions. Why do you predict that?
- (b) What is the $\Delta E'_0$ for the oxidation of isocitrate by NAD^+ under standard conditions? Does this calculation support the prediction you made in part a? Explain your answer.
- (c) Calculate the $\Delta G'^o$ for the oxidation of isocitrate by NAD^+ under standard conditions. In what way is this calculation relevant to aerobic energy metabolism?
- (d) Repeat parts a–c for the oxidation of lactate to pyruvate by NAD^+ . In what way is this calculation relevant to aerobic energy metabolism?
- (e) Now repeat parts a–c for the oxidation of succinate to fumarate with NAD^+ as the electron acceptor. You should find that the $\Delta G'^o$ is highly positive. What does this tell us about the likelihood that NAD^+ could serve as the electron acceptor for the succinate dehydrogenase reaction of the TCA cycle?
- (f) Finally, repeat parts a–c for the oxidation of succinate to fumarate with coenzyme Q as the electron acceptor. Why does it make sense to regard coenzyme Q as the electron acceptor when succinate dehydrogenase is shown in Figure 10-8 with FAD as the immediate electron acceptor?

10-7 Calculating Maximum ATP Yields. **Table 10-5** is intended as a means of summarizing the ATP yield during the aerobic oxidation of glucose.

- (a) Complete Table 10-5 for an aerobic bacterium. What is the maximum ATP yield?
- (b) Indicate on Table 10-5 the changes that are necessary to calculate the maximum ATP yield for a eukaryotic cell that uses the glycerol phosphate shuttle to move electrons from the cytosol into the matrix of the mitochondrion.

10-8 Regulation of Catabolism. Explain the advantage to the cell of each of the following regulatory mechanisms.

- (a) Isocitrate dehydrogenase (Figure 10-8, Reaction TCA-3) is allosterically activated by ADP.

Table 10-5 Calculation of the Maximum ATP Yield from Aerobic Oxidation of Glucose

Stage of Respiration	Glycolysis (glucose \rightarrow 2 pyruvate)	Pyruvate Oxidation (2 pyruvate \rightarrow 2 acetyl CoA)	TCA Cycle (2 turns)
Yield of CO_2			
Yield of NADH			
ATP per NADH			
Yield of FADH_2			
ATP per FADH_2			
ATP from substrate-level phosphorylation			
ATP from oxidative phosphorylation			
Maximum ATP yield			

- (b) The dehydrogenases that oxidize isocitrate, α -ketoglutarate, and malate (Reactions TCA-3, TCA-4, and TCA-8) are all allosterically inhibited by NADH.
- (c) Pyruvate dehydrogenase (Figure 10-8, Reaction 10-1, page 261) is allosterically inhibited by ATP.
- (d) Phosphofructokinase (Figure 9-7, Reaction Gly-3) is allosterically inhibited by citrate.
- (e) Pyruvate dehydrogenase kinase (Figure 10-10, enzyme E₁) is allosterically activated by NADH.
- (f) α -ketoglutarate dehydrogenase (Figure 10-8, Reaction TCA-4) is allosterically inhibited by succinyl CoA.

10-9 Lethal Synthesis. The leaves of *Dichapetalum cymosum*, a South African plant, are very poisonous. Animals that eat the leaves have convulsions and usually die shortly thereafter. One of the most pronounced effects of poisoning is a marked elevation in citrate concentration and a blockage of the TCA cycle in many organs of the affected animal. The toxic agent in the leaves of the plant is fluoroacetate, but the actual poison in the tissues of the animal is fluorocitrate. If fluoroacetate is incubated with purified enzymes of the TCA cycle, it has no inhibitory effect on enzyme activity.

- (a) Why might you expect fluorocitrate to have an inhibitory effect on one or more of the TCA cycle enzymes if incubated with the purified enzymes in vitro, even though fluoroacetate has no effect?
- (b) Which enzyme in the TCA cycle do you suspect is affected by fluorocitrate? Give two reasons for your answer.
- (c) How could fluoroacetate be converted to fluorocitrate?
- (d) Why is this phenomenon referred to as *lethal synthesis*?

10-10 Oxidation of Saturated Fatty Acids.

- (a) Calculate the number of FADH₂, NADH, and acetyl CoA produced when a molecule of palmitate (16 carbons) is degraded by β oxidation.
- (b) Compare that to the number produced from β oxidation of stearate (18 carbons).
- (c) Write an equation for the number of acetyl CoA, FADH₂, and NADH molecules produced from a fatty acid of n carbons ($n =$ an even number).
- (d) Following complete oxidation of the acetyl CoA molecules in the TCA cycle and electron transport from FADH₂ and NADH to oxygen, how many ATP will be produced from palmitate and stearate?
- (e) Write an equation for the number of ATP produced from complete oxidation of a fatty acid of n carbons ($n =$ an even number).

10-11 Oxidation of Cytosolic NADH. In some eukaryotic cells, the NADH generated by glycolysis in the cytosol is reoxidized by the glycerol phosphate shuttle shown in Figure 10-23.

- (a) Write balanced reactions for the reduction of dihydroxyacetone phosphate (DHAP) to glycerol-3-phosphate (glycerol-3-P) by cytosolic NADH and for the oxidation of glycerol-3-P to DHAP by the FAD-linked glycerol-3-P dehydrogenase in the inner membrane of the mitochondrion.
- (b) Add the two reactions in part a to obtain a summary reaction for the transfer of electrons from cytosolic NADH to mitochondrial FAD. Calculate $\Delta E'_0$ and ΔG° for this

reaction. Is the inward movement of electrons thermodynamically feasible under standard conditions?

- (c) Write a balanced reaction for the reoxidation of FADH₂ by coenzyme Q within the inner membrane, assuming that CoQ is reduced to CoQH₂. Calculate $\Delta E'_0$ and ΔG° for this reaction. Is this transfer thermodynamically feasible under standard conditions?
- (d) Write a balanced reaction for the transfer of electrons from cytosolic NADH to mitochondrial CoQ, and calculate $\Delta E'_0$ and ΔG° for this reaction. Is this transfer thermodynamically feasible under standard conditions?
- (e) Assume that the [NADH]/[NAD⁺] ratio in the cytosol is 5.0 and that the [CoQH₂]/[CoQ] ratio in the inner membrane is 2.0. What is $\Delta G'$ for the reaction in part d at 25°C and pH 7.0?
- (f) Is $\Delta G'$ for the inward transfer of electrons from NADH to CoQ affected by the ratio of the reduced to the oxidized forms of the enzyme-bound FAD in the inner membrane? Why or why not?

• 10-12 Brown Fat and Thermogenin. Most newborn mammals, including human infants, have a special type of adipose tissue called brown fat, in which a naturally occurring uncoupling protein called *thermogenin* is present in the inner mitochondrial membrane. Thermogenin uncouples ATP synthesis from electron transport so that the energy released as electrons flow through the electron transport chain is lost as heat instead.

- (a) What happens to the energy that is released as electron transport continues but ATP synthesis ceases? Why might it be advantageous for a baby to have thermogenin present in the inner membrane of the mitochondria that are present in brown fat tissue?
- (b) Some adult mammals also have brown fat. Would you expect to find more brown fat tissue and more thermogenin in a hibernating bear or in a physically active bear? Explain your reasoning.
- (c) Given its location in the cell, suggest a mode of action for thermogenin. What kind of an experiment can you suggest to test your hypothesis?
- (d) What would happen to a mammal if all of its mitochondria were equipped with uncoupling protein, rather than just those in brown fat tissue?

• 10-13 Dissecting the Electron Transport System. To determine which segments of the electron transport system (ETS) are responsible for proton pumping and hence for ATP synthesis, investigators usually incubate isolated mitochondria under conditions such that only a portion of the ETS is functional. One approach is to supply the mitochondria with an electron donor and an electron acceptor that are known to tap into the ETS at specific points. In addition, inhibitors of known specificity are often added. In one such experiment, mitochondria were incubated with β -hydroxybutyrate, oxidized cytochrome c, ADP, P_i, and cyanide. (Mitochondria have an NAD⁺-dependent dehydrogenase that is capable of oxidizing β -hydroxybutyrate to β -ketobutyrate.)

- (a) What is the electron donor in this system? What is the electron acceptor? What is the most likely pathway of electron transport in this system?

- (b) Based on what you already know about the ETS, how many moles of ATP would you expect to be formed per mole of β -hydroxybutyrate oxidized? Write a balanced equation for the reaction that occurs in this system.
- (c) Cyanide is the only reagent added to the system that is not a part of the balanced equation for the reaction. What was the purpose of adding cyanide to the system? What result would you expect if the cyanide had not been added?
- (d) Would you expect the enzymes of the TCA cycle to be active in this assay system? Explain your reasoning.
- (e) Why is it important that β -ketobutyrate cannot be further metabolized in this system? Lactate is quite similar in structure to β -ketobutyrate; what effect would it have had if the investigators had used lactate as the oxidizable substrate instead of β -hydroxybutyrate?

Phototrophic Energy Metabolism: Photosynthesis

In the two preceding chapters, we studied fermentation and respiration, two chemotrophic solutions to the universal challenge of meeting the energy and carbon needs of a living cell. Most chemotrophs (us included) depend on an external source of organic substrates for survival. As you may recall, chemotrophs obtain energy by oxidizing high-energy, reduced compounds such as carbohydrates, fats, and proteins in catabolic pathways. They can also use intermediates of these oxidative pathways as sources of carbon skeletons for biosynthesis via anabolic pathways. However, left alone, chemotrophs would soon perish without an ongoing supply of these reduced organic compounds.

In this chapter, we will learn how photosynthetic organisms produce the chemical energy and organic carbon that are drained from the biosphere by chemotrophs. These photosynthetic organisms use solar energy to drive the reduction of CO₂ to produce carbohydrates, fats, and proteins—the reduced forms of carbon that all chemotrophs depend upon.

The use of solar energy to drive the anabolic pathways that produce these building blocks of life is aptly named **photosynthesis**—the conversion of light energy to chemical energy and its subsequent use in synthesizing organic molecules. Nearly all life on Earth is sustained by the energy that arrives at the planet as sunlight. **Phototrophs** are organisms that convert solar energy to chemical energy in the form of ATP and the reduced coenzyme NADPH. NADPH is the electron and hydrogen carrier for a large number of anabolic pathways and is closely related to NADH, which we have previously encountered in catabolic pathways.

Some phototrophs, such as the halobacteria described in Chapter 7, are **photoheterotrophs**, organisms that acquire energy from sunlight but depend on organic sources of reduced carbon. Most other phototrophs—including plants, algae, and most photosynthetic bacteria—are known as **photoautotrophs**, organisms that use solar energy to synthesize energy-rich organic molecules from simple inorganic starting materials such as carbon dioxide and water.

Many photoautotrophs release molecular oxygen as a by-product of photosynthesis. Thus, phototrophs not only replenish reduced carbon in the biosphere but also provide the oxygen in the atmosphere used by aerobic organisms to oxidize these reduced compounds for energy.

In this chapter, we will study two general aspects of photosynthesis: how photoautotrophs capture solar energy and convert it to chemical energy and how this energy is used to transform energy-poor carbon dioxide and water into energy-rich organic molecules such as carbohydrates, fats, and proteins.

An Overview of Photosynthesis

Photosynthesis involves two major biochemical processes: energy transduction and carbon assimilation (Figure 11-1). During the **energy transduction reactions**, light energy is captured by chlorophyll molecules and converted to chemical energy in the form of ATP and NADPH. The ATP and NADPH generated by the energy transduction reactions subsequently provide energy and reducing power, respectively, for the **carbon assimilation reactions**, also known as *carbon fixation reactions*. During the carbon assimilation reactions, commonly known as the *Calvin cycle*, fully oxidized carbon atoms from carbon dioxide are fixed (reduced and covalently joined), forming carbohydrates. These processes take place in the chloroplast of eukaryotic phototrophs or in specialized membrane systems of photosynthetic bacteria.

The Energy Transduction Reactions Convert Solar Energy to Chemical Energy

Light energy from the sun is captured by a variety of green pigment molecules called *chlorophylls*, which are present in the green leaves of plants and in the cells of algae and photosynthetic bacteria. Light absorption by a chlorophyll molecule excites one of its electrons, which is then ejected

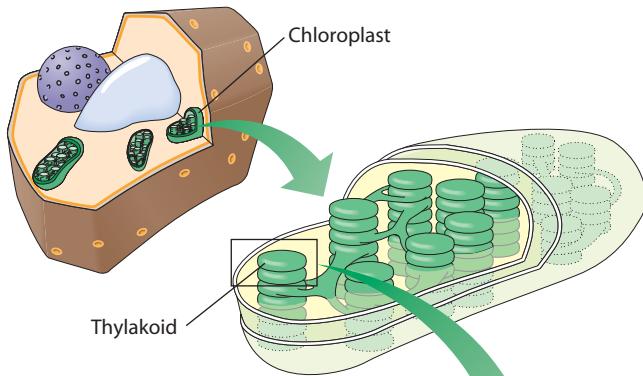

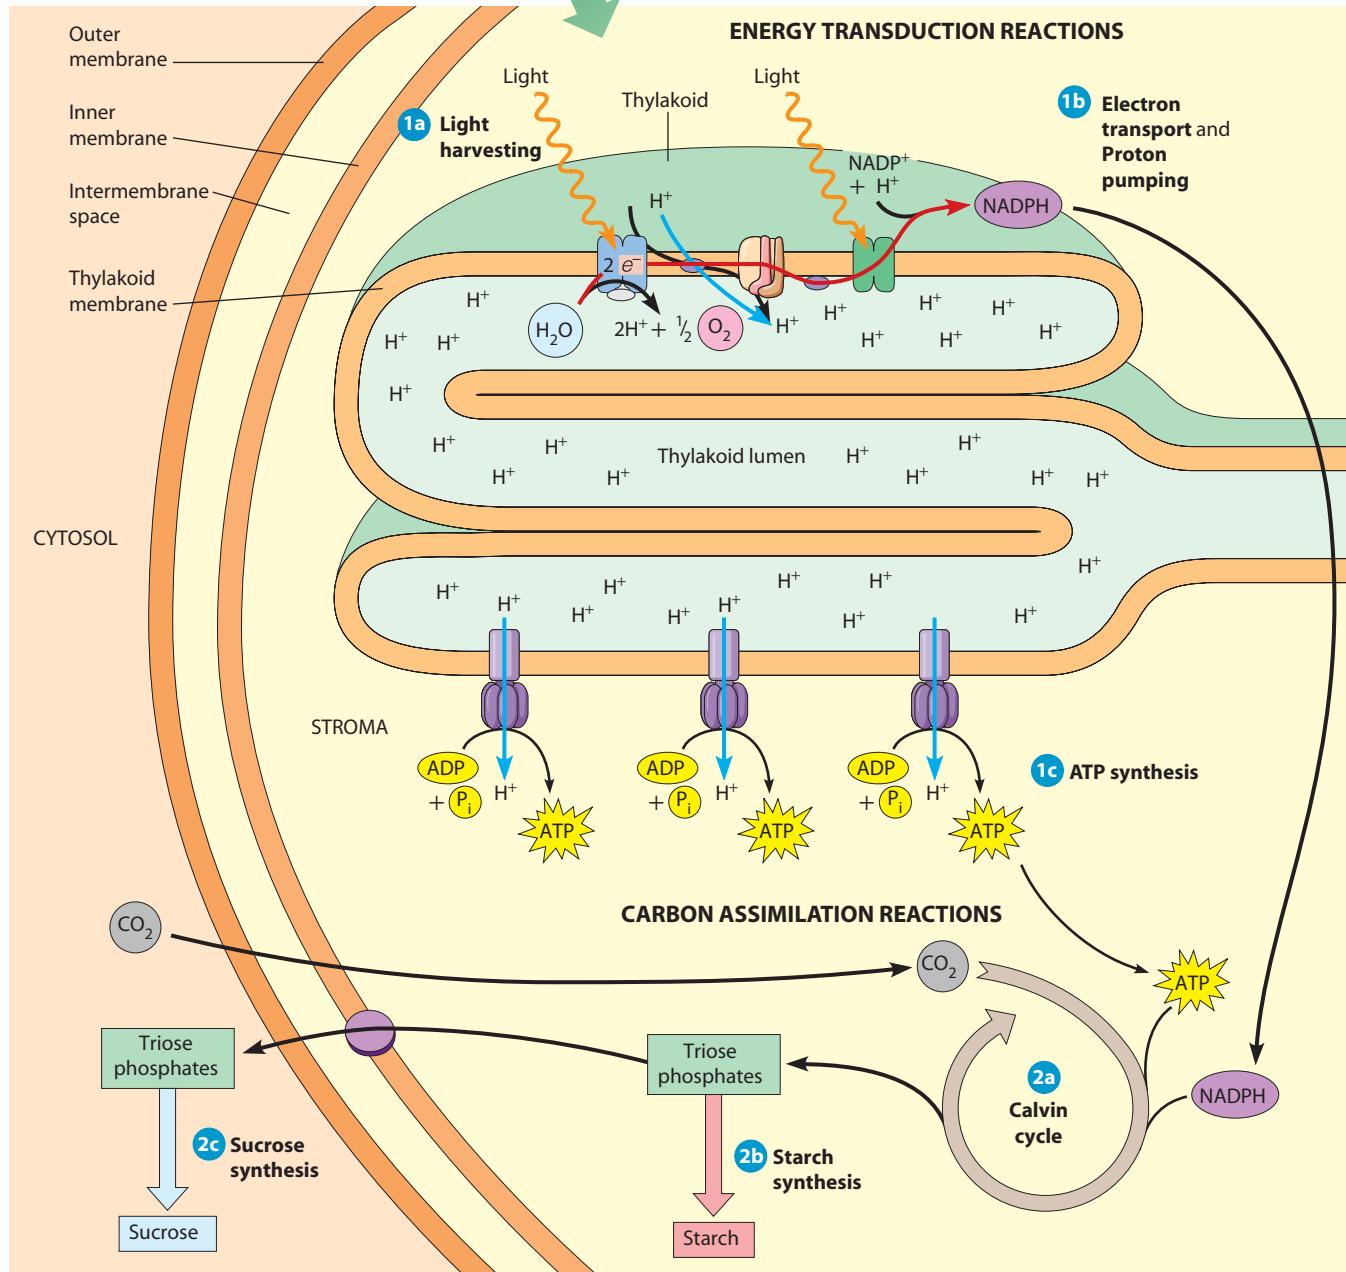

FIGURE 11-1 An Overview of Photosynthesis. This diagram of a chloroplast, the site of photosynthesis in eukaryotic cells, shows the location of major photosynthetic processes within the chloroplast. Photosynthesis can be divided into two major stages: energy transduction and carbon assimilation. The energy transduction reactions occur in the chloroplast thylakoids and include 1a light harvesting, 1b electron transport to NADPH with simultaneous proton pumping, and 1c ATP synthesis. The carbon assimilation reactions include 2a the Calvin cycle and 2b starch biosynthesis in the chloroplast stroma, plus 2c sucrose biosynthesis in the cytosol.

 www.thecellplace.com Photosynthesis

from the molecule and flows energetically downhill through an electron transport system (ETS) much like the ETS we saw previously in mitochondria. As in mitochondria, this flow of electrons is coupled to unidirectional proton pumping, which first stores energy in an electrochemical proton gradient that subsequently drives an ATP synthase. As you may recall, in mitochondria this process is known as *oxidative phosphorylation*—ATP synthesis driven by energy derived from the oxidation of organic compounds. In photosynthetic organisms, ATP synthesis driven by energy derived from the sun is called *photophosphorylation*.

To incorporate fully oxidized carbon atoms from carbon dioxide into organic molecules, these carbon atoms must be reduced. Therefore, photoautotrophs need not only energy in the form of ATP but also reducing power, which is provided by NADPH, a coenzyme related to NADH (see Figure 9-5). In **oxygenic phototrophs**—plants, algae, and cyanobacteria—water is the electron donor, and light energy absorbed by chlorophyll powers the movement of two electrons from water to NADP^+ , which is reduced to NADPH. Molecular oxygen is released as water is oxidized. In **anoxygenic phototrophs**—green and purple photosynthetic bacteria—compounds such as sulfide (S^{2-}), thiosulfate ($\text{S}_2\text{O}_3^{2-}$), or succinate serve as electron donors, and oxidized forms of these compounds are released. In both oxygenic and anoxygenic phototrophs, the light-dependent generation of NADPH is called *photoreduction*.

Usually it is the oxygenic phototrophs such as trees, grasses, and other common plants that come to mind when we think of photosynthesis. However, it was work with the anoxygenic green and purple photosynthetic bacteria conducted by C. B. van Niel in the 1930s and 1940s that led to our understanding that photosynthesis is a light-driven oxidation-reduction process.

The Carbon Assimilation Reactions Fix Carbon by Reducing Carbon Dioxide

Most of the energy accumulated within photosynthetic cells by the light-dependent generation of ATP and NADPH is used for carbon dioxide fixation and reduction. A general reaction for the complete process of photosynthesis may be written as

where H_2A is a suitable *electron donor*, $[\text{CH}_2\text{O}]$ represents a carbohydrate, and A is the oxidized form of the electron donor. By expressing photosynthesis in this way, we avoid perpetuating the incorrect notion that all phototrophs use water as an electron donor.

When we focus on oxygenic phototrophs, which do use water as an electron donor, we can rewrite Reaction 11-1 by substituting H_2O for H_2A , multiplying all reactants and products by six, and subtracting water molecules that appear on both sides of the reaction. This gives the fol-

lowing more specific and familiar form of the general reaction for photosynthesis:

We will soon see, however, that the *immediate* product of photosynthetic carbon fixation is a three-carbon sugar (a triose), not a hexose as shown above. These trioses are then used for a variety of biosynthetic pathways, including the biosynthesis of glucose (as shown in Reaction 11-2), sucrose, and starch. Sucrose is the major transport carbohydrate in most plant species. It conveys energy and reduced carbon through the plant from photosynthetic cells to nonphotosynthetic cells. Starch (or glycogen in photosynthetic bacteria) is the major storage carbohydrate in phototrophic cells.

The Chloroplast Is the Photosynthetic Organelle in Eukaryotic Cells

Our model organisms for studying photosynthesis in this chapter are the most familiar oxygenic phototrophs—green plants. Therefore, we will look at the structure and function of the **chloroplast**, the organelle responsible for most of the events of photosynthesis in eukaryotic phototrophs. In plants and algae, the primary events of photosynthetic energy transduction and carbon assimilation are confined to these specialized organelles.

Because chloroplasts are usually large (1–5 μm wide and 1–10 μm long) and opaque, they were described and studied early in the history of cell biology by Antonie van Leeuwenhoek and Nehemiah Grew in the seventeenth century. The prominence of chloroplasts within a *Coleus* leaf cell is shown in **Figure 11-2a**. A mature leaf cell usually contains 20–100 chloroplasts, whereas an algal cell typically contains only one or a few chloroplasts. The shapes of these organelles vary from the simple flattened spheres common in plants to the more elaborate forms found in green algae. A cell of the filamentous green alga *Spirogyra*, for example, contains one or more ribbon-shaped chloroplasts, as shown in Figure 11-2b.

Not all plant cells contain chloroplasts. Newly differentiated plant cells have smaller organelles called **proplastids**, which can develop into any of several kinds of **plastids** equipped to serve different functions. Chloroplasts are only one example of a plastid. Some proplastids differentiate into **amyloplasts**, which are sites for storing starch. Other proplastids acquire red, orange, or yellow pigments, forming the **chromoplasts** that give flowers and fruits their distinctive colors. Proplastids can also develop into organelles for storing protein (**proteinoplasts**) and lipids (**elaioplasts**).

Chloroplasts Are Composed of Three Membrane Systems

A closer view of a plant leaf cell chloroplast is shown in the electron micrographs of **Figure 11-3a and b**. A chloroplast, like a mitochondrion, has both an **outer membrane**

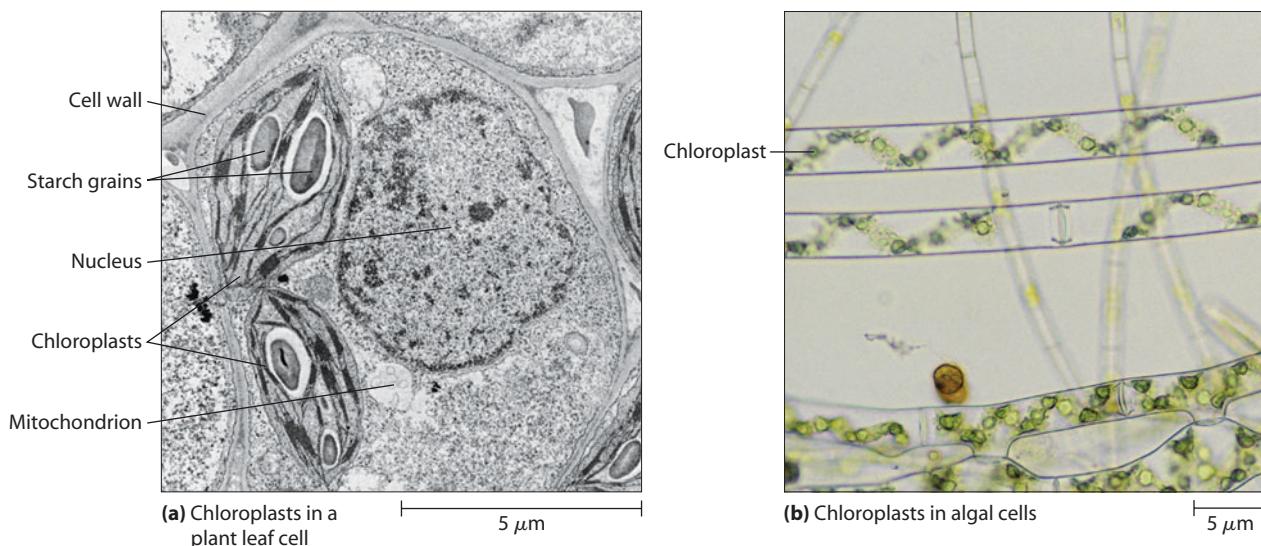

FIGURE 11-2 Chloroplasts. (a) The prominence of chloroplasts in a leaf cell of a plant is demonstrated by this electron micrograph of a parenchyma cell from a *Coleus* leaf. The cell contains many chloroplasts, three of which are seen in this particular cross section. The presence of large starch granules in the chloroplasts indicates that the cell was photosynthetically active just prior to fixation for electron microscopy (TEM). (b) This light micrograph reveals the unusual ribbon-shaped chloroplasts in cells of the filamentous green alga *Spirogyra*.

(b) A more magnified electron micrograph of the chloroplast in part a shows the arrangement of grana and stroma thylakoids (TEM). (c) An illustration showing the three-dimensional structure of a typical chloroplast. (d) An illustration depicting the continuity of the thylakoid membranes, the arrangement of thylakoids into stacks called grana, and the stroma thylakoids that interconnect the grana. The thylakoid membranes enclose a separate compartment called the thylakoid lumen.

VIDEOS www.thecellplace.com Chloroplast structure

and an **inner membrane**, often separated by a narrow **intermembrane space** (Figure 11-3c). The inner membrane encloses the **stroma**, a gel-like matrix teeming with enzymes for carbon, nitrogen, and sulfur reduction and assimilation. The outer membrane contains transmembrane proteins called **porins** that are similar to those found in the outer membrane of mitochondria. Because porins permit the passage of solutes with molecular weights up to about 5000, the outer membrane is freely permeable to most small organic molecules and ions. However, the inner membrane forms a significant permeability barrier. Transport proteins in the inner membrane control the flow of most metabolites between the intermembrane space and the stroma. Three important metabolites that are able to diffuse freely across both the outer and the inner membranes, however, are water, carbon dioxide, and oxygen.

In addition, chloroplasts have **thylakoids**, a third membrane system inside the chloroplast that creates an internal compartment. Thylakoids, illustrated in Figure 11-3c and d, are flat, saclike structures suspended in the stroma. They are usually arranged in stacks called **grana** (singular: **granum**). Grana are interconnected by a network of longer thylakoids called **stroma thylakoids**. Essentially all of the photosynthetic components, such as pigments, enzymes, and electron carriers, are localized on or in the thylakoid membranes.

Electron micrographs of serial sections show that the grana and stroma thylakoids enclose a single continuous compartment, the **thylakoid lumen**. The semipermeable barrier formed by the thylakoid membrane separates the lumen from the stroma and plays an important role in the generation of an electrochemical proton gradient and the synthesis of ATP. The high concentration of protons pumped across this membrane barrier into the lumen during light-driven electron transport stores potential energy that later drives ATP synthesis when the protons return to the stroma. This is analogous to the situation when water in a reservoir is held back by a dam, which acts as a physical barrier to the water. The elevated water level stores potential energy (gravitational in this case) that can be converted to mechanical energy when water is released through controlled openings in the dam, thereby turning the turbines that generate electrical energy.

Photosynthetic bacteria do not have chloroplasts. In some of them, however, such as the cyanobacteria, the plasma membrane is folded inward and forms **photosynthetic membranes**. Such structures, shown in **Figure 11-4**, are analogous to the thylakoids. Indeed, to some extent cyanobacteria appear to be free-living chloroplasts. Similarities among mitochondria, chloroplasts, and bacterial cells have led biologists to formulate the **endosymbiont theory**, which suggests mitochondria and chloroplasts evolved from bacteria that were engulfed by

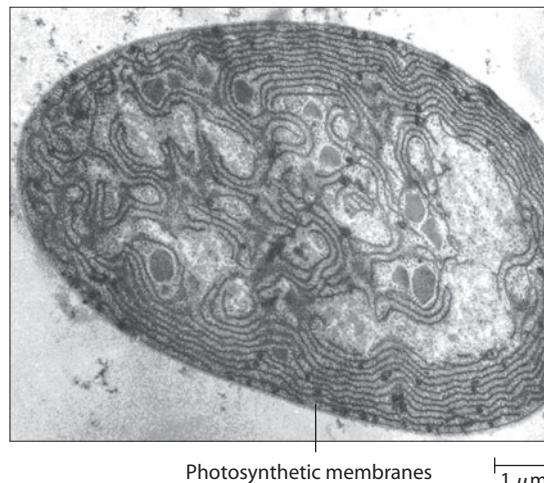

FIGURE 11-4 The Photosynthetic Membranes of a Cyanobacterium. Cyanobacteria, like other photoautotrophs, are capable of photosynthetic carbon fixation. This electron micrograph of a thin section of *Anabaena azollae* reveals the extensive folded membranes of cyanobacterial cells that resemble the thylakoids of chloroplasts (TEM).

primitive cells 1 to 2 billion years ago. A summary of this theory is presented in **Box 11A**.

Photosynthetic Energy Transduction I: Light Harvesting

The first stage of photosynthetic energy transduction is the capture of light energy from the sun. As with all electromagnetic radiation, light has both wave-like and particle-like properties. The portion of the electromagnetic spectrum visible to us, for example, consists of light having wavelengths ranging from about 380 to 750 nm. However, light also behaves as a stream of discrete particles called **photons**, each photon carrying a **quantum** (indivisible packet) of energy. The wavelength of a photon and the precise amount of energy it carries are inversely related (see Figure 2-3). A photon of ultraviolet or blue light, for example, has a shorter wavelength and carries a larger quantum of energy than a photon of red or infrared light does.

When a photon is absorbed by a **pigment** (light-absorbing molecule), such as chlorophyll, the energy of the photon is transferred to an electron, which is energized from its *ground state* in a low-energy orbital to an *excited state* in a high-energy orbital. This event, called **photoexcitation**, is the first step in photosynthesis. Because each pigment has a different configuration of atoms and electrons, pigments display characteristic **absorption spectra** that describe the particular wavelengths of light absorbed by a pigment. The absorption spectra of several common pigments found in photosynthetic organisms, along with the spectrum of solar

The Endosymbiont Theory and the Evolution of Mitochondria and Chloroplasts from Ancient Bacteria

The debate on the evolutionary origins of mitochondria and chloroplasts has a long history. As early as 1883, Andreas F. W. Schimper suggested that chloroplasts arose from a symbiotic relationship between photosynthetic bacteria and nonphotosynthetic cells. By the mid-1920s, other investigators had extended Schimper's idea by proposing a symbiotic origin for mitochondria. Such ideas encountered ridicule and neglect for decades, however, until the 1960s, when it was discovered that mitochondria and chloroplasts contain their own DNA. Further research revealed that mitochondria and chloroplasts are **semiautonomous organelles**, organelles that can divide on their own and contain not only DNA but also mRNA, tRNAs, and ribosomes.

We now realize that the processes of DNA, RNA, and protein synthesis in mitochondria and chloroplasts are more similar to the analogous processes in bacterial cells than they are to those in eukaryotic cells. This led biologists to formulate the **endosymbiont theory**. This theory, developed most fully by Lynn Margulis, proposes that mitochondria and chloroplasts evolved from ancient bacteria that established a **symbiotic relationship** (a mutually beneficial association) with primitive nucleated cells 1 to 2 billion years ago. The proposed sequence of events leading to mitochondria and chloroplasts is outlined in **Figure 11A-1**.

A preliminary assumption of the endosymbiont theory is that the absence of molecular oxygen in Earth's primitive atmosphere limited early cells to *anaerobic* mechanisms for acquiring energy. A few anaerobic cells subsequently developed pigments capable of converting light energy to chemical energy, allowing them to use sunlight as a source of energy. Some of these photosynthetic organisms developed mechanisms for using water as an electron donor. As a result, oxygen was released as a by-product and the composition of Earth's atmosphere was dramatically altered.

As oxygen accumulated in Earth's atmosphere, some anaerobic bacteria evolved into *aerobic* organisms by developing oxygen-dependent electron transport and oxidative phosphorylation

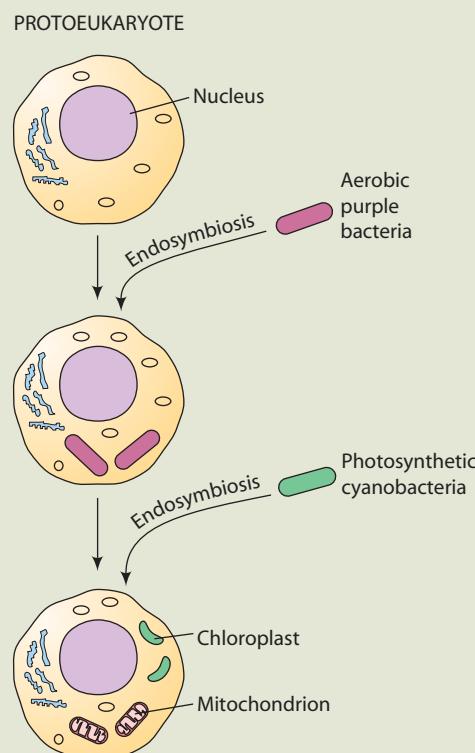

FIGURE 11A-1 Major Events That Might Have Occurred During the Evolution of Eukaryotic Cells. Considerable evidence exists for an endosymbiotic origin for mitochondria and chloroplasts. Most biologists agree that the primitive cells that were ingested by protoeukaryotes and then evolved into mitochondria and chloroplasts were, respectively, purple bacteria and cyanobacteria. This is based on similarities in size and membrane lipid composition, comparisons of rRNA base sequences, the presence of circular DNA molecules, and the ability to reproduce autonomously.

radiation reaching the Earth's surface, are shown in **Figure 11-5**. Note how the overlapping absorption spectra of various chlorophylls and accessory pigments effectively utilize almost the entire spectrum of sunlight that reaches the Earth.

A photoexcited electron in a pigment molecule is unstable and must either return to its ground state in a low-energy orbital or undergo transfer to a relatively stable high-energy orbital, usually in a different molecule. When the electron returns to a low-energy orbital in the pigment molecule, the absorbed energy is lost either as heat released or as light emitted (fluorescence). Alternatively, the absorbed energy can be transferred from the photoexcited electron to an electron in an adjacent pigment molecule in a process known as **resonance energy transfer**. This process is very important for

moving captured energy from light-absorbing molecules to molecules such as chlorophyll that are capable of passing an excited electron to an organic acceptor molecule. The transfer of the photoexcited electron itself to another molecule is called **photochemical reduction**. This transfer is essential for converting light energy to chemical energy.

Chlorophyll Is Life's Primary Link to Sunlight

Chlorophyll, which is found in nearly all photosynthetic organisms, is the primary energy-transduction pigment that channels solar energy into the biosphere. The structures of two types of chlorophyll—chlorophylls *a* and *b*—are shown in **Figure 11-6**. The skeleton of each molecule consists of a central **porphyrin ring** and a strongly

pathways. The endosymbiont theory suggests that the ancestor of eukaryotic cells (called a **protoeukaryote**) developed at least one important feature distinguishing it from other primitive cells: the ability to ingest nutrients and particles from the environment by *phagocytosis*. This characteristic enabled protoeukaryotes to establish endosymbiotic relationships with primitive bacteria. How these primitive cells acquired a membrane-bound nucleus is still unclear.

Mitochondria Apparently Evolved from Ancient Purple Bacteria

The first step toward the evolution of mitochondria may have occurred when an anaerobic protoeukaryote that depended upon glycolysis for energy ingested smaller aerobic bacteria by phagocytosis (Figure 11A-1). The ingested aerobic bacteria were capable of aerobic respiration and would have provided larger amounts of useful energy to the anaerobic host cell. In turn, the host cell provided protection and nutrients to the bacteria residing in its cytoplasm. Thus, the ingested bacteria and the protoeukaryote established a mutually beneficial symbiotic relationship. Gradually, over hundreds of millions of years, the bacteria lost functions that were not essential in their new cytoplasmic environment and developed into mitochondria. When the base sequences of mitochondrial ribosomal RNAs (rRNAs) are compared with those of various bacterial rRNAs, the closest matches occur among *purple bacteria*, suggesting that the ingested ancestor of mitochondria was an ancient member of this group.

Chloroplasts Apparently Evolved from Ancient Cyanobacteria

According to the endosymbiont theory, the first step toward the evolution of chloroplasts occurred when members of a subgroup of early eukaryotes, already equipped with aerobic bacteria or primitive mitochondria, ingested primitive photosynthetic cells. As just described for the evolution of mitochondria, the ingested organisms probably provided energy for the host cell in exchange

for shelter and nutrients. The photosynthetic cells gradually lost functions that were not essential in their new environment and evolved into an integral component of the eukaryotic host. When the base sequences of chloroplast rRNAs are compared with those of various bacterial rRNAs, the closest matches occur among *cyanobacteria*, suggesting that the ancestor of chloroplasts was an ancient member of this group.

The endosymbiont theory is based primarily on biochemical similarities observed among mitochondria, chloroplasts, and bacteria, but support is also provided by contemporary symbiotic relationships that resemble what might have occurred in the distant past. Algae, dinoflagellates, diatoms, and photosynthetic bacteria live as endosymbionts in the cytoplasm of cells occurring in more than 150 kinds of existing protists and invertebrates. The cell wall of the ingested organism is often no longer present, and in a few instances the cell structure is even further reduced, with only the chloroplasts of the endosymbiont remaining.

A striking example of endosymbiosis occurs in certain marine slugs and related mollusks, where the cells lining the animal's digestive tract contain clearly identifiable chloroplasts. These chloroplasts, which originate from the green algae the mollusks feed on, continue to carry out photosynthesis long after being incorporated into the animal's cells. The carbohydrates produced by the photosynthetic process are even distributed as a source of nutrients to the rest of the organism. Although the chloroplasts do not grow and divide, the organelles continue to function in the cytoplasm of the animal cell for several months, and these host organisms have been referred to as "green animals."

In the final analysis, our ideas about how eukaryotic cells acquired their complex array of organelles over billions of years of evolution must remain speculative because the events under consideration are inaccessible to direct laboratory experimentation. However, one strength of the proposed role of endosymbiosis in the evolutionary origins of eukaryotic organelles is that it involves interactions and events that are observed in contemporary cells.

hydrophobic *phytol* side chain. The alternating double bonds in the porphyrin ring are responsible for absorbing visible light, while the phytol side chain interacts with lipids of the thylakoid or cyanobacterial membranes, anchoring the light-absorbing molecules in these membranes.

The magnesium ion (Mg^{2+}) found in chlorophylls *a* and *b* affects the electron distribution in the porphyrin ring and ensures that a variety of high-energy orbitals are available. As a result, several specific wavelengths of light can be absorbed. Chlorophyll *a*, for example, has a broad absorption spectrum, with maxima at about 420 and 660 nm (Figure 11-5). Chlorophyll *b* is distinguished from chlorophyll *a* by the presence of a *formyl* ($-CHO$) group in place of one of the *methyl* ($-CH_3$) groups on the porphyrin ring. This minor structural alteration shifts the

absorption maxima toward the center of the visible spectrum (Figure 11-5).

All plants and green algae contain both chlorophyll *a* and *b*. The combined absorption spectra of the two forms of chlorophyll provide access to a broader range of wavelengths of sunlight and enable such organisms to collect more photons. Because chlorophylls absorb mainly blue and red wavelengths of light, they appear green. Other oxygenic photosynthetic organisms supplement chlorophyll *a* with either chlorophyll *c* (brown algae, diatoms, and dinoflagellates), chlorophyll *d* (red algae), or phycobilin (red algae and cyanobacteria).

Bacteriochlorophyll is a subfamily of chlorophyll molecules restricted to anoxygenic phototrophs (photosynthetic bacteria) and is characterized by a saturated site not found in other chlorophyll molecules (indicated by an

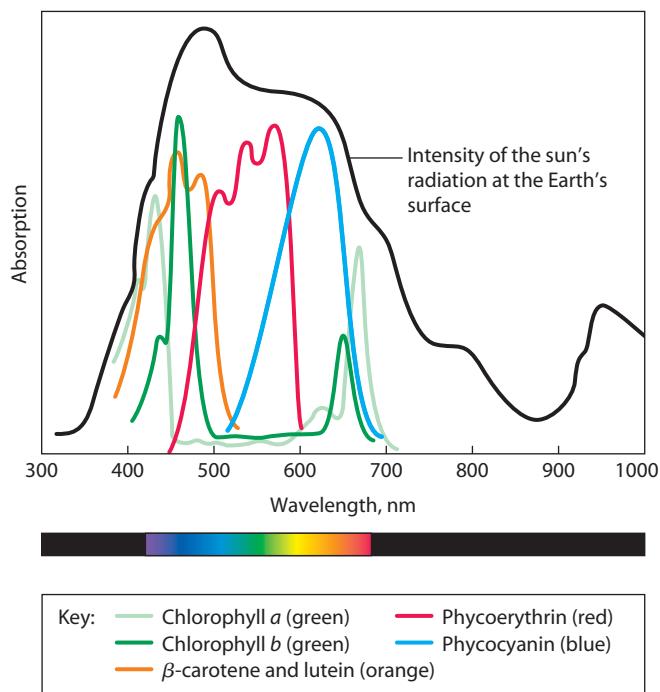

FIGURE 11-5 The Absorption Spectra of Common Photosynthetic Pigments. The graph shows absorption spectra of various chlorophylls and accessory pigments (colored lines) and compares them with the spectral distribution of solar energy reaching the Earth's surface (black line). The small reference strip below the graph shows the color that each wavelength appears to the human eye.

arrow in Figure 11-6). In this case, structural alterations shift the absorption maxima of bacteriochlorophylls toward the near-ultraviolet and far-red regions of the spectrum.

Accessory Pigments Further Expand Access to Solar Energy

Most photosynthetic organisms also contain **accessory pigments**, which absorb photons that cannot be captured by chlorophyll. They then transfer the energy of these photons to a chlorophyll molecule by resonance energy transfer. This feature enables organisms to collect energy from a much larger portion of the sunlight reaching the Earth's surface, as shown in Figure 11-5, which shows the emission spectrum of solar energy in black and the absorption spectra of various accessory pigments in color. Two types of accessory pigments are **carotenoids** and **phycobilins**. Two carotenoids that are abundant in the thylakoid membranes of most plants and green algae are β -*carotene* and *lutein*, which have very similar absorption spectra. When sufficiently abundant and not masked by chlorophyll, these pigments confer an orange or yellow tint to leaves (or to carrots, from which they got their name). With absorption maxima between 420 and 480 nm, carotenoids absorb photons from a broad range of the blue region of the spectrum and thus appear yellow.

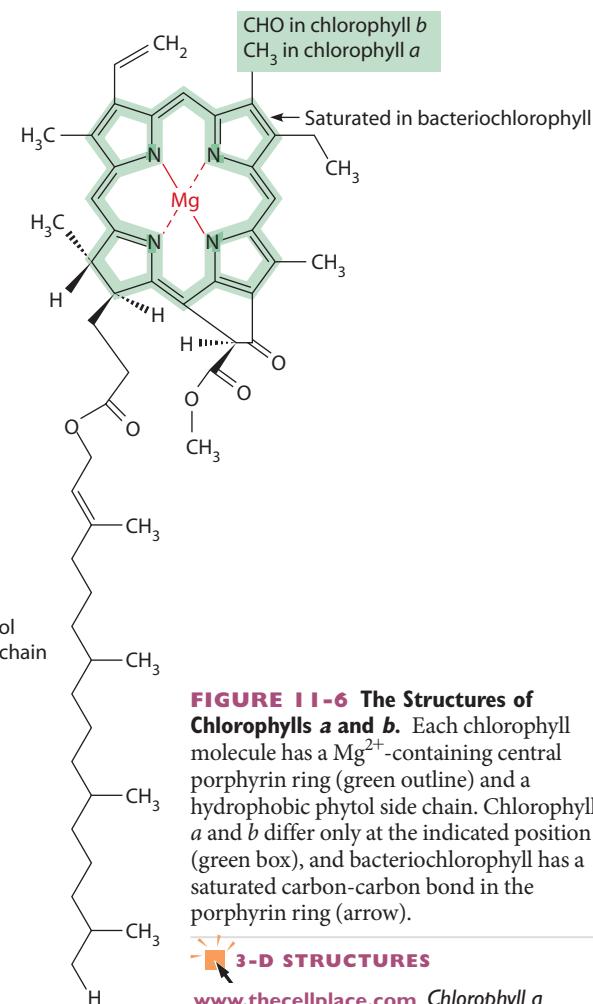

FIGURE 11-6 The Structures of Chlorophylls a and b. Each chlorophyll molecule has a Mg^{2+} -containing central porphyrin ring (green outline) and a hydrophobic phytol side chain. Chlorophylls *a* and *b* differ only at the indicated position (green box), and bacteriochlorophyll has a saturated carbon–carbon bond in the porphyrin ring (arrow).

 **3-D STRUCTURES**
www.thecellplace.com Chlorophyll a

Phycobilins are found only in red algae and cyanobacteria. Two common examples are *phycoerythrin* and *phycocyanin*. *Phycoerythrin* absorbs photons from the blue, green, and yellow regions of the spectrum (thus appearing red) and enables red algae to utilize the dim light that penetrates an ocean's surface water. *Phycocyanin*, on the other hand, absorbs photons from the orange region of the spectrum, thus appearing blue, and is characteristic of cyanobacteria living close to the surface of a lake or on land. Thus, variations in the amounts and properties of accessory pigments often reflect a phototroph's adaptation to a specific environment.

Light-Gathering Molecules Are Organized into Photosystems and Light-Harvesting Complexes

Chlorophyll molecules, accessory pigments, and associated proteins are organized into functional units called **photosystems**, which are localized to thylakoid or photosynthetic bacterial membranes. The chlorophyll molecules are anchored to the membranes by the long hydrophobic phytol side chains. **Chlorophyll-binding**

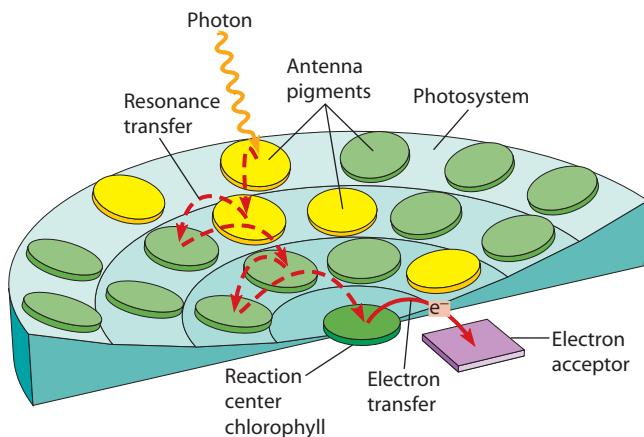

FIGURE 11-7 The Transfer of Energy to the Reaction Center of a Photosystem.

Center of a Photosystem. Light energy absorbed by antenna pigments is passed along by resonance energy transfer until it reaches a specific chlorophyll *a* molecule at the reaction center of a photosystem. The energy is conserved as an excited electron that is ejected from the chlorophyll and passed along to an organic acceptor molecule.

proteins stabilize the chlorophyll within a photosystem and modify the absorption spectra of specific chlorophyll molecules. Other proteins in the photosystems bind components of electron transport systems or catalyze oxidation-reduction reactions.

Most pigments of a photosystem serve as light-gathering **antenna pigments**, which collect light energy much like a radio antenna collects radio waves. These antenna pigments absorb photons and pass the energy to a neighboring chlorophyll molecule or accessory pigment by resonance energy transfer, as shown in **Figure 11-7**. However, recent work with photosynthetic algae suggests that this energy transfer involves quantum mechanical effects not previously seen in biology. Rather than simply a stepwise linear process from molecule to molecule, energy transfer can proceed in a wave-like manner, following several paths simultaneously! This suggests that some antenna pigments are “wired” together by quantum-mechanical probability effects that can increase the efficiency of light harvesting.

The photochemical events that drive electron flow and proton pumping do not begin until the energy reaches the **reaction center** of a photosystem, where two distinct chlorophyll *a* molecules known as the *special pair* reside. Surrounded by other components of the reaction center, this pair of chlorophyll molecules catalyzes the conversion of solar energy into chemical energy. The structure of a bacterial reaction center is shown in **Box 11B**.

Each photosystem is generally associated with a **light-harvesting complex** (LHC), which, like a photosystem, collects light energy. The LHC does not, however, contain a reaction center. Instead, it passes the collected energy to a nearby photosystem by resonance energy transfer. These LHCs are mobile in the thylakoid membrane and can move to take advantage of changing light

conditions. Plants and green algae have LHCs composed of about 80–250 chlorophyll *a* and *b* molecules, along with carotenoids and pigment-binding proteins. Red algae and cyanobacteria have a different type of LHC, called a **phycobilisome**, which contains phycobilins rather than chlorophyll and carotenoids. Together, a photosystem and the associated LHCs are referred to as a **photosystem complex**.

Oxygenic Phototrophs Have Two Types of Photosystems

In the 1940s, Robert Emerson and his colleagues at the University of Illinois discovered that two separate photo-reactions are involved in oxygenic photosynthesis. Using the green alga *Chlorella*, they measured the rate of photosynthesis versus wavelength by monitoring the rate of oxygen release as they changed the wavelength of light supplied to the cells. Initially, they observed a dramatic drop in photosynthesis rate above a wavelength of about 690 nm. This seemed odd to them because *Chlorella* contains chlorophyll molecules that strongly absorb light at wavelengths above 690 nm. When they supplemented the longer wavelengths of light with a shorter wavelength (about 650 nm), the decrease in photosynthesis was nearly eliminated. Indeed, they discovered that photosynthesis driven by a combination of long and short wavelengths of red light exceeded the sum of activities obtained with either wavelength alone. This synergistic phenomenon became known as the **Emerson enhancement effect**.

We now know that the Emerson enhancement effect is the result of two distinct photosystems working together in series. **Photosystem I (PSI)** has an absorption maximum of 700 nm, whereas **photosystem II (PSII)** has an absorption maximum of 680 nm. Each electron that passes from water to NADP⁺ must be photoexcited twice, once by each photosystem. When illumination is restricted to wavelengths above 690 nm, PSII is not active, and photosynthesis is severely impaired.

As we will soon see, each electron is first excited by PSII and then by PSI. But don’t be confused by the nomenclature. The photosystems were named based on the order of their discovery, so although PSI was discovered first, it was later shown that the initial photoexcitation event occurs in PSII.

In the reaction center of each photosystem is a distinctive **special pair** of chlorophyll *a* molecules that have the electrons that will be photoexcited following photon absorption. These chlorophyll molecules are designated **P680** for PSII and **P700** for PSI to reflect their specific absorption maxima. The granal and stromal thylakoid membranes have differing amounts of the two photosystems. As we saw earlier with the associated light-harvesting complexes, these photosystems are somewhat mobile in the membrane and thus able to move to allow the cell to adapt to changing conditions of light quantity (brightness) and quality (wavelength).

A Photosynthetic Reaction Center from a Purple Bacterium

Much of our knowledge of photosynthetic reaction centers and light harvesting has come from studies of reaction center complexes from photosynthetic bacteria. In the late 1960s, Roderick Clayton and co-workers purified the reaction center complex of a purple bacterium, *Rhodopseudomonas sphaerooides* (now *Rhodobacter sphaerooides*). More recently, Hartmut Michel, Johann Deisenhofer, and Robert Huber crystallized a reaction center complex from a different purple bacterium, *Rhodopseudomonas viridis* (now *Blastochloris viridis*) and determined its molecular structure by X-ray crystallography. They not only provided the first detailed look at how pigment molecules are arranged to capture light energy but also were the first group to crystallize any membrane protein complex. For their exciting and ground-breaking contributions, Michel, Deisenhofer, and Huber shared a Nobel Prize in 1988.

As shown in **Figure 11B-1**, the reaction center of *R. viridis* includes four protein subunits. The first subunit is a cytochrome c molecule bound to the outer surface of the bacterial membrane. The L and M subunits span the membrane and stabilize a total of four bacteriochlorophyll *b* molecules, two bacteriopheophytin molecules, and two quinones. Subunits L and M are homologous to proteins D1 and D2, respectively, of PSII in oxygenic phototrophs (see Figure 11-9). The H subunit is bound to the cytoplasmic surface of the membrane and is homologous to a PSII protein called CP43. Electron flow through this bacterial photosystem resembles the flow of electrons through PSII oxygenic phototrophs, with one major difference: The bacterial photosystem does not include an oxygen-evolving complex.

Two of the bacteriochlorophyll *b* molecules, designated P960 to indicate their absorption maxima at 960 nm, have a direct role in catalyzing the light-dependent transfer of an electron to an ETS. Absorption of a photon, either directly or by accessory pigments, lowers the reduction potential of P960 from about +0.5 to −0.7 V. The photoexcited electron is immediately transferred to bacteriopheophytin, thereby stabilizing the charge separation. From bacteriopheophytin, the electron flows exergonically through two quinones and a cytochrome *b/c₁* complex to cytochrome *c*. This electron flow is coupled to unidirectional proton pumping across the bacterial membrane. Cytochrome *c* then returns the electron to oxidized P960. As in chloroplasts, the electrochemical proton gradient across the membrane drives ATP synthesis by a CF₀CF₁ complex.

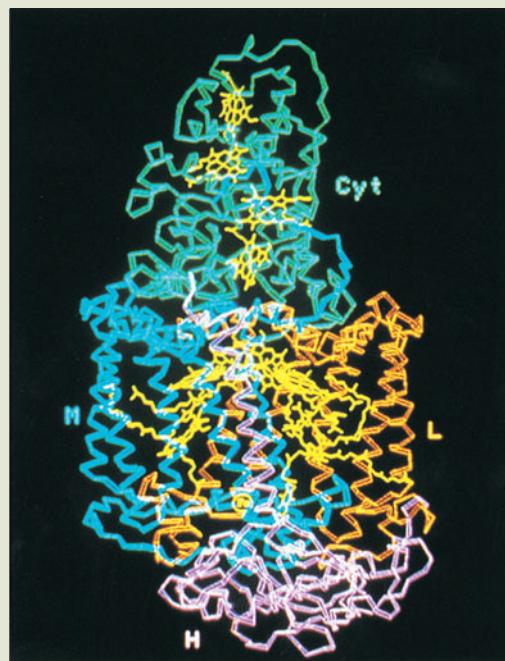

FIGURE 11B-1 A Bacterial Photosynthetic Reaction Center. The structure for the reaction center from *Rhodopseudomonas viridis* shows the cytochrome at the bacterial surface (cyan) with four bound heme groups (yellow), the transmembrane L and M subunits containing bacteriochlorophyll (yellow), and the cytoplasmic H subunit.

Notice that the flow of electrons just described is cyclic, with no net gain of reducing power. How, then, does the cell generate reductant? In *R. viridis*, the cytochrome *b/c₁* complex and cytochrome *c* accept electrons from donors such as hydrogen sulfide, thiosulfate, or succinate. The ATP generated by cyclic photophosphorylation is then used to push electrons energetically uphill from the cytochrome *b/c₁* complex or from cytochrome *c* to NAD⁺. The cyclic flow of electrons described earlier is very different from the cyclic flow through PSII in oxygenic phototrophs. Thus, the bacterial photosystem is most accurately described as a somewhat simplified version of PSII in plants, green algae, and cyanobacteria.

Photosynthetic Energy Transduction II: NADPH Synthesis

The second stage of photosynthetic energy transduction uses a series of electron carriers to transport excited electrons from chlorophyll to the coenzyme **nicotinamide adenine dinucleotide phosphate** (NADP⁺), forming NADPH, the reduced form of NADP⁺. This process is known as **photoreduction** and involves a chloroplast **electron transport system** (ETS) that resembles the mitochondrial ETS we studied in Chapter 10. The complete photoreduction pathway (**Figure 11-8**) includes several

components, and many of the molecules of the chloroplast ETS are similar to those found in the mitochondrial ETS—cytochromes, iron-sulfur proteins, and quinones.

Recall from Equation 10-11 that $\Delta G'$ (standard free energy) and E_0' (standard reduction potential) are opposite in sign, meaning that electrons will spontaneously flow toward a compound with a higher reduction potential. Absorption of light energy by each photosystem boosts electrons to the “top” of an ETS (lower E_0'). As the electrons flow exergonically from PSII to PSI, a portion of their energy is conserved in a proton gradient across the thylakoid membrane. From PSI, electrons are passed to

ferredoxin and then to NADP⁺, generating reducing power in the form of NADPH. NADP⁺ differs from NAD⁺ only by having an additional phosphate group attached to its adenosine (see Figure 9-5). NADP⁺ is the coenzyme of choice for a large number of anabolic pathways, whereas NAD⁺ is usually involved in catabolic pathways.

Photosystem II Transfers Electrons from Water to a Plastoquinone

Our detailed tour of the photoreduction pathway begins at photosystem II, which uses electrons from water to reduce a plastoquinone (Q_B) to a plastoquinol (Q_BH₂). The PSII reaction center, part of which is shown in **Figure 11-9**, contains approximately 25 polypeptides, including D1 and

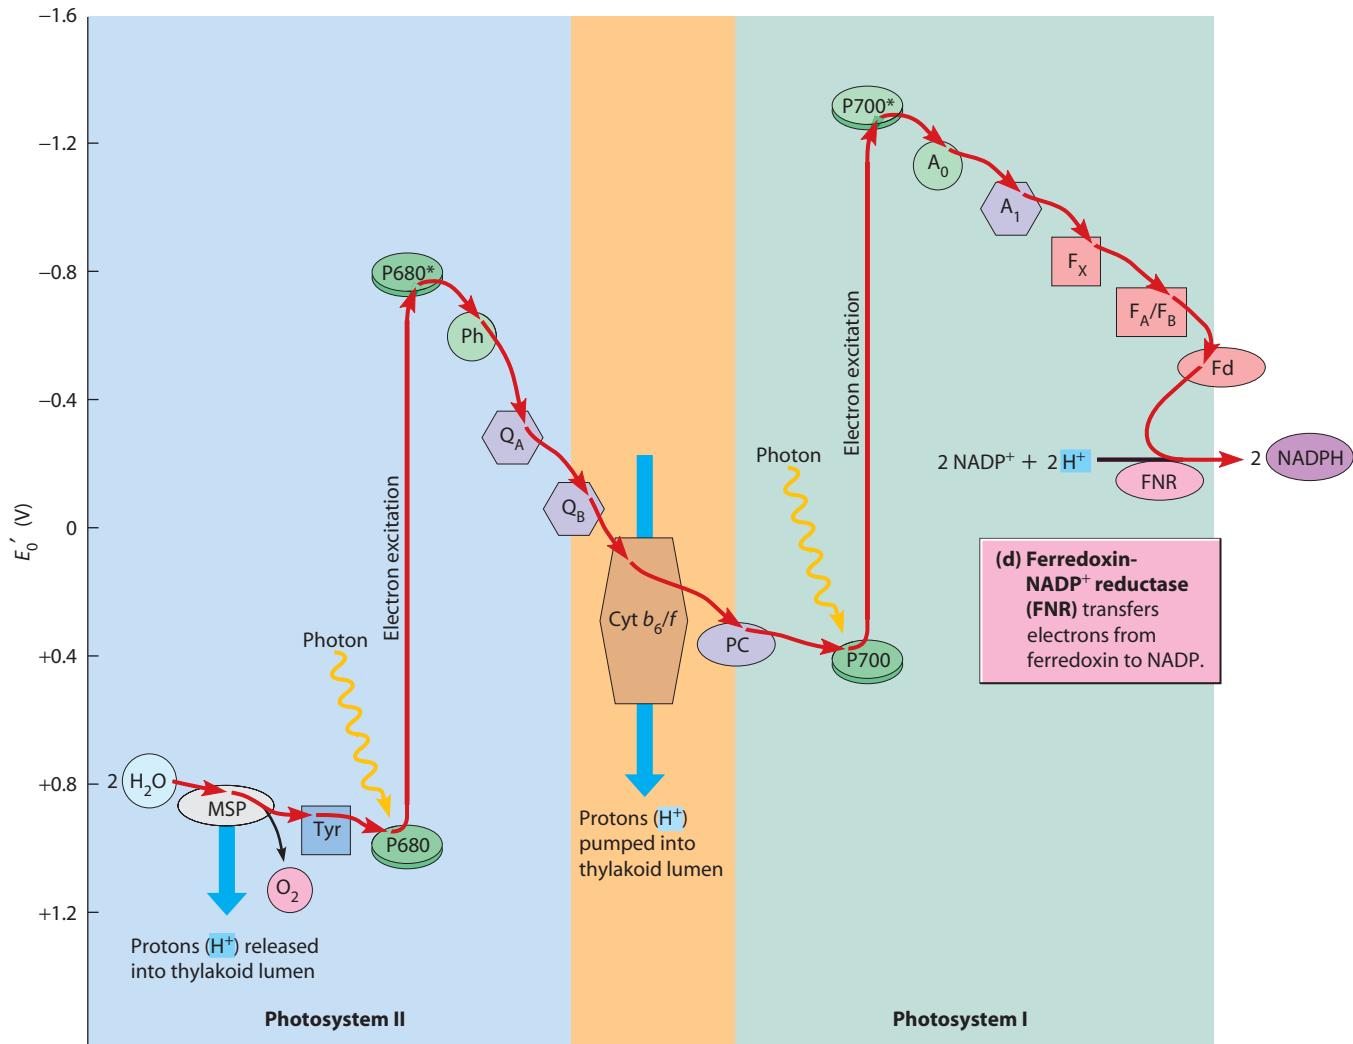

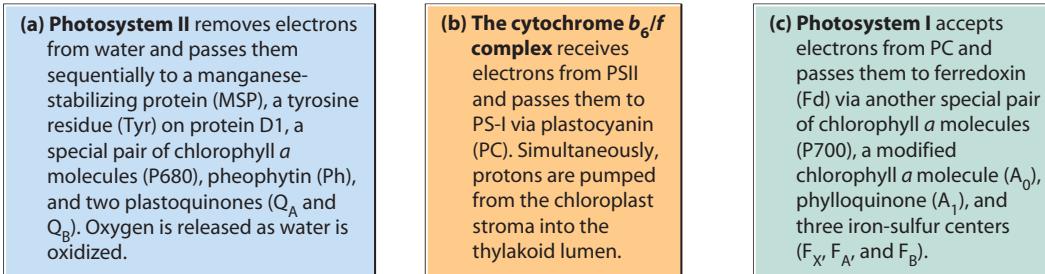

FIGURE 11-8 Noncyclic Electron Flow in Oxygenic Phototrophs. The flow of electrons from water to NADPH (red arrows) involves a linear pathway through (a) photosystem II (PSII), (b) the cytochrome *b*/*f* complex, (c) photosystem I (PSI), and (d) ferredoxin-NADP⁺ reductase (FNR). Note how absorption of photons by chlorophylls P680 and P700 causes a large decrease in their reduction potentials (vertical axis), enabling them to donate excited electrons to an acceptor with a highly negative reduction potential. Figure 11-9 shows the orientation of these components plus the ATP synthase complex within a thylakoid membrane.

(a) PSII includes 25 polypeptides, two of which (D1 and D2) bind chlorophyll P680 and components of the electron transport system. The cluster of four manganese atoms aids in the oxidation of water.

(b) The cytochrome *b*₆/*f* complex contains seven polypeptides and includes two cytochromes (*b*₆ and *f*) and an iron-sulfur protein (Fe-S).

(c) PSI contains more than ten polypeptides and binds chlorophyll P700 and several additional electron carriers. Electrons are transferred to NADPH via soluble ferredoxin (Fd) using ferredoxin-NADP⁺ reductase (FNR).

(d) The ATP synthase complex uses the proton gradient generated by electron transport to synthesize ATP.

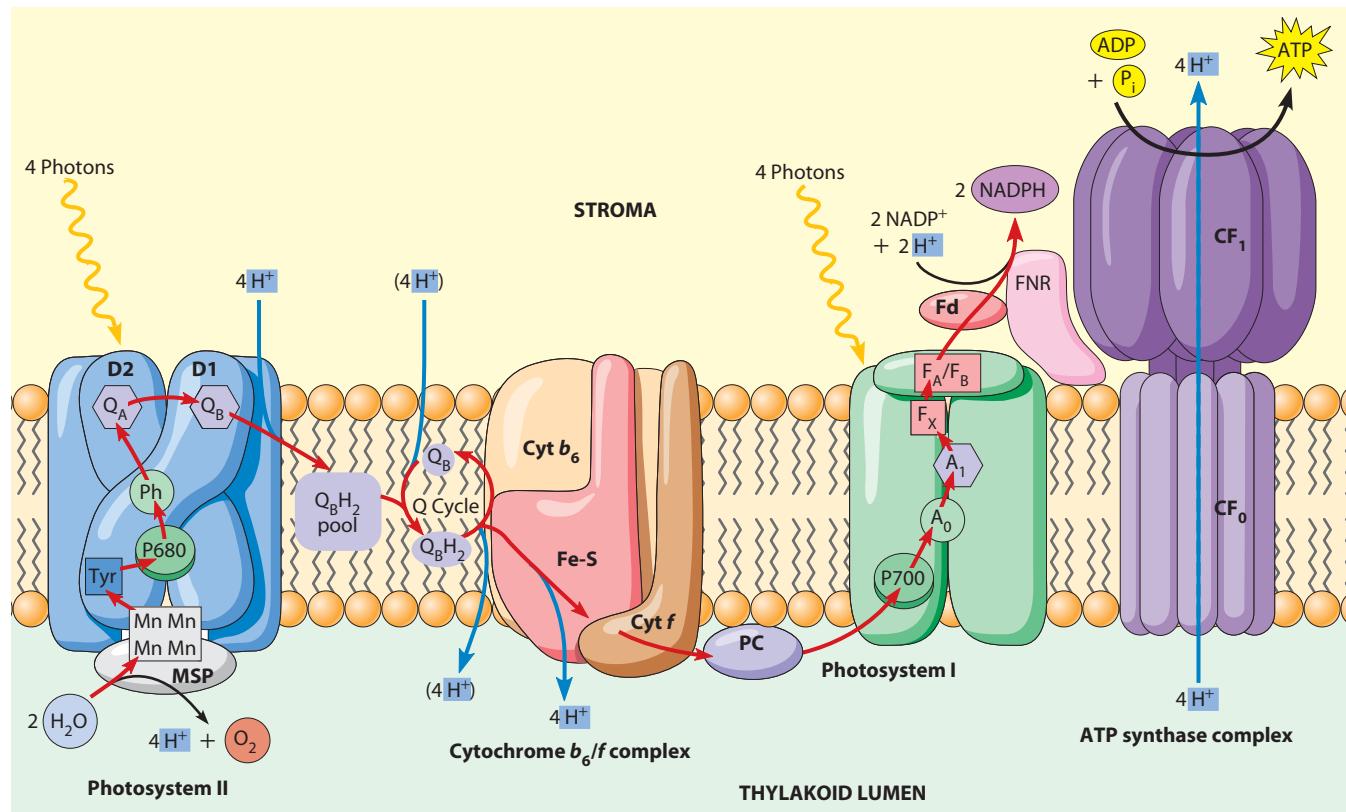

FIGURE 11-9 A Model of the Orientation of the Major Energy Transduction Complexes Within the Thylakoid Membrane. This diagram shows the predicted arrangement of (a) photosystem II (PSII), (b) the cytochrome *b*₆/*f* complex, (c) photosystem I (PSI), and (d) the CF_oCF₁-ATP synthase complex within the thylakoid membrane. The stoichiometry shown is for the transport of four electrons (red arrows) from H₂O to NADP⁺ as four photons are absorbed by each photosystem. This removes 6 H⁺ from the stroma and adds 8 H⁺ to the lumen. Operation of the Q cycle can transfer an additional four protons from the stroma to the lumen per four electrons transported, as shown in parentheses. See Figure 11-8 for a general key to symbols.

D2, that bind not only chlorophyll P680 but also the water-splitting complex and the components of an ETS. Surrounding the reaction center of PSII are 40–50 additional chlorophyll *a* and about 10 β-carotene molecules that enhance photon collection.

In plants and green algae, PSII is generally associated with **light-harvesting complex II (LHCII)**, which contains about 250 chlorophyll and numerous carotenoid molecules. Energy captured by antenna pigments of PSII or LHCII is funneled to the reaction center by resonance energy transfer. When the energy reaches the reaction center, it lowers the reduction potential of a P680 chlorophyll *a* molecule to about −0.80 V, making it a better electron donor (see Figure 11-8). The lowering of P680's

reduction potential allows a photoexcited electron to be passed from it to *pheophytin* (Ph), a modified chlorophyll *a* molecule with two protons in place of the magnesium ion. The *charge separation* produced between the oxidized P680⁺ and the reduced pheophytin (Ph[−]) conserves the increased potential energy of the excited electron and prevents the electron from returning to its ground state in P680, where its energy would simply be lost as heat or fluorescence. Thus, solar energy has been harvested and converted into electrochemical potential energy in the form of this charge separation.

Next the electron is passed to Q_A, a **plastoquinone** that is tightly bound to protein D2 (Figure 11-9). Plastoquinone is similar to *coenzyme Q*, a component of the

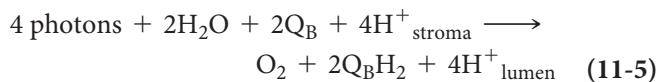

mitochondrial electron transport system (see Figure 10-15). Another plastoquinone, Q_B , receives two electrons from Q_A and picks up two protons from the stroma, thereby becoming reduced to **plastoquinol**, Q_BH_2 . It then enters a mobile pool of Q_BH_2 in the interior lipid phase of the photosynthetic membrane. Q_BH_2 can then pass two electrons and two protons to the *cytochrome b₆/f complex* as it is oxidized back to Q_B . Because a chlorophyll molecule transfers one electron per photon absorbed, the formation of one mobile plastoquinol molecule depends on two sequential photoreactions at the same reaction center:

To replace the electron lost to plastoquinone, oxidized P680⁺ is reduced by an electron obtained from water. To do this, PSII includes an **oxygen-evolving complex (OEC)**, an assembly of proteins and manganese ions that catalyzes the splitting and oxidation of water, producing molecular oxygen (O_2), electrons, and protons. Two water molecules donate four electrons, one at a time by way of a tyrosine residue on protein D1, to four molecules of oxidized P680⁺ (see Figures 11-8 and 11-9). A manganese-stabilizing protein (MSP) holds a cluster of four manganese ions that serve to accumulate the four electrons released as the two water molecules are oxidized. This prevents the formation of partly oxidized intermediates, such as hydrogen peroxide (H_2O_2) or superoxide anion (O_2^-), that can be toxic to the cell if released. In the process, four protons and one oxygen molecule are released within the thylakoid lumen as shown here:

The protons accumulating in the lumen contribute to an electrochemical proton gradient across the thylakoid membrane, and the oxygen molecule diffuses out of the chloroplast. Because the complete oxidation of two water molecules to molecular oxygen depends on four photoreactions, the net reaction catalyzed by four photoexcitations at PSII can be summarized by doubling Reaction 11-3 and adding it to Reaction 11-4:

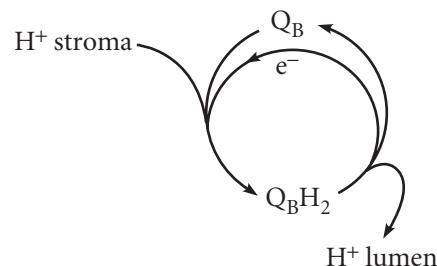

Note that the protons removed from the stroma are actually still in transit to the lumen as part of Q_BH_2 , while the protons added to the lumen at this point are derived from oxidation of water. The light-dependent oxidation of water to protons and molecular oxygen, called *water photolysis*, is believed to have appeared in cyanobacteria between 2 and 3 billion years ago, thereby permitting exploitation of water as an abundant electron donor. The oxygen released by the process dramatically changed the Earth's early atmosphere, which did not originally contain free oxygen, and allowed the development of aerobic respiration.

The Cytochrome b₆/f Complex Transfers Electrons from a Plastoquinol to Plastocyanin

Electrons carried by Q_BH_2 flow through an ETS coupled to unidirectional proton pumping across the thylakoid membrane into the lumen. This happens by way of the **cytochrome b₆/f complex**, which is analogous to the mitochondrial *respiratory complex III* described in Chapter 10 (see Figures 10-15 and 10-16). The cytochrome b₆/f complex is composed of seven distinct integral membrane proteins, including two cytochromes and an iron-sulfur protein.

Mobile Q_BH_2 donates the two electrons received from PSI, one at a time via *cytochrome b₆* and the iron-sulfur protein, to *cytochrome f*. Oxidation of each Q_BH_2 releases two protons into the thylakoid lumen and enables Q_B to return to the pool of plastoquinone, where it is available for accepting more electrons from PSII and more protons from the stroma.

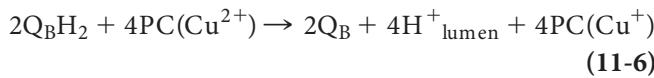

Recent work supports a model explaining how additional protons can be pumped from the stroma into the lumen by operation of a proposed chloroplast **Q cycle**, first suggested for mitochondria by Peter Mitchell in 1975. In this model, for every electron transferred from Q_BH_2 to plastocyanin (PC), one electron from Q_BH_2 is used in the Q cycle to reduce a second molecule of Q_B that is associated with cytochrome b₆. As this Q_B is reduced to Q_BH_2 , additional protons from the stroma are taken up and eventually released into the lumen once Q_BH_2 is reoxidized, as shown here:

Because half of the electrons from Q_BH_2 are recycled back to Q_B , the operation of this proposed Q cycle would double the number of protons translocated from the stroma to the lumen per electron passed to PC, as shown by the additional $4H^+$ enclosed in parentheses in Figure 11-9. This result agrees with recent work showing that, under certain circumstances, such as low light intensity or induction of photosynthesis in dark-adapted plants, for every electron transported through the photosystems, three H^+ are accumulated in the lumen (one from water splitting, one during electron transfer to PC via cytochrome b₆/f, and one from the Q cycle).

Next, reduced cytochrome f donates electrons to a copper-containing protein called **plastocyanin (PC)**. Plastocyanin, like plastoquinol, is a mobile electron carrier, and it will carry electrons to PSI. Unlike plastoquinol, however, it

is a peripheral membrane protein found on the luminal side of the thylakoid membrane, and it carries only one electron at a time. Starting with the two Q_BH₂ molecules generated at PSII (see Reaction 11-5), the net reaction catalyzed by the cytochrome *b*₆/*f* complex for every electron directly transferred to PC can be summarized as

In addition, operation of the proposed Q cycle would double the number of protons moved into the lumen to eight because half of the electrons move through the Q cycle on their way to PC. Thus, four photoreactions at PSII add a total of eight (to 12) protons to the thylakoid lumen: four from the oxidation of water to oxygen and four (to eight) carried to the lumen by plastoquinol (Figure 11-9).

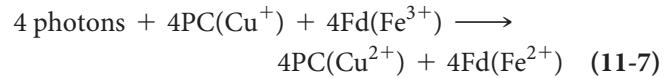

Photosystem I Transfers Electrons from Plastocyanin to Ferredoxin

The task of photosystem I is to transfer photoexcited electrons from reduced plastocyanin to a protein known as *ferredoxin*, the immediate electron donor to NADP⁺. As indicated in Figure 11-9, the reaction center of PSI includes a third chlorophyll *a* molecule, called A₀, instead of a pheophytin molecule. Other components of the reaction center include a *phylloquinone* (A₁) and three *iron-sulfur centers* (F_X, F_A, and F_B) that form an ETS linking A₀ to ferredoxin.

PSI in plants and green algae is associated with **light-harvesting complex I (LHCI)**, which contains fewer antennae molecules than LHCII does—between 80 and 120 chlorophyll and a few carotenoid molecules. As in the PSII complex, energy is funneled to a reaction center containing a special pair of chlorophyll *a* molecules. The energy absorbed by PSI lowers the reduction potential of its special pair of chlorophylls, designated P700, to about -1.30 V (see Figure 11-8). A photoexcited electron is then rapidly passed from P700 to A₀, and charge separation between oxidized P700⁺ and the reduced A₀ prevents the electron from returning to its original ground state. As in PSII, this charge separation preserves part of the light energy absorbed as electrochemical potential energy. The electron lost by P700 is replaced by an incoming electron from reduced plastocyanin.

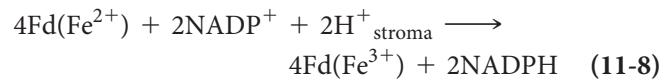

From A₀, electrons flow exergonically through the ETS to ferredoxin, the final electron acceptor for PSI. **Ferredoxin (Fd)** is a mobile iron-sulfur protein found in the chloroplast stroma. Ferredoxin is an important reductant in several other metabolic pathways in the chloroplast, including those for nitrogen and sulfur assimilation. Starting with the four reduced plastocyanin molecules generated at the cytochrome *b*₆/*f* complex

(Reaction 11-6), the net reaction catalyzed by PSI can be summarized as

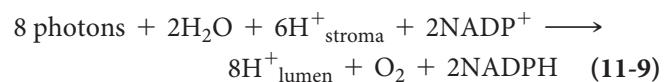

Ferredoxin-NADP⁺ Reductase Catalyzes the Reduction of NADP⁺

The final step in the photoreduction pathway is the transfer of electrons from ferredoxin to NADP⁺, thereby providing the NADPH essential for photosynthetic carbon reduction and assimilation. This transfer is catalyzed by the enzyme **ferredoxin-NADP⁺ reductase (FNR)**, a peripheral membrane protein found on the stromal side of the thylakoid membrane. Starting with the four reduced ferredoxin molecules generated at PSI (see Reaction 11-7), we obtain the following:

Notice that the reduction of one NADP⁺ molecule consumes one H⁺ from the stroma plus two electrons, each from a single reduced ferredoxin. While not actually moving protons from the stroma to the lumen, this reaction lowers the proton concentration of the stroma and contributes to the electrochemical proton gradient across the thylakoid membrane.

Functioning together within the chloroplast, the various components of the ETS provide a continuous, unidirectional flow of electrons from water to NADP⁺, as indicated in Figures 11-8 and 11-9. This is referred to as **noncyclic electron flow**, primarily to distinguish it from the *cyclic electron flow* from ferredoxin back to cytochrome *b*₆/*f* that we will encounter shortly. The net result of the complete light-dependent oxidation of two water molecules to molecular oxygen can be obtained by summing Reactions 11-5 through 11-8, assuming ferredoxin does not donate electrons to other pathways:

For every eight photons absorbed (four by PSII and four by PSI), two NADPH molecules are generated. Furthermore, the ETS for photoreduction is coupled to a mechanism for unidirectional proton pumping across the thylakoid membrane from the stroma to the lumen. Operation of the proposed Q cycle would increase the number of protons accumulating in the lumen to 12. Thus, solar energy has been captured and stored as potential energy in two forms: the reductant NADPH and an electrochemical proton gradient.

Next we will see how the potential energy of this proton gradient is used to synthesize ATP in a manner resembling mitochondrial ATP synthesis. Despite the

differences between chloroplasts and mitochondria, both have an outer membrane, an inner membrane, and an internal space in which protons are accumulated—the intracristal space in mitochondria and the thylakoid in chloroplast. Both involve exergonic electron transport through an ordered array of membrane-bound carriers that are alternatively reduced and oxidized as they create the proton gradient used for ATP synthesis. However, in mitochondria, electrons travel from high-energy reduced coenzymes to oxygen, forming water, as chemical energy is converted from one form (NADH) to another (ATP). In chloroplasts, solar energy is used to remove electrons from water, forming oxygen, as solar energy is converted into chemical energy in the form of NADPH and ATP.

Photosynthetic Energy Transduction III: ATP Synthesis

Now we will see how, in the final stage of photosynthetic energy transduction, the potential energy now stored in the proton gradient is used to synthesize ATP from ADP and P_i. Because the energy used to phosphorylate ADP originated in the sun, this process is known as **photophosphorylation**. Since the thylakoid membrane is virtually impermeable to protons, a substantial electrochemical proton gradient can develop across the membrane in illuminated chloroplasts. As described in Chapter 10 for mitochondria, we can calculate the total proton motive force (pmf) across the thylakoid membrane by summing a proton concentration (pH) term and a membrane potential (V_m) term (see Equation 10-13). This can be used to determine the standard free energy change (ΔG°) for the movement of protons from the lumen to the stroma.

In mitochondria, the pH difference (ΔpH) across the inner membrane is only about 1 unit, contributing about 0.06 V (30%) of the total pmf of 0.22 V. The other 70% of the pmf comes from the membrane potential difference of about 0.16 V (see Equation 10-14). In chloroplasts, however, ΔpH is more important than ΔV_m and contributes about 80% of the total pmf. Light-induced proton pumping into the thylakoid lumen causes its pH to drop to about 6. Coupled with a rise in stromal pH to about 8 due to proton depletion, this creates a ΔpH of about 2 units, which is enough to generate a pmf of about 0.12 V at 25°C. Assuming current estimates of a membrane potential difference of approximately 0.03 V, this gives a total pmf of 0.15 V, representing a ΔG° of about 3.5 kcal/mol of protons moving across the thylakoid membrane.

The ATP Synthase Complex Couples Transport of Protons Across the Thylakoid Membrane to ATP Synthesis

In chloroplasts as in mitochondria and bacteria, the movement of protons across a membrane from high to

low concentration drives the synthesis of ATP by an **ATP synthase** complex. The ATP synthase complex found in chloroplasts, designated the **CF_oCF₁ complex**, is remarkably similar to the F_oF₁ complexes of mitochondria and bacteria described in Chapter 10 (see Figure 10-19). The CF₁ component is a hydrophilic assembly of polypeptides that protrudes from the stromal side of the thylakoid membrane and contains three catalytic sites for ATP synthesis. Like the bacterial F₁, CF₁ is composed of five distinct polypeptides with a stoichiometry of $\alpha_3\beta_3\gamma\delta\epsilon$. These CF₁ polypeptides have similar structures and functions as the analogous F₁ polypeptides.

The CF_o component is a hydrophobic assembly of polypeptides anchored to the thylakoid membrane, much like the F_o component of the F_oF₁-ATP synthase. CF_o subunits I and II form a peripheral stalk that connects CF_o with CF₁, thus serving the same function as the two *b* subunits of F₁ (see Figure 10-19). CF_o subunit IV (similar to the *a* subunit of F_o) is the **proton translocator** through which protons flow from the lumen back to the stroma under the pressure of the pmf. Proton flow through subunit IV causes rotation of an adjacent ring composed of subunit III polypeptides (similar to the *c* subunits in the *c* ring of F_o). This rotation is coupled to ATP synthesis by the CF₁ component as described in Chapter 10 for the F_oF₁-ATP synthase.

In the past, results of biochemical experiments suggested that one ATP was synthesized for every three protons passing through the CF_oCF₁ complex. Other experimental models, however, indicate that four protons are translocated for every ATP synthesized. Recent structural evidence that there are 14 copies of subunit III in the rotating ring of spinach chloroplast CF_oCF₁ suggests that translocation of 14 protons through this CF_oCF₁ causes one rotation and leads to the synthesis of 3 ATP (greater than 4 H⁺/ATP). Perhaps differences in the number of subunit III polypeptides in different organisms explains the different H⁺/ATP ratios obtained by researchers using different experimental systems.

Assuming a H⁺/ATP ratio of four, the reaction catalyzed by the ATP synthase complex can be summarized as

This result is quite reasonable in terms of thermodynamics. The $\Delta G'$ value for the synthesis of ATP within the chloroplast stroma is usually 10–14 kcal/mol, whereas the energy available is about 14 kilocalories per 4 moles of protons passing through the ATP synthase complex (3.5 kcal/mol \times 4 mol = 14 kcal). Thus, the flow of four electrons through the noncyclic pathway shown in Figures 11-8 and 11-9 (without the Q cycle) not only generates two NADPH molecules but also leads to the synthesis of two ATP molecules (4 electrons \times 2 protons/electron \times 1 ATP/4 protons = 2 ATP molecules).

Cyclic Photophosphorylation Allows a Photosynthetic Cell to Balance NADPH and ATP Synthesis

Before we conclude our discussion of the photosynthetic energy transduction reactions, we must consider how phototrophs might balance NADPH and ATP synthesis to meet the precise energy needs of a living cell. Notice that noncyclic electron flow leads to the generation of two ATP for every two NADPH molecules. Because both ATP and NADPH are consumed by a variety of metabolic pathways, it is very unlikely that a photosynthetic cell will always require them in the precise ratio generated by noncyclic electron flow. Typically, cells will require more ATP than NADPH because many cellular activities, such as active transport across membranes, require ATP but not NADPH.

When NADPH consumption is low and/or when additional ATP is needed, an optional process known as **cyclic electron flow** can divert the reducing power generated at PSI into ATP synthesis rather than NADP^+ reduction. Cyclic electron flow is illustrated in **Figure 11-10** and is distinct from the Q cycle discussed previously. In cyclic electron flow, the reduced ferredoxin generated by PSI transfers electrons back to a cytochrome b_6/f complex instead of donating them to NADP^+ . The exergonic flow of electrons from ferredoxin through the cytochrome b_6/f complex to plastocyanin is coupled to proton pumping, thereby contributing to the pmf across the thylakoid membrane. From plastocyanin, electrons return to an oxidized $\text{P}700^+$ molecule in PSI, completing a closed circuit and allowing P700 to absorb another photon. The excess ATP synthesis resulting from this cyclic electron flow is called *cyclic photophosphorylation*. No water is oxidized and no oxygen is released since the flow of electrons from PSII is not involved.

A Summary of the Complete Energy Transduction System

The model shown in Figure 11-9 represents the entire photosynthetic energy transduction system within a thylakoid membrane. The essential features of the complete system for the transfer of electrons from water to NADP^+ and the resulting ATP synthesis can be summarized in terms of the following component parts:

1. **Photosystem II complex:** An assembly of chlorophyll molecules, accessory pigments, and proteins that contains the P680 reaction center chlorophyll. Water is oxidized and split by the oxygen-evolving complex, and electrons flow from water to P680. Following photon absorption, photoexcited P680 molecules donate electrons to plastoquinone, reducing it to plastoquinol, a mobile electron carrier.
2. **Cytochrome b_6/f complex:** An electron transport system that transfers electrons from plastoquinol to

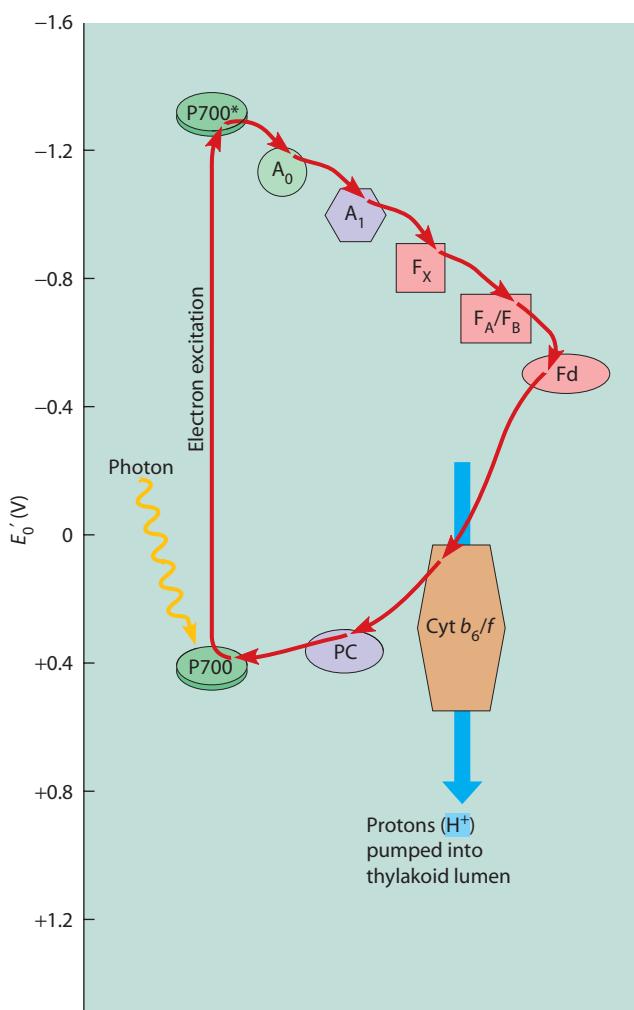

FIGURE 11-10 Cyclic Electron Flow. Cyclic electron flow through PSI enables oxygenic phototrophs to increase the ratio of ATP/NADPH production within photosynthetic cells. When the concentration of NADP^+ is low (i.e., when the concentration of NADPH is high), ferredoxin (Fd) donates electrons to the cytochrome b_6/f complex. Electrons then return to P700 via plastocyanin (PC). Because this cyclic electron flow is coupled to unidirectional proton pumping across the thylakoid membrane, excess reducing power is channeled into ATP synthesis. See Figure 11-8 for a general key to symbols.

plastocyanin, thereby linking PSII with PSI. Electron flow through this complex is coupled to unidirectional proton pumping across the thylakoid membrane, establishing an electrochemical proton gradient that drives ATP synthesis. Optional cyclic electron flow allows additional ATP synthesis.

3. **Photosystem I complex:** An assembly of chlorophyll molecules, accessory pigments, and proteins that contains the P700 reaction center chlorophyll, which accepts electrons from plastocyanin. Following photo-excitation, P700 donates electrons to ferredoxin, a stromal protein.
4. **Ferredoxin-NADP⁺ reductase:** An enzyme on the stromal side of the thylakoid membrane that catalyzes

the transfer of electrons from two reduced ferredoxin proteins along with a proton to a single NADP⁺ molecule. The NADPH generated in the stroma is an essential reducing agent in many anabolic pathways.

5. *ATP synthase complex (CF₀CF₁)*: A proton channel and ATP synthase that couples the exergonic flow of protons from the thylakoid lumen to the stroma with the synthesis of ATP. Like NADPH, the ATP accumulates in the stroma, where it provides energy for carbon assimilation.

Within a chloroplast, both noncyclic and cyclic pathways of electron flow operate (with or without the Q cycle), thereby providing flexibility in the relative amounts of ATP and NADPH generated. ATP can be produced on a close to equimolar basis with respect to NADPH if the noncyclic pathway is operating alone, or ATP can be generated in excess by using either the Q cycle or the cyclic pathway of PSI.

Photosynthetic Carbon Assimilation I: The Calvin Cycle

With information about chloroplast structure and photosynthetic energy transduction in mind, we are now prepared to look closely at photosynthetic carbon assimilation. More specifically, we will look at the primary events of carbon assimilation: the initial fixation and reduction of carbon dioxide to form simple three-carbon carbohydrates. The fundamental pathway for the movement of inorganic carbon into the biosphere is the **Calvin cycle**, which is found in all oxygenic and most anoxygenic phototrophs.

This pathway is named after Melvin Calvin, who received a Nobel Prize in 1961 for the work he and his colleagues Andrew Benson and James Bassham did to elucidate the process. Taking advantage of the availability of radioactive isotopes following World War II, they were able to use ¹⁴CO₂ to show that the primary products of photosynthetic carbon fixation are triose phosphates. As mentioned earlier, these triose phosphates enter a variety of metabolic pathways, the most important of these being sucrose and starch biosynthesis. An overview of the Calvin cycle is shown in **Figure 11-11**, with more biochemical and structural detail shown in **Figure 11-12**.

In plants and algae, the Calvin cycle is confined to the chloroplast stroma, where the ATP and NADPH generated by photosynthetic energy transduction reactions accumulate. In plants, carbon dioxide generally enters a leaf through special pores called **stomata** (singular: **stoma**). Once inside the leaf, carbon dioxide molecules diffuse into **mesophyll cells** and, in most plant species, travel unhindered into the chloroplast stroma, the site of carbon fixation.

For convenience, we will divide the Calvin cycle into three stages:

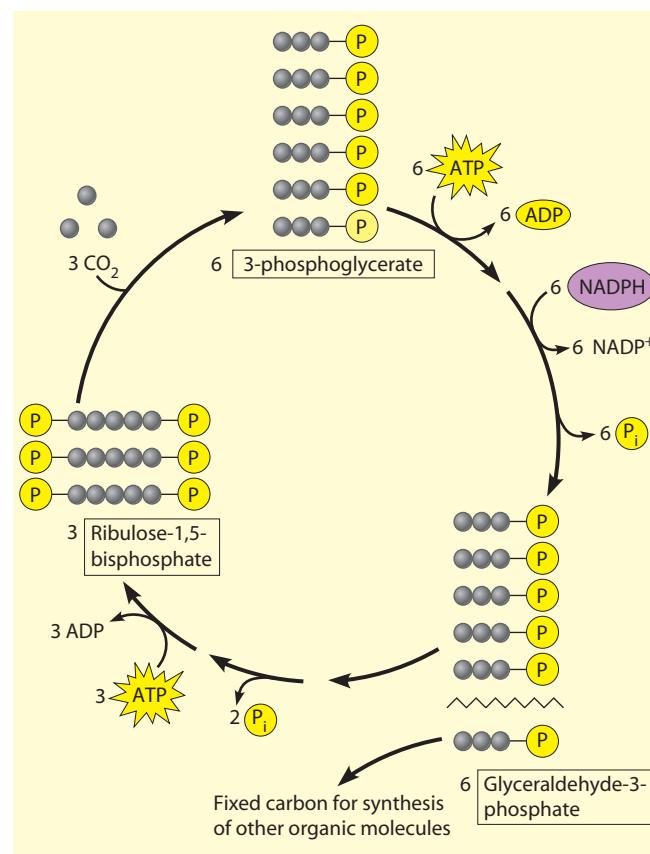

FIGURE 11-11 Overview of the Calvin Cycle. Starting with three molecules of ribulose-1,5-bisphosphate, three molecules of CO₂ are fixed and the products are rearranged to form six molecules of 3-phosphoglycerate. Using ATP and NADPH, these six molecules of 3-phosphoglycerate are reduced to six molecules of glyceraldehyde-3-phosphate. More ATP is used as five of these glyceraldehyde-3-phosphate molecules are rearranged to regenerate three molecules of Ru-P₂, which will accept three more CO₂. The sixth glyceraldehyde-3-phosphate, representing the three CO₂ that were fixed, leaves the cycle for synthesis of other organic compounds in the cell.

ACTIVITIES www.thecellplace.com The Calvin cycle

1. The carboxylation of the organic acceptor molecule *ribulose-1,5-bisphosphate* and immediate hydrolysis to generate two molecules of *3-phosphoglycerate*.
2. The reduction of 3-phosphoglycerate to form the triose phosphate *glyceraldehyde-3-phosphate*.
3. The regeneration of the initial acceptor molecule to allow continued carbon assimilation.

Carbon Dioxide Enters the Calvin Cycle by Carboxylation of Ribulose-1,5-Bisphosphate

The first stage of the Calvin cycle begins with the covalent attachment of carbon dioxide to the carbonyl carbon of ribulose-1,5-bisphosphate (Reaction CC-1 in Figure 11-12). Carboxylation of this five-carbon acceptor molecule would seem to generate a six-carbon product, but no one has

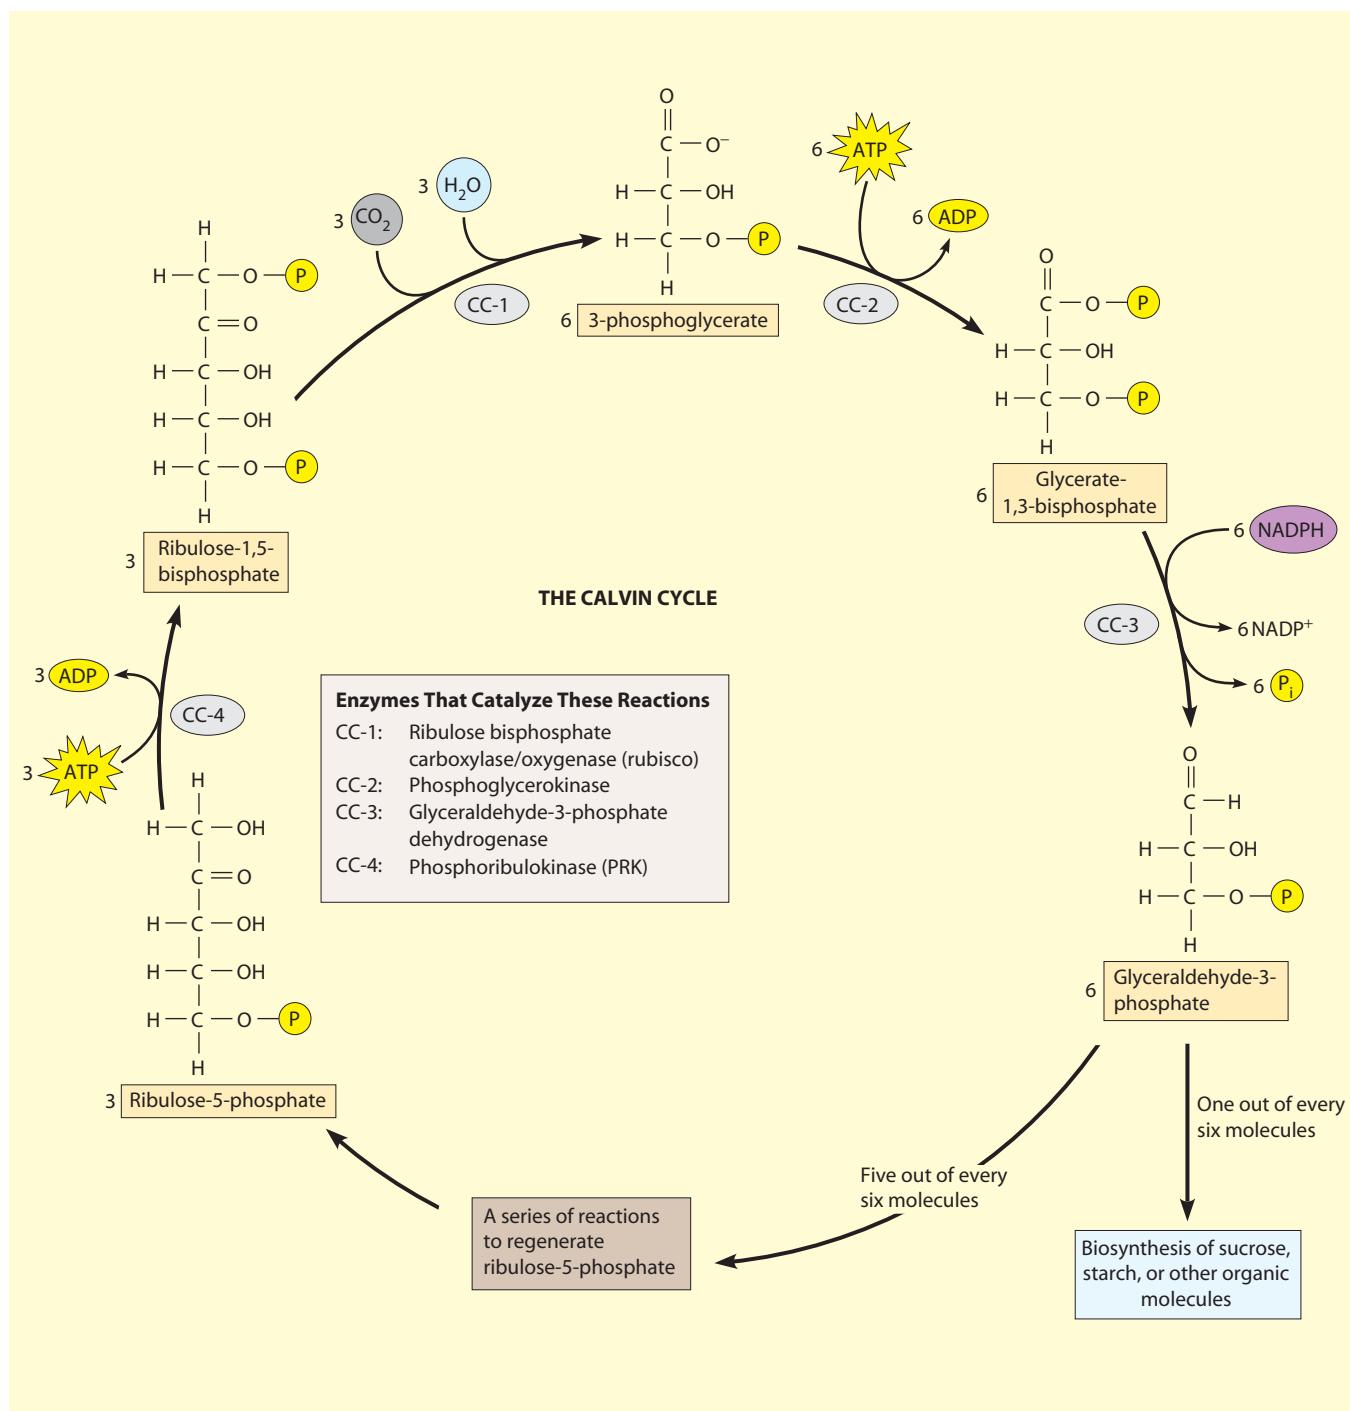

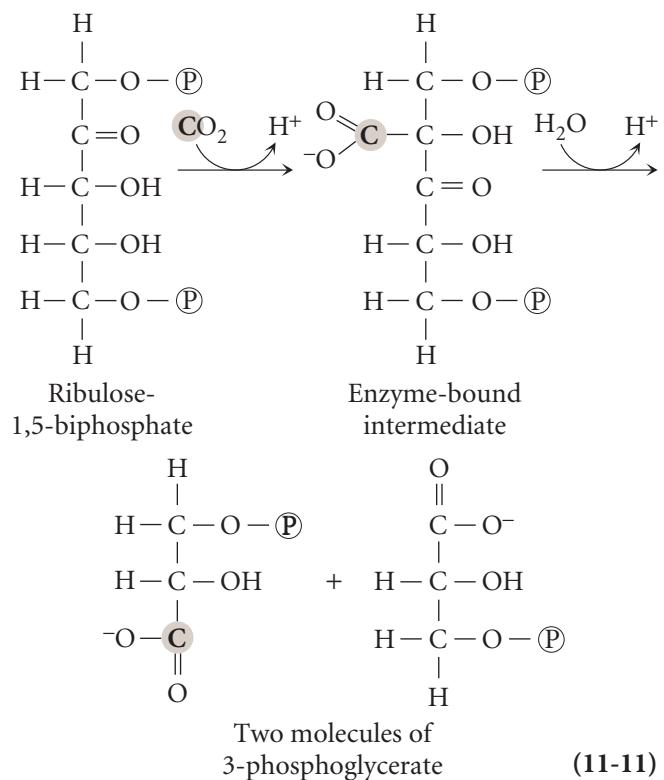

FIGURE 11-12 The Calvin Cycle for Photosynthetic Carbon Assimilation. During one turn of the Calvin cycle (CC), 3 CO₂ molecules are fixed, forming one molecule of triose phosphate. CO₂ is fixed in Reaction CC-1, forming 3-phosphoglycerate. Reactions CC-2 and CC-3 use ATP and NADPH to reduce 3-phosphoglycerate to glyceraldehyde-3-phosphate. One out of every six glyceraldehyde-3-phosphate molecules is used for the biosynthesis of sucrose, starch, or other organic molecules. The other five glyceraldehyde-3-phosphate molecules are used to form three molecules of ribulose-5-phosphate. The ribulose-5-phosphate is then phosphorylated using ATP in Reaction CC-4 to regenerate ribulose-1,5-bisphosphate, the acceptor molecule for Reaction CC-1, thus completing one turn of the cycle.

isolated such a molecule. As Calvin and his colleagues showed by exposing the alga *Chlorella* to radiolabeled ¹⁴CO₂, the first detectable product of carbon dioxide fixation by this pathway is a three-carbon molecule,

3-phosphoglycerate. Presumably, the six-carbon compound exists only as a transient enzyme-bound intermediate, which is immediately hydrolyzed to generate two molecules of 3-phosphoglycerate as shown below:

The newly fixed carbon dioxide (grey shading) appears as a carboxyl group on one of the two 3-phosphoglycerate molecules.

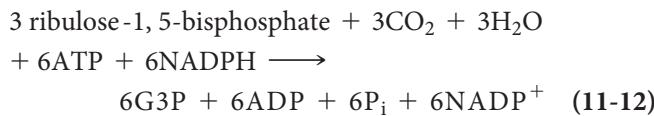

The enzyme that catalyzes the capture of the carbon dioxide and the formation of 3-phosphoglycerate is called **ribulose-1,5-bisphosphate carboxylase/oxygenase (rubisco)**. This relatively large enzyme (a molecular weight of about 560,000) is unique to phototrophs and is found in all photosynthetic organisms except for a few photosynthetic bacteria. Considering its essential role in carbon dioxide fixation for virtually the entire biosphere, it is hardly surprising that rubisco is thought to be the most abundant protein on the planet. About 10–25% of soluble leaf protein is rubisco, and one estimate puts the total amount of rubisco on the Earth at 40 million tons, or almost 15 lb (about 7 kg) for each living person.

3-Phosphoglycerate Is Reduced to Form Glyceraldehyde-3-Phosphate

In the second stage of the Calvin cycle, the 3-phosphoglycerate molecules formed during carbon dioxide fixation are reduced to glyceraldehyde-3-phosphate. This involves a sequence of reactions that is essentially the reverse of the oxidative sequence of glycolysis (Reactions Gly-6 and Gly-7 in Figure 9-7) except that the coenzyme involved is NADPH, not NADH. The steps for NADPH-mediated reduction are shown in Figure 11-12 as Reactions CC-2 and CC-3. In the first reaction, *phosphoglycerokinase* catalyzes the transfer of a phosphate group from ATP to 3-phosphoglycerate. This reaction generates an activated intermediate, glyceraldehyde-1,3-bisphosphate. In the second

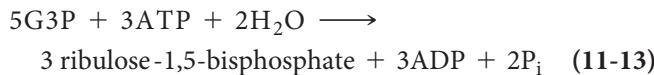

reaction, *glyceraldehyde-3-phosphate dehydrogenase* catalyzes the transfer of two electrons and one proton from NADPH to glyceraldehyde-1,3-bisphosphate, reducing it to glyceraldehyde-3-phosphate (G3P).

Some accounting is in order at this point. For every carbon dioxide molecule that is fixed by rubisco (Reaction CC-1), two 3-phosphoglycerate molecules are generated. The reduction of both of these molecules to glyceraldehyde-3-phosphate requires the hydrolysis of two ATP molecules and the oxidation of two NADPH molecules—all for a net gain of only one carbon atom. The net synthesis of one triose phosphate molecule requires the fixation and reduction of *three* carbon dioxide molecules to maintain carbon balance and will therefore consume six ATP and six NADPH:

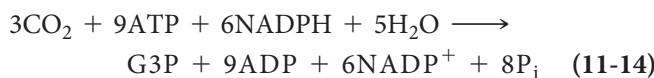

Regeneration of Ribulose-1,5-Bisphosphate Allows Continuous Carbon Assimilation

One out of every six triose phosphate molecules—the net gain following three carboxylations in the Calvin cycle—is used for the biosynthesis of sucrose, starch, or other organic molecules. The five remaining triose phosphates are required in the third and final stage of the Calvin cycle for regeneration of three molecules of the acceptor pentose ribulose-1,5-bisphosphate (Reaction CC-4). Four basic reactions—catalyzed by *aldolases*, *transketolases*, *phosphatases*, and *isomerasases*—transform five molecules of glyceraldehyde-3-phosphate to three molecules of *ribulose-5-phosphate*. After this, *phosphoribulokinase (PRK)* phosphorylates each ribulose-5-phosphate to form the ribulose-1,5-bisphosphate that accepts carbon dioxide in Reaction CC-1. Regeneration of ribulose-1,5-bisphosphate from glyceraldehyde-3-phosphate consumes three more ATP molecules. The series of events may be summarized by the following net reaction:

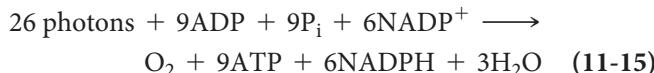

The Complete Calvin Cycle and Its Relation to Photosynthetic Energy Transduction

Primary carbon assimilation by the Calvin cycle may be summarized by combining Reactions 11-12 and 11-13, which encompass all the chemistry of the cycle from carbon dioxide fixation and reduction through triose phosphate synthesis and regeneration of the organic acceptor molecule. The resulting net reaction is

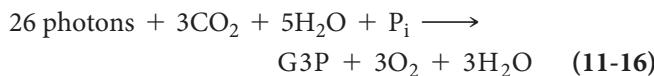

Note the requirements for ATP and NADPH: The Calvin cycle consumes nine ATP molecules and six NADPH molecules for every three-carbon carbohydrate synthesized, which is three ATP and two NADPH for each carbon dioxide molecule fixed. Thus, activity of the cyclic pathway of PSI and/or the Q cycle is required to produce this excess ATP.

We are now ready to write an overall reaction for photosynthesis that takes both energy transduction and carbon assimilation into account. Considering the needs of the Calvin cycle and assuming no diversion of ATP or NADPH to other pathways, the requirements are clear. According to Reaction 11-14, the synthesis of one molecule of glyceraldehyde-3-phosphate requires nine ATP and six NADPH molecules. This demand can be met by the flow of 12 electrons through the noncyclic pathway, which requires 24 photons to be absorbed by the two photosystems in series. This provides all six of the NADPH molecules ($3 \times$ Reaction 11-9) and eight of the nine ATP molecules ($8 \times$ Reaction 11-10). The flow of two electrons through the cyclic pathway of PSI will require two more photons and will provide one more ATP molecule ($1 \times$ Reaction 11-10). Thus, the net reaction for energy transduction is

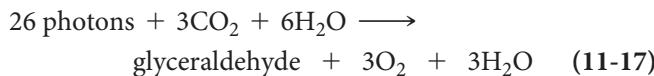

The absorption of 26 photons is accounted for by 12 photoexcitation events at PSI and 12 at PSII during noncyclic electron flow and 2 photoexcitation events at PSI during cyclic electron flow. (If the Q cycle is operating, somewhat fewer photons would be needed.)

By adding the summary reaction for the Calvin cycle (Reaction 11-14) to the net reaction for energy transduction (Reaction 11-15), we obtain the following overall expression:

Because the phosphate group is generally removed by hydrolysis when glyceraldehyde-3-phosphate is incorporated into more complex organic compounds, we may rewrite Reaction 11-16 as

This reaction is almost identical to the net photosynthetic reaction we introduced near the beginning of this chapter (Reaction 11-2). We are now, however, in a much better position to understand some of the photochemical and metabolic complexity behind what might otherwise appear to be a simple reaction. Moreover, we have replaced the vague terms *light* and $\text{C}_3\text{H}_6\text{O}_3$ with a specific number of photons and a primary product of carbon dioxide fixation.

This information enables us to calculate the maximum efficiency of photosynthetic energy transduction and carbon assimilation. For red light, assuming a wavelength of 670 nm, 26 moles of photons represent 26×43 kcal/mol of photons, or a total of 1118 kcal of

energy. Since glyceraldehyde differs in free energy from carbon dioxide and water by 343 kcal/mol, the efficiency of photosynthetic energy transduction is about 31% ($343/1118 = 0.31$). This is greater than the efficiencies of most man-made energy-transducing machinery.

Regulation of the Calvin Cycle

In the dark, phototrophs must meet the steady demand for energy and carbon by tapping the surplus of carbohydrates that accumulates when light is available. This activity would be futile, however, if the Calvin cycle continued to fix carbon while the glycolytic and other pathways consume storage carbohydrates. The organism would be using energy to reduce carbon dioxide to produce sugars and other carbohydrates while simultaneously oxidizing these carbohydrates to produce energy. And, because all biological pathways run at less than 100% thermodynamic efficiency, this futile cycle of synthesis and degradation would result in a net loss of energy as heat. It is not surprising, then, that phototrophs have several regulatory systems to ensure that the Calvin cycle does not operate unless light is available.

The Calvin Cycle Is Highly Regulated to Ensure Maximum Efficiency

The first level of control is the regulation of synthesis of key enzymes of the Calvin cycle. Enzymes that are important only for light-dependent carbon dioxide fixation and reduction are generally not present in plant tissues that are not exposed to light. Plastids in root cells, for example, contain less than 1% of the amount of rubisco activity found in the chloroplasts of leaf cells.

Enzymes of the Calvin cycle are also regulated by the levels of key metabolites. Consider the changes that occur in the chloroplast stroma as light drives the movement of electrons from water to ferredoxin. As protons are pumped from the stroma to the lumen, the pH of the stroma rises from about 7.2 (a typical value in the dark) to about 8.0. Simultaneously, magnesium ions diffuse in the opposite direction from the lumen to the stroma, and the concentration of magnesium ions in the stroma rises about fivefold. Eventually, high levels of reduced ferredoxin, NADPH, and ATP also accumulate. Each of these factors serves as a signal that can activate enzymes of the Calvin cycle as well as enzymes of other metabolic pathways.

Three enzymes that are unique to the Calvin cycle are logical points for metabolic control. Rubisco is an obvious candidate because it catalyzes the carboxylation reaction of the Calvin cycle. The others are *sedoheptulose bisphosphatase* and *PRK*, which have roles in regenerating the organic acceptor molecule ribulose-1,5-bisphosphate. These three enzymes are all stimulated by a high pH and a high concentration of magnesium ions. In the dark, pH and magnesium ion levels in the stroma decline, rendering these enzymes less active. Each of these enzymes not only is unique to the Calvin cycle but also catalyzes an

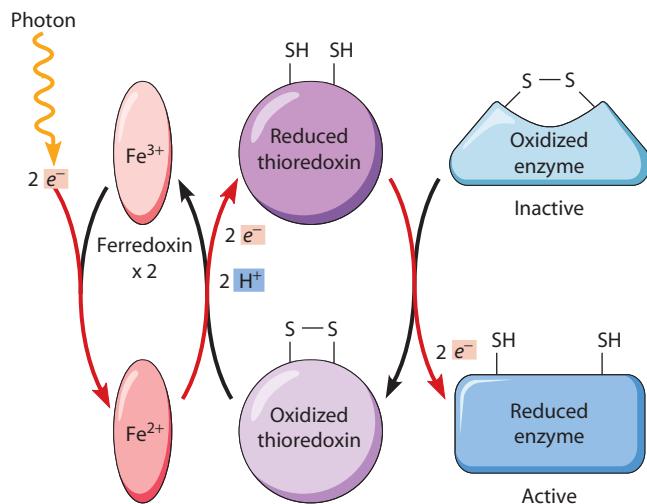

FIGURE 11-13 Thioredoxin-Mediated Activation of a Calvin Cycle Enzyme. Two reduced ferredoxin molecules generated by the photoreduction pathway donate electrons to thioredoxin, an intermediate electron carrier. Thioredoxin subsequently activates a target enzyme by reducing a disulfide bond to two sulfhydryl groups. In other cases, thioredoxin may inactivate enzymes.

essentially irreversible reaction. Recall from Chapter 9 that the glycolytic pathway is also regulated at sites of unique and irreversible reactions. This method of regulation of irreversible, pathway-specific enzymes is a common theme in metabolism.

Another system for coordinating photosynthetic energy transduction and carbon assimilation, shown in **Figure 11-13**, depends on ferredoxin. During illumination, electrons donated by water are used to reduce ferredoxin. An enzyme known as *ferredoxin-thioredoxin reductase* then catalyzes the transfer of electrons from ferredoxin to *thioredoxin*, another mobile electron carrier. Thioredoxin affects enzyme activity by reducing disulfide ($S-S$) bonds to sulfhydryl (SH) groups, which causes a protein to undergo a conformational change. Glyceraldehyde-3-phosphate dehydrogenase (Reaction CC-3 in Figure 11-12), sedoheptulose bisphosphatase, and PRK are all activated by the conformational change resulting from reduction of disulfide bonds by thioredoxin. In the dark, no reduced ferredoxin is available, and the sulfhydryl groups spontaneously reoxidize to disulfide bonds, thereby inactivating the enzymes. The CF_0CF_1 -ATP synthase described earlier is also affected by the thioredoxin system.

Because the Calvin cycle produces three-carbon molecules that can directly enter the glycolytic pathway, the breakdown of complex carbohydrates is not necessary in the light. Not surprisingly, the same mechanisms that activate enzymes of the Calvin cycle inactivate enzymes of degradative pathways. An example is *phosphofructokinase*, the most important control point in glycolysis. While the Calvin cycle is operating in the light, inhibition of phosphofructokinase by high levels of ATP ensures that the early steps of the glycolytic pathway are bypassed, thereby preventing the development of another potentially futile cycle.

Rubisco Activase Regulates Carbon Fixation by Rubisco

Calvin cycle activity is also regulated by **rubisco activase**, a protein that can modulate the activity of rubisco. Rubisco activase functions by removing inhibitory sugar-phosphate compounds from the rubisco active site, thus stimulating rubisco's ability to fix carbon. This allows rubisco to have maximum catalytic activity and promotes carbon fixation at otherwise suboptimal concentrations of CO_2 . Rubisco activase also has an inherent ATPase activity, which is essential for its ability to activate rubisco. This ATPase activity is sensitive to the ADP/ATP ratio and is highest when this ratio is low (in the light). In the dark, accumulation of ADP inhibits the ATPase activity of rubisco activase, down-regulating rubisco and conserving supplies of ATP when rubisco is not needed.

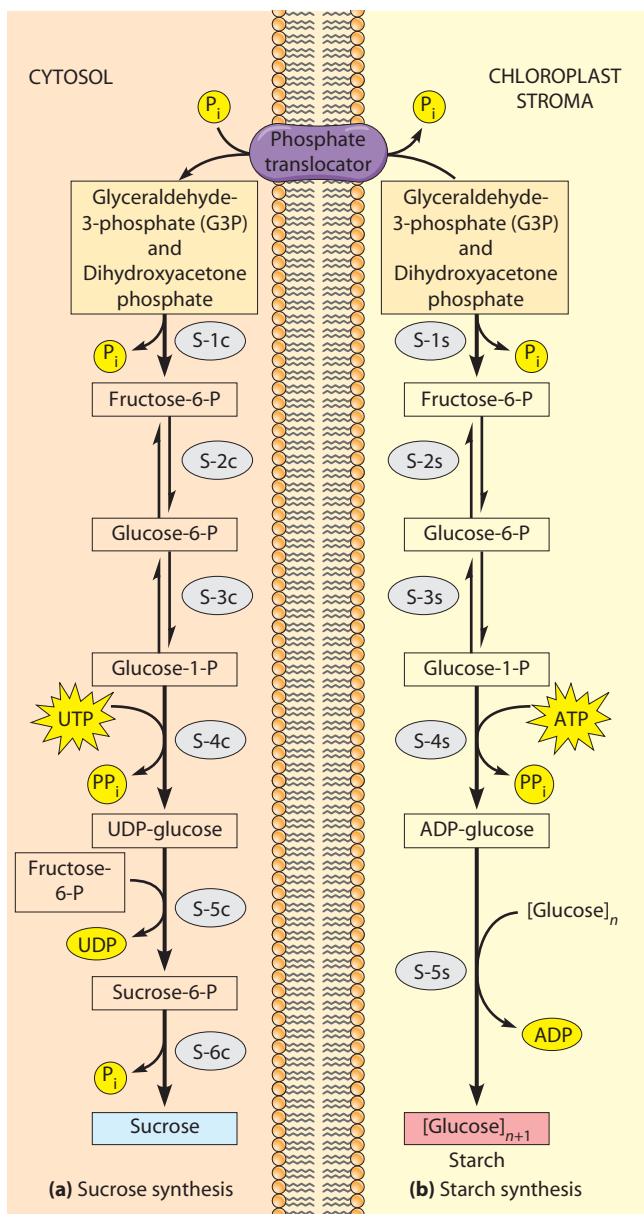

In addition to sensing the energy status of the cell, rubisco activase is responsive to the redox state of the cell via interaction with thioredoxin. Recent work by Archie Portis and co-workers shows that the ADP-induced inhibition of activity is greatly diminished in the light by thioredoxin-mediated reduction of a disulfide bridge in rubisco activase, allowing enhanced activity. Thus, rubisco activase helps to regulate the level of carbon fixation by rubisco by responding to the level of light, the ADP/ATP ratio, and the redox state of the cell.

Photosynthetic Carbon Assimilation II: Carbohydrate Synthesis

Because triose phosphates generated by the Calvin cycle are consumed by metabolic pathways in the cytosol as well as the chloroplast stroma, there must be a mechanism for transporting them across the chloroplast inner membrane. The most abundant protein in the chloroplast inner membrane is a *phosphate translocator* that catalyzes the exchange of dihydroxyacetone phosphate, glyceraldehyde-3-phosphate, or 3-phosphoglycerate in the stroma for P_i in the cytosol. This *antiport* system (see Figure 8-6) ensures that triose phosphates will not be exported unless P_i —which is required for synthesizing new triose phosphates—returns to the stroma. Moreover, the phosphate translocator is specific enough to prevent other intermediates of the Calvin cycle from leaving the stroma. Within the cytosol, triose phosphates may be used for sucrose synthesis, as we will describe shortly, or they may enter the glycolytic pathway to provide ATP and NADH in the cytosol. The triose phosphates remaining in the stroma are generally used for starch synthesis, which we will also describe shortly.

Glucose-1-Phosphate Is Synthesized from Triose Phosphates

The key hexose phosphate required for both starch and sucrose synthesis is glucose-1-phosphate, which is formed from two triose phosphates as shown in **Figure 11-14**,

Enzymes That Catalyze These Reactions	
S-1:	Aldolase and fructose-1,6-bisphosphatase
S-2:	Phosphoglucoisomerase
S-3:	Phosphoglucomutase
S-4c:	UDP-glucose pyrophosphorylase
S-5c:	Sucrose phosphate synthase
S-6c:	Sucrose phosphatase
S-4s:	ADP-glucose pyrophosphorylase
S-5s:	Starch synthase

FIGURE 11-14 The Biosynthesis of Sucrose and Starch from Products of the Calvin Cycle. The triose phosphates glyceraldehyde-3-phosphate and dihydroxyacetone phosphate from the chloroplast stroma are exchanged for inorganic phosphate from the cytosol via a phosphate translocator. (a) Sucrose synthesis is confined to the cytosol, whereas (b) starch synthesis occurs only in the chloroplast stroma. The enzymes and isoenzymes that catalyze these reactions are restricted to either the cytosol (c) or the stroma (s).

Reactions S-1 through S-3. This set of reactions occurs both in the cytosol (c) and in the chloroplast stroma (s). Hexoses and hexose phosphates must be synthesized in each compartment because they cannot cross the chloroplast inner membrane. The initial steps in the sequence resemble reactions we encountered in our discussion of gluconeogenesis in Chapter 9 (see Figure 9-11). The first step in triose phosphate utilization is a condensation reaction catalyzed by aldolase that generates fructose-1,6-bisphosphate. As in gluconeogenesis, the pathway is rendered exergonic by the hydrolytic removal of a phosphate group from fructose-1,6-bisphosphate to form fructose-6-phosphate. The enzyme that catalyzes this reaction, fructose-1,6-bisphosphatase, exists in two forms, one in the cytosol and the other in the chloroplast stroma. The multiple forms of such an enzyme are called **isoenzymes**—physically distinct proteins that catalyze the same reaction. The fructose-6-phosphate can then be converted, via glucose-6-phosphate, to glucose-1-phosphate (Reactions S-2 and S-3). Again, separate isoenzymes catalyze each of these reactions in the cytosol and in the chloroplast stroma.

Textbooks often depict glucose as the end-product of photosynthetic carbon assimilation. But this portrayal is more a definition of convenience for writing summary reactions than a metabolic fact, as very little free glucose actually accumulates in photosynthetic cells. Most glucose is converted either into transport carbohydrates (such as sucrose) or into storage carbohydrates (such as starch in plants or glycogen in photosynthetic bacteria). In reality, the designation of an end-product for photosynthetic carbon assimilation becomes rather arbitrary once you get past the pool of triose phosphates produced by the Calvin cycle. Indeed, we could regard the whole phototrophic organism—plant, algal cell, or bacterium—as the “end-product” of photosynthesis.

The Biosynthesis of Sucrose Occurs in the Cytosol

Recall from Chapter 3 that sucrose is a disaccharide consisting of one molecule each of glucose and fructose linked by a glycosidic bond (see Figure 3-23). Sucrose is of interest because it is the major carbohydrate used for transporting stored energy and reduced carbon in most plant species. Moreover, in some species, such as sugar beets and sugar cane, sucrose also serves as a storage carbohydrate. As shown in Figure 11-14a, sucrose synthesis is localized in the cytosol of a photosynthetic cell. Triose phosphates exported from the chloroplast stroma that are not consumed by other metabolic pathways are converted to fructose-6-phosphate and glucose-1-phosphate. Glucose from glucose-1-phosphate is then activated by the reaction of glucose-1-phosphate with *uridine triphosphate* (UTP), generating *UDP-glucose* (Reaction S-4c). Finally, the glucose is transferred to fructose-6-phosphate to form the phosphorylated disaccharide *sucrose-6-phosphate*, and hydrolytic removal of the phosphate group generates free

sucrose (Reactions S-5c and S-6c). (In some plant species, glucose may be transferred directly from UDP-glucose to free fructose.) The sucrose is exported from leaves and conveys energy and reduced carbon to nonphotosynthetic tissues of the organism.

Like the Calvin cycle, sucrose synthesis is precisely controlled to prevent conflict with degradation pathways. *Cytosolic* fructose-1,6-bisphosphatase, for example, is inhibited by *fructose-2,6-bisphosphate*, a metabolite introduced in Chapter 9 as an important regulator of glycolysis and gluconeogenesis in liver cells. In plant cells, fructose-2,6-bisphosphate accumulates in response to high levels of fructose-6-phosphate and P_i (signals that indicate low sucrose demand) or low levels of 3-phosphoglycerate and dihydroxyacetone phosphate (signals that indicate high triose phosphate demand). Another control point for sucrose synthesis is *sucrose phosphate synthase*, the enzyme that catalyzes the transfer of glucose from UDP-glucose to fructose-6-phosphate (Reaction S-5c). This enzyme is stimulated by glucose-6-phosphate and inhibited by sucrose-6-phosphate, UDP, and P_i .

The Biosynthesis of Starch Occurs in the Chloroplast Stroma

Starch synthesis in plant cells is confined to plastids. In photosynthetic plant cells, starch synthesis is generally restricted to chloroplasts, which are essentially photosynthetic plastids. When sufficient energy and carbon are available to meet the metabolic needs of a plant, the triose phosphates within the chloroplast stroma are converted to glucose-1-phosphate, which is then used for starch synthesis. As shown in Figure 11-14b, glucose is activated by the reaction of glucose-1-phosphate with ATP, generating *ADP-glucose* (Reaction S-4s). The activated glucose is then transferred directly to a growing starch chain by *starch synthase*, leading to elongation of the polysaccharide (Reaction S-5s). As shown in Figure 11-2a, starch may accumulate in large storage granules within the chloroplast stroma. When photosynthesis is limited by darkness or other factors, starch is degraded to triose phosphates, which can then enter glycolysis or be converted to sucrose in the cytosol and exported from the cell.

Like the Calvin cycle and sucrose synthesis, starch synthesis is precisely controlled. Chloroplast fructose bisphosphatase, which channels fructose-1,6-bisphosphate into glucose and starch biosynthesis in the stroma, is activated by the same thioredoxin system that affects enzymes of the Calvin cycle. This regulation ensures that starch synthesis occurs only when there is sufficient illumination for photoreduction. The key enzyme for regulation, though, is *ADP-glucose pyrophosphorylase*, which catalyzes the activation of glucose and commits it to starch synthesis by forming ADP-glucose (Reaction S-4s). ADP-glucose pyrophosphorylase is stimulated by glyceraldehyde-3-phosphate and inhibited by P_i . Thus, when triose phosphates are diverted to the cytosol and ATP is

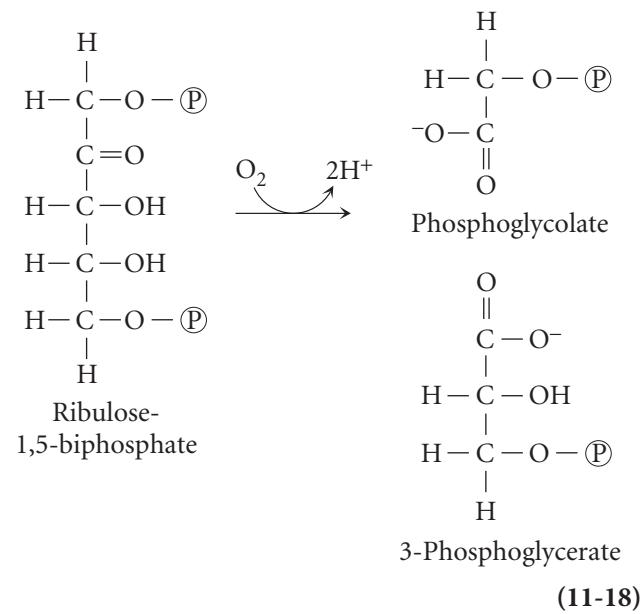

hydrolyzed to ADP and P_i (signals that indicate high energy demand), starch synthesis is blocked.

Photosynthesis Also Produces Reduced Nitrogen and Sulfur Compounds

Photosynthesis encompasses more than carbon dioxide fixation and carbohydrate synthesis. In plants and algae, the ATP and NADPH generated by photosynthetic energy transduction reactions are consumed by a variety of other anabolic pathways found in chloroplasts. Carbohydrate synthesis is only one example of carbon metabolism; the synthesis of fatty acids, chlorophyll, and carotenoids also occurs in chloroplasts. Moving beyond carbon metabolism, several key steps of nitrogen and sulfur assimilation are localized in chloroplasts. The reduction of nitrite (NO_2^-) to ammonia (NH_3), for example, is catalyzed by a reductase enzyme in the chloroplast stroma, with reduced ferredoxin serving as an electron donor. The ammonia is then channeled into amino acid and nucleotide synthesis, portions of which also occur in chloroplasts. Furthermore, much of the reduction of sulfate (SO_4^{2-}) to sulfide (S^{2-}) is catalyzed by enzymes in the chloroplast stroma. In this case, ATP and reduced ferredoxin provide energy and reducing power. The sulfide, like ammonia, may then be used for amino acid synthesis.

Rubisco's Oxygenase Activity Decreases Photosynthetic Efficiency

The primary reaction catalyzed by rubisco—acting as a *carboxylase*—is the addition of carbon dioxide and water to ribulose-1,5-bisphosphate, forming two molecules of 3-phosphoglycerate. However, rubisco can also function as an *oxygenase*. Through this activity, rubisco catalyzes the addition of molecular oxygen, rather than carbon dioxide, to ribulose-1,5-bisphosphate:

The result of rubisco's oxygenase activity is a single three-carbon product—3-phosphoglycerate—and one two-carbon product, **phosphoglycolate**. Because phosphoglycolate cannot be used in the next step of the Calvin cycle, it appears to be a wasteful diversion of material from carbon assimilation. No alternative functions for rubisco's oxygenase activity have been clearly demonstrated.

Efforts to reduce rubisco's oxygenase activity through alteration of the amino acid sequence of the enzyme have been largely unsuccessful, as a decrease in oxygenase activity is typically accompanied by a compensatory decline in carboxylase activity. Why then does rubisco have this detrimental oxygenase activity? According to one theory, the oxygenase activity is an evolutionary relic from a time when oxygen did not make up a large part of the Earth's atmosphere, and it cannot be eliminated without seriously compromising the carboxylase function. Not even natural selection appears to be up to the task of altering this enzyme. Instead, phototrophs that depend on rubisco have developed three alternative strategies for coping with the enzyme's apparently wasteful oxygenase activity. We will

briefly consider each strategy in the following discussions of the *photorespiratory glycolate pathway*, *C₄ photosynthesis*, and *crassulacean acid metabolism*.

The Glycolate Pathway Returns Reduced Carbon from Phosphoglycolate to the Calvin Cycle

In all photosynthetic plant cells, phosphoglycolate generated by rubisco's oxygenase activity is channeled into the **glycolate pathway** (Figure 11-15). This pathway disposes of phosphoglycolate and returns about 75% of the reduced carbon present in phosphoglycolate to the Calvin cycle as 3-phosphoglycerate, with the other 25% released as CO₂. Because the glycolate pathway is characterized by light-dependent uptake of oxygen and evolution of carbon dioxide, it is also referred to as **photorespiration**.

Several steps of the glycolate pathway are localized in a specific type of peroxisome called a **leaf peroxisome**. As we learned in Chapter 4, peroxisomes are organelles containing oxidase enzymes that generate hydrogen peroxide.

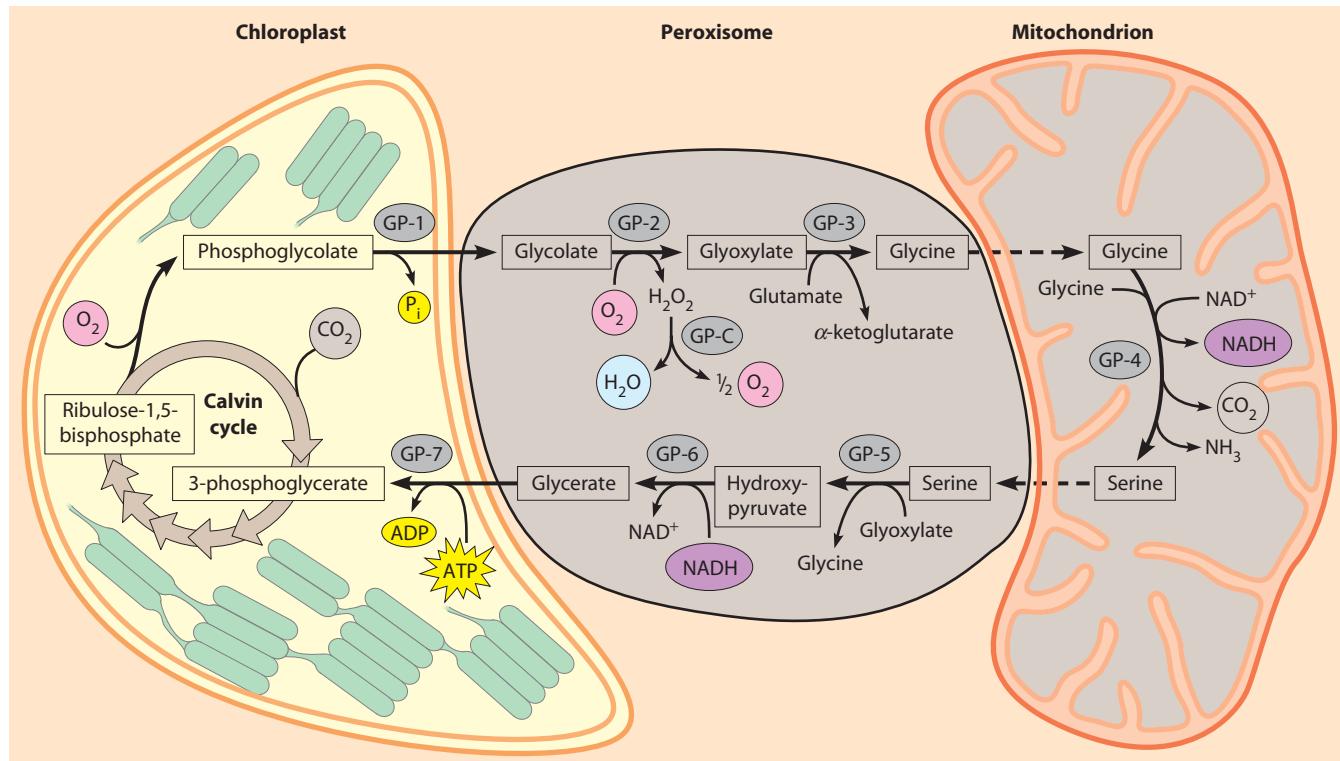

FIGURE 11-15 The Glycolate Pathway. Glycolate arises as a result of the oxygenase activity of rubisco. The immediate product is phosphoglycolate, which is converted to free glycolate by a phosphatase localized in the chloroplast membrane (Reaction GP-1). Free glycolate diffuses out of the chloroplast stroma and is metabolized by a five-step pathway (Reactions GP-2 through GP-6) that occurs partially in the peroxisome and partially in the mitochondrion. Glycerate then diffuses into the chloroplast and is phosphorylated to form 3-phosphoglycerate (Reaction GP-7), which enters the Calvin cycle. The oxygen uptake and carbon dioxide evolution characteristic of photorespiration occur in the peroxisome (Reaction GP-2) and mitochondrion (Reaction GP-4), respectively. Note that two molecules of glycolate are required to form one molecule of 3-phosphoglycerate.

Enzymes That Catalyze These Reactions

- GP-1: Phosphoglycolate phosphatase
- GP-2: Glycolate oxidase
- GP-3: Glutamate: glyoxylate aminotransferase
- GP-4: Glycine decarboxylase and serine hydroxymethyl transferase
- GP-5: Serine: glyoxylate aminotransferase
- GP-6: Hydroxypyruvate reductase
- GP-7: Glycerate kinase
- GP-C: Catalase

The potentially destructive hydrogen peroxide is then eliminated by another peroxisomal enzyme, catalase, which degrades it to water and oxygen. Because of their essential role in the glycolate pathway, peroxisomes are found in all photosynthetic plant tissues.

A typical leaf peroxisome from a mesophyll cell is shown in the electron micrograph of Figure 4-20b. The crystalline core within the matrix of the organelle is composed of catalase, a marker enzyme for peroxisomes. Notice the close proximity of the leaf peroxisome to a chloroplast and a mitochondrion. This association is frequently found in photosynthetic plant cells and most likely reflects a way to facilitate metabolite transfer among the three organelles involved in the glycolate pathway.

In the chloroplast, the phosphoglycolate generated by rubisco is rapidly dephosphorylated by a phosphatase in the stroma (Reaction GP-1). The product is *glycolate*, which diffuses to a nearby leaf peroxisome, where an *oxidase* converts it to *glyoxylate* (Reaction GP-2). The oxidation of glycolate is accompanied by the uptake of oxygen and the generation of hydrogen peroxide, which is immediately degraded to oxygen and water by catalase (Reaction GP-C). During the next reaction in the peroxisome, an *aminotransferase* catalyzes the transfer of an amino group from glutamate to glyoxylate, forming glycine (Reaction GP-3).

Glycine diffuses from the leaf peroxisome to a mitochondrion, where two enzyme activities working in series—a *decarboxylase* and a *hydroxymethyl transferase*—convert two glycine molecules to a single *serine*, concomitant with the generation of NADH and the release of carbon dioxide and ammonia (Reaction GP-4). Rubisco's oxygenase activity therefore leads not only to a loss of carbon but also to a potential loss of nitrogen. To prevent depletion of nitrogen reserves, the ammonia must be reassimilated at the expense of ATP and reductant.

Serine diffuses back to the peroxisome, where another aminotransferase removes the amino group, generating *hydroxypyruvate* (Reaction GP-5). A *reductase*, using NADH as an electron donor, then reduces hydroxypyruvate to *glycerate* (Reaction GP-6). Finally, glycerate diffuses to the chloroplast, where it is phosphorylated by *glycerate kinase* to generate 3-phosphoglycerate (Reaction GP-7), a key intermediate of the Calvin cycle.

What is the benefit of this long salvage pathway, winding through several organelles? Three out of every four carbon atoms that exit the Calvin cycle as part of phosphoglycolate are recovered as 3-phosphoglycerate. Without this pathway, phosphoglycolate would accumulate to toxic levels, and the triose phosphates essential for the regeneration of ribulose-1,5-bisphosphate and the continuation of the Calvin cycle would be depleted. In terms of energy and reduced carbon, however, phosphoglycolate metabolism is expensive. For every three carbon atoms salvaged, an ammonia molecule must be reassimilated at the expense of one ATP and two reduced ferredoxin molecules, and the glycerate generated by Reaction GP-6 must be phosphorylated at the expense of one ATP molecule.

With rubisco's apparently unavoidable oxygenase activity, however, photorespiration is a net gain for the plant. Just consider the value of the three carbon atoms salvaged: Nine ATP and six NADPH were consumed when each carbon dioxide was originally fixed and reduced.

C₄ Plants Minimize Photorespiration by Confining Rubisco to Cells Containing High Concentrations of CO₂

Plants in hot, arid environments under intense illumination are particularly affected by rubisco's oxygenase activity. As the temperature increases, the solubility of carbon dioxide declines more rapidly than the solubility of oxygen, thereby lowering the CO₂:O₂ ratio in solution. Another problem occurs when plants respond to drought by closing their stomata during the day to reduce water loss. When the stomata are closed, carbon dioxide cannot enter the leaf, and the concentration of carbon dioxide in leaf cells may decline. Moreover, water photolysis continues to generate oxygen, which accumulates because it cannot diffuse out of the leaf when the stomata are closed.

In some cases, the potential for energy and carbon drain through photorespiration is so overwhelming that plants must depend on adaptive strategies for solving the problem. One general approach is to confine rubisco to cells that contain a high concentration of carbon dioxide, thereby minimizing the enzyme's inherent oxygenase activity.

In many tropical grasses, including economically important plants such as maize, sorghum, and sugarcane, the isolation of rubisco is accomplished by a short carboxylation/decarboxylation pathway referred to as the **Hatch–Slack cycle**, after Marshall D. Hatch and C. Roger Slack, two plant physiologists who played key roles in the elucidation of the pathway. Plants containing this pathway are referred to as **C₄ plants** because the immediate product of carbon dioxide fixation by the Hatch–Slack cycle is the four-carbon organic acid oxaloacetate. This term distinguishes such plants from **C₃ plants**, in which the first detectable product of carbon dioxide fixation is the three-carbon compound 3-phosphoglycerate.

To appreciate the advantage of the Hatch–Slack cycle, we must first consider the arrangement of the Hatch–Slack and Calvin cycles within the leaf of a C₄ plant. As shown in **Figure 11-16**, C₄ plants, unlike C₃ plants, have in their leaves two distinct types of photosynthetic cells—*mesophyll cells* and *bundle sheath cells*—that differ in their enzyme composition and hence their metabolic activities. The carbon dioxide fixation step within a C₄ plant is accomplished by an enzyme other than rubisco in mesophyll cells, which are exposed to the carbon dioxide and oxygen that enter a leaf through its stomata. The carbon dioxide that is fixed in mesophyll cells is subsequently released in **bundle sheath cells**, which are relatively isolated from the atmosphere. The entire Calvin cycle, including rubisco, is confined to chloroplasts in the bundle sheath cells. Due to the activity of the Hatch–Slack

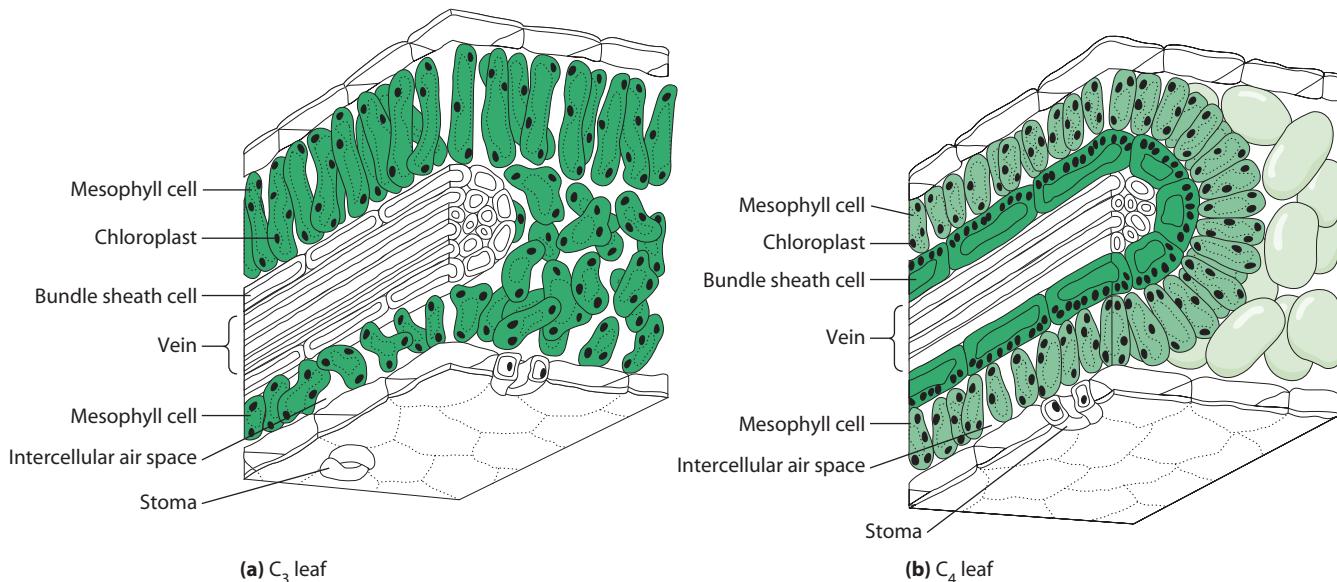

FIGURE 11-16 Structural Differences Between Leaves of C₃ and C₄ Plants. (a) In C₃ plants, the Calvin cycle occurs in mesophyll cells. (b) In C₄ plants, the Calvin cycle is confined to bundle sheath cells, which are relatively isolated from atmospheric carbon dioxide and oxygen. C₄ plants utilize the Hatch–Slack cycle for collecting carbon dioxide in mesophyll cells and concentrating it in bundle sheath cells. The bundle sheath cells surround the vascular bundles (veins) of the leaf, which carry carbohydrates to other parts of the plant. This concentric arrangement is called Kranz (German for “halo” or “wreath”) anatomy and is essential to the photosynthetic efficiency of C₄ plants.

cycle, the carbon dioxide concentration in bundle sheath cells may be as much as ten times the level in the atmosphere, strongly favoring rubisco's carboxylase activity and minimizing its oxygenase activity.

As detailed in **Figure 11-17**, the Hatch–Slack cycle begins with the carboxylation of *phosphoenolpyruvate* (PEP) to form oxaloacetate (Reaction HS-1). Carboxylation is catalyzed by a specific cytosolic form of *PEP carboxylase*, which is particularly abundant in mesophyll cells of C₄ plants. Not only does this carboxylase lack rubisco's oxygenase activity, it is an excellent scavenger for carbon dioxide in the form of the bicarbonate that is produced when carbon dioxide dissolves in water.

In one version of the Hatch–Slack pathway, the oxaloacetate generated by PEP carboxylase is rapidly converted to malate by an *NADPH-dependent malate dehydrogenase* (Reaction HS-2 in Figure 11-17). Malate is a stable four-carbon acid that carries carbon from mesophyll cells to chloroplasts of bundle sheath cells, where decarboxylation by *NADP⁺ malic enzyme* releases CO₂ (Reaction HS-3). The liberated carbon dioxide is then refixed and reduced by the Calvin cycle. Because decarboxylation of malate is accompanied by the generation of NADPH, the Hatch–Slack cycle also conveys reducing power from mesophyll to bundle sheath cells. This decreases the demand for noncyclic electron flow from water to NADP⁺ in the bundle sheath cells, thereby minimizing the formation of oxygen by PSII complexes and further favoring rubisco's carboxylase activity.

The pyruvate generated by decarboxylation of malate diffuses into a mesophyll cell, where it is phosphorylated at the expense of ATP to regenerate PEP (Reaction HS-4),

the original carbon dioxide acceptor of the Hatch–Slack cycle. Thus, the overall process is cyclic, and the net result is a feeder system that captures carbon dioxide in mesophyll cells and passes it to the Calvin cycle in bundle sheath cells. The Hatch–Slack cycle is not a substitute for the Calvin cycle: It is simply a preliminary carboxylation/decarboxylation sequence that concentrates CO₂ in the bundle sheath cells where there is less oxygen to compete with rubisco's carboxylation activity.

Because ATP is hydrolyzed to AMP in Reaction HS-4, the actual cost of moving carbon from mesophyll to bundle sheath cells is equivalent to two ATP molecules per carbon dioxide molecule. Carbon assimilation within a C₄ plant therefore consumes a total of five ATP molecules per carbon atom, rather than the three required in C₃ plants. In an environment that enhances rubisco's oxygenase activity, however, the energy required to prevent the formation of phosphoglycolate may be far less than the energy that would otherwise be lost through photorespiration.

When temperatures exceed about 30°C, the photosynthetic efficiency of a C₄ plant exposed to intense sunlight may be twice that of a C₃ plant. This is one reason that crabgrass, a C₄ plant, often outgrows other C₃ lawn grasses. While the higher efficiency of a C₄ plant is largely due to reduced photorespiration, other factors are also important. For example, because of their ability to concentrate CO₂, C₄ plants are less affected by the lowered CO₂ concentrations that can exist in dense growth where CO₂ is being rapidly consumed.

Enrichment of carbon dioxide in the vicinity of rubisco by the Hatch–Slack cycle confers an additional advantage

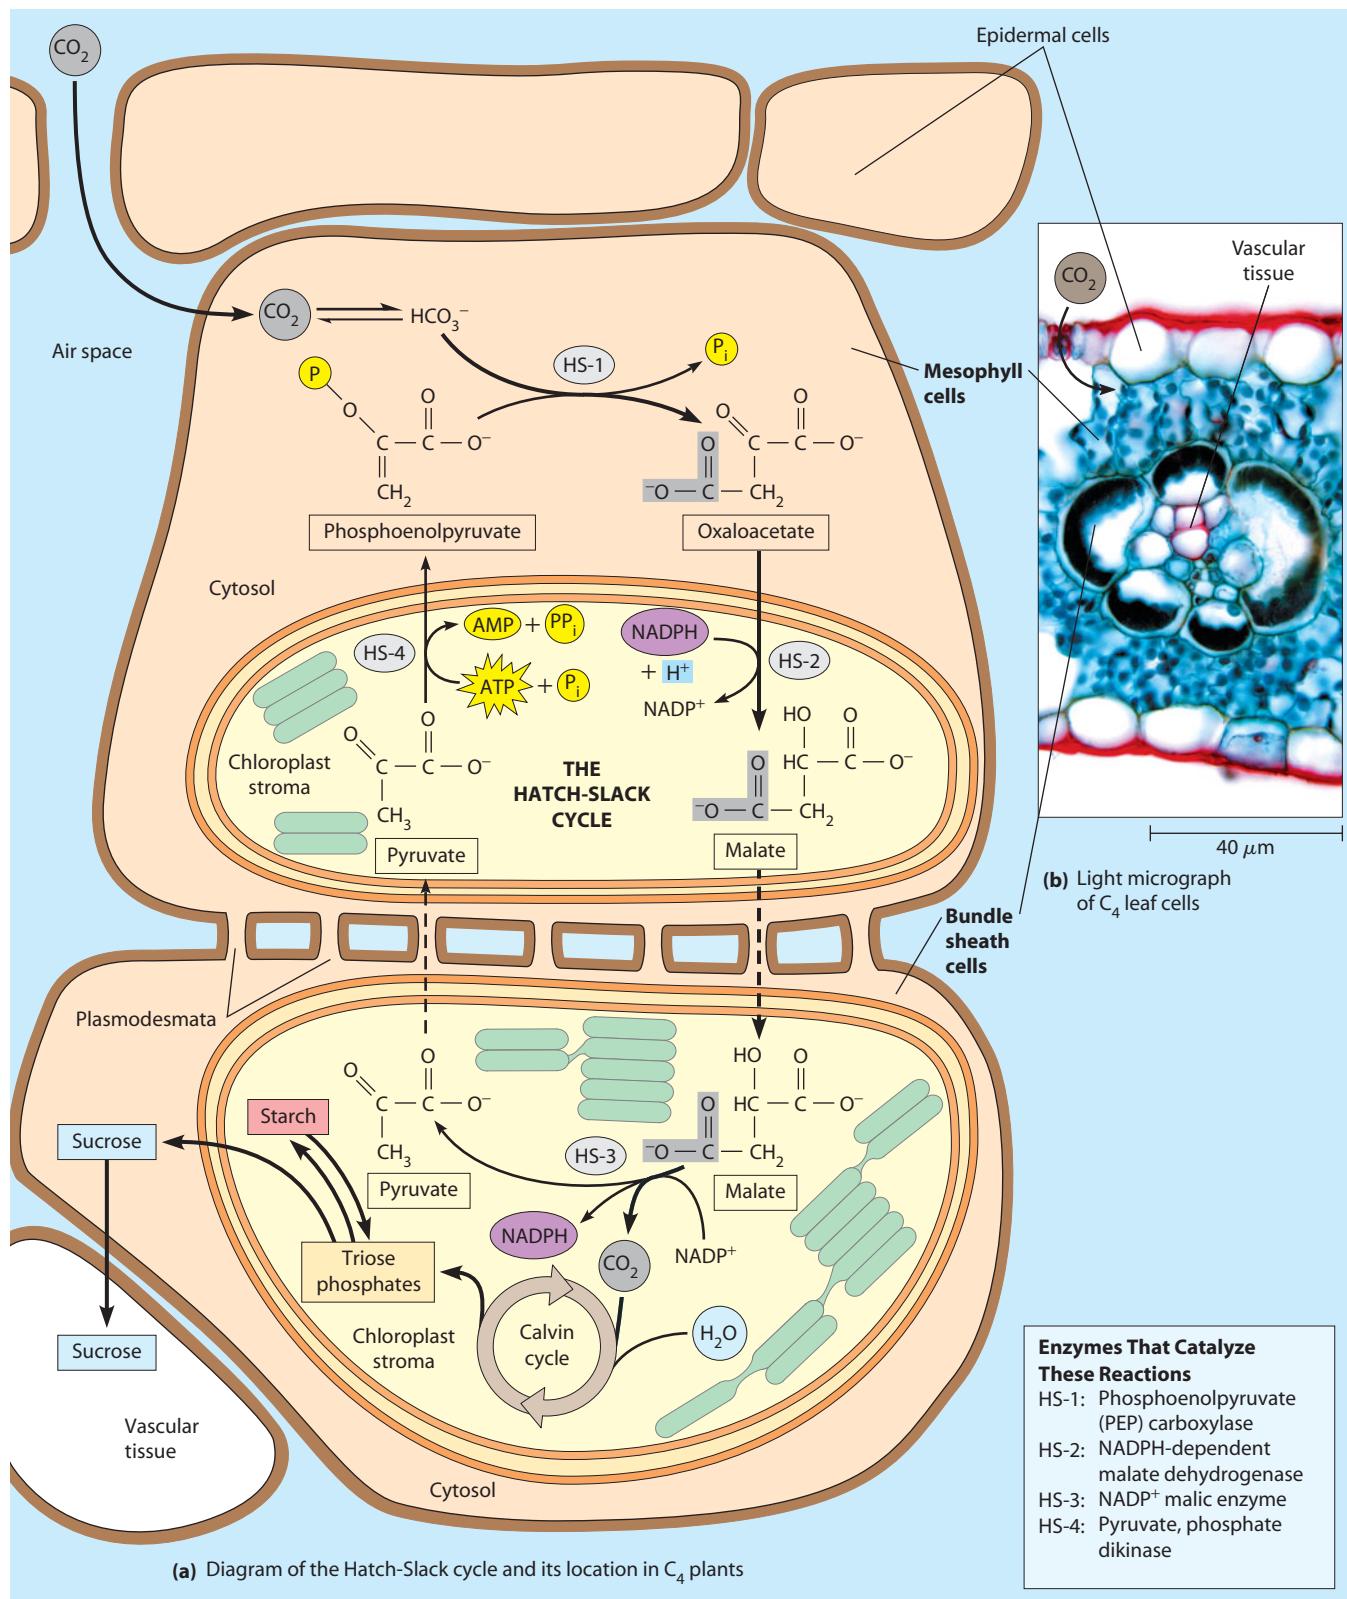

FIGURE 11-17 Localization of the Hatch-Slack Cycle Within Different Cells of a C_4 Leaf. (a) Carbon dioxide fixation in C_4 plants occurs by the Hatch-Slack cycle within mesophyll cells, initially forming oxaloacetate. (The path of incoming carbon is indicated by heavy black arrows.) The malate formed by reduction of oxaloacetate is then passed inward to the bundle sheath cells, where it is decarboxylated. The carbon dioxide is refixed by the Calvin cycle, eventually yielding sucrose, which passes into the adjacent vascular tissue for transport to other parts of the plant. The enzymes that catalyze the Hatch-Slack reactions are listed in the box at lower right. The enzyme pyruvate, phosphate dikinase, which catalyzes phosphorylation of pyruvate, is unique to the Hatch-Slack cycle. (b) The C_4 leaf cells shown in cross section in this light micrograph are of maize, *Zea mays*.

on C₄ plants. Because PEP carboxylase is an efficient scavenger of carbon dioxide, gas exchange through the stomata of C₄ plants can be substantially reduced to conserve water without adversely affecting photosynthetic efficiency. As a result, C₄ plants are able to assimilate over twice as much carbon as C₃ plants for each unit of water transpired. This adaptation makes C₄ plants suitable for regions of periodic drought, such as tropical savannas.

Although fewer than 1% of plant species investigated depend on the Hatch–Slack cycle, the pathway is of particular interest because several economically important species are in this group. Also, C₄ plants such as maize and sugarcane are characterized by net photosynthetic rates that are often two or three times those of C₃ plants such as cereal grains. Little wonder then, that crop physiologists and plant breeders have devoted so much attention to C₄ species and to the question of whether it is possible to improve on the relatively inefficient carbon dioxide fixation pathway of the C₃ plants. Some scenarios of genetic engineering even envision genetically converting C₃ plants into C₄ plants.

CAM Plants Minimize Photorespiration and Water Loss by Opening Their Stomata Only at Night

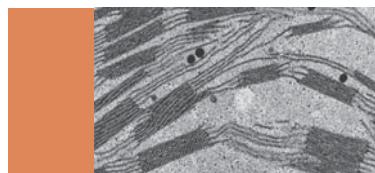

Finally, we will consider a third strategy used by some plants to cope with the wasteful oxygenase activity of rubisco. Certain plant species that live in deserts, salt marshes, and other environments where access to water is severely limited contain a preliminary carbon dioxide fixation pathway closely related to the Hatch–Slack cycle. The sequence of reactions is similar, but these plants segregate the carboxylation and decarboxylation reactions by *time* rather than by *space*. Because the pathway was first recognized in the family of succulent plants known as the Crassulaceae, it is called **crassulacean acid metabolism** (CAM), and plants that take advantage of CAM photosynthesis are called **CAM plants**. CAM photosynthesis has

been found in about 4% of plant species investigated, including many succulents, cacti, orchids, and bromeliads such as pineapple.

CAM plants, unlike most C₃ and C₄ plants, generally open their stomata only at night, when the atmosphere is relatively cool and moist. As carbon dioxide diffuses into mesophyll cells, it is assimilated by the first two steps of a pathway similar to the Hatch–Slack cycle and accumulates within the cells as malate. Instead of being exported from mesophyll cells, however, the malate is stored in large vacuoles, which become very acidic. The process of moving malate into vacuoles consumes ATP but is necessary to protect cytosolic enzymes from a large drop in pH at night.

During the day, CAM plants close their stomata to conserve water. The malate then diffuses from vacuoles to the cytosol, where the Hatch–Slack cycle continues. Carbon dioxide released by decarboxylation of malate diffuses into the chloroplast stroma, where it is refixed and reduced by the Calvin cycle. The high carbon dioxide and low oxygen concentrations established when light is available for generating ATP and NADPH strongly favor rubisco's carboxylase activity and minimize the loss of carbon through photorespiration. Notice that the carboxylation of PEP and decarboxylation of malate occur in the same compartment. Because of this, the activity of PEP carboxylase in CAM plants must be strictly inhibited during the day to prevent a futile cycle from developing.

With their remarkable ability to conserve water, CAM plants may assimilate over 25 times as much carbon as a C₃ plant does for each unit of water transpired. Moreover, some CAM plants display a process called *CAM idling*, whereby the plant keeps its stomata closed night *and* day. Carbon dioxide is simply recycled between photosynthesis and respiration, with virtually no loss of water. Such plants will not, of course, display a net gain of carbohydrate and will not show much if any growth. This ability, however, can enable them to survive droughts lasting up to several months and may contribute to their long life spans, which can exceed 100 years.

SUMMARY OF KEY POINTS

An Overview of Photosynthesis

- Photosynthesis is the single most vital metabolic process for virtually all forms of life on Earth because all of us, whatever our immediate sources of energy, ultimately depend on the energy radiating from the sun.
- The energy transduction reactions of photosynthesis convert solar energy into chemical energy in the form of NADPH and ATP. The carbon assimilation reactions use this chemical energy to fix and reduce carbon dioxide to carbohydrates.
- In eukaryotic phototrophs, photosynthesis occurs in the chloroplasts, which contain an internal membrane system

known as the thylakoids that contains many of the required components.

Photosynthetic Energy Transduction I: Light Harvesting

- Photons of light are absorbed by chlorophyll or accessory pigment molecules within the thylakoid or photosynthetic bacterial membranes. Their energy is rapidly passed to a special pair of chlorophyll molecules at the reaction center of a photosystem.

- At the reaction center, the energy is used to excite and eject an electron from chlorophyll and induce charge separation. In oxygenic phototrophs, this electron is replaced by an electron obtained from a water molecule, generating oxygen.

Photosynthetic Energy Transduction II: NADPH Synthesis

- Electron transfer from water to NADP^+ relies on two photosystems acting in series, with photosystem II responsible for the oxidation of water and photosystem I responsible for the reduction of NADP^+ to NADPH in the stroma.
- Electron flow between the two photosystems passes through a cytochrome b_6/f complex, which pumps protons into the thylakoid lumen. The resulting proton gradient represents the stored energy of sunlight.

Photosynthetic Energy Transduction III: ATP Synthesis

- The proton motive force across the thylakoid membrane is used to drive ATP synthesis by the CF_0CF_1 complex embedded in the membrane.
- As protons flow back from the lumen to the stroma through the CF_0 proton channel in the membrane, ATP is synthesized by the CF_1 portion of the complex that extends into the stroma.

Photosynthetic Carbon Assimilation I: The Calvin Cycle

- In the stroma, ATP and NADPH are used for the fixation and reduction of carbon dioxide into organic form by enzymes of the Calvin cycle.
- The Calvin cycle involves three main stages: fixation of carbon dioxide by rubisco to form 3-phosphoglycerate, reduction of 3-phosphoglycerate to glyceraldehyde-3-phosphate, and regeneration of ribulose-1,5-bisphosphate, the initial carbon dioxide acceptor.
- The net synthesis of one triose phosphate molecule requires the fixation of three CO_2 molecules and uses nine ATP and six NADPH molecules. For each three CO_2 fixed, one molecule of glyceraldehyde-3-phosphate leaves the cycle to be used for further carbohydrate synthesis.

MAKING CONNECTIONS

In this chapter, we have seen how the transduction of solar energy into chemical energy by phototrophic cells provides the fixed carbon that is crucial to the continued existence of the biological world. Nearly all the energy stored in organic molecules on which chemotrophs depend represents the energy of sunlight, originally trapped within the molecules of organic compounds during photosynthesis. Throughout the rest of our studies, we will see numerous examples of how chemotrophic cells use the energy obtained from these organic com-

Regulation of the Calvin Cycle

- Key enzymes of the Calvin cycle are regulated to ensure maximum efficiency. Several of them are regulated at the level of synthesis, being made only in photosynthetic tissues that are exposed to the light. They are also activated by the high stromal pH and magnesium concentrations that occur in the light.
- Additional means of regulation involve thioredoxin, which senses the redox state of the cell, and rubisco activase, which removes inhibitors from the rubisco active site in the light.

Photosynthetic Carbon Assimilation II: Carbohydrate Synthesis

- The initial product of carbon dioxide fixation is glyceraldehyde-3-phosphate, which can be converted to a second triose phosphate called dihydroxyacetone phosphate. Some of these triose phosphate molecules are used for the biosynthesis of more complex carbohydrates, such as glucose, sucrose, starch, or glycogen. Others are used as sources of energy or carbon skeletons for other metabolic pathways.
- In addition, ATP produced in the chloroplast is used for fatty acid and chlorophyll synthesis and for nitrogen and sulfur reduction and assimilation.

Rubisco's Oxygenase Activity Decreases Photosynthetic Efficiency

- Rubisco can use oxygen as well as CO_2 , resulting in the production of phosphoglycolate, which cannot be used in the Calvin cycle. The glycolate pathway converts two molecules of phosphoglycolate into one molecule of 3-phosphoglycerate, which can enter the Calvin cycle.
- The glycolate pathway involves the chloroplast, the peroxisome, and the mitochondrion. Because CO_2 is released and oxygen is consumed in a light-dependent manner, this process is also called photorespiration.
- In C₄ and CAM plants, carbon dioxide is fixed by a preliminary carboxylation that does not involve rubisco. Then it is decarboxylated under conditions of low oxygen and concentrated CO_2 —either in a different cell type or at a different time of day—conditions that favor rubisco's carboxylase activity.

pounds to carry out vital processes: movement, biosynthesis, transport, and cell division. Keep in mind that all the energy to drive these processes originated in the sun above us, and that life is possible only because photosynthetic organisms are able to fix and reduce carbon dioxide using solar energy to drive a highly endergonic process. Because of the photochemical events that are initiated when light is absorbed by chlorophyll, this remarkable molecule has transformed the biosphere of an entire planet—Earth.

PROBLEM SET

More challenging problems are marked with a •.

11-1 True, False, or Insufficient Information. Indicate whether each of the following statements is true (T), false (F), or does not provide enough information for you to make a decision (I).

- (a) Sucrose is synthesized in the chloroplast stroma and exported from photosynthetic cells to provide energy and reduced carbon for nonphotosynthetic plant cells.
- (b) Ninety percent of the solar energy collected by a photosystem complex is absorbed when photons strike a special pair of chlorophyll molecules at the reaction center of the complex.
- (c) The energy requirement expressed as ATP consumed per molecule of carbon dioxide fixed is higher for a C₃ plant than for a C₄ plant.
- (d) The ultimate electron donor for the photosynthetic generation of NADPH is always water.
- (e) The enzyme rubisco is unusual in that, depending on conditions, it exhibits two different enzymatic activities.

11-2 The *hcef* mutant. Recently, Livingston et al. (*The Plant Cell* 22: 221, 2010) isolated an *Arabidopsis thaliana* mutant with unusually high cyclic electron flow (*hcef*). See if you can predict the results they observed when comparing the *hcef* mutant plants with normal *Arabidopsis* plants.

- (a) How was noncyclic electron flow affected in *hcef* mutant plants?
- (b) What happened to the light-driven proton flux across the thylakoid membrane?
- (c) How was the activity of PSII affected?
- (d) The researchers observed a large increase in the level of fructose-1,6-bisphosphate in the stroma of the *hcef* mutant. What enzyme do you predict is defective?
- (e) What would you predict is the effect on starch synthesis in the stroma?

11-3 The Role of Sucrose. A plant uses solar energy to make ATP and NADPH, which then drive the synthesis of carbohydrates in the leaves. At least one carbohydrate, sucrose, is translocated to nonphotosynthetic parts of the plant (stems, roots, flowers, and fruits) for use as a source of energy. Thus, ATP is used to make sucrose, and the sucrose is then used to make ATP. It would seem simpler for the plant just to make ATP and translocate the ATP itself directly to other parts of the plant, thereby completely eliminating the need for a Calvin cycle, a glycolytic pathway, and a TCA cycle (and making life a lot easier for cell biology students). Suggest at least two major reasons that plants do not manage their energy economies in this way.

11-4 Effects on Photosynthesis. Assume that you have an illuminated suspension of *Chlorella* cells carrying out photosynthesis in the presence of 0.1% carbon dioxide and 20% oxygen. What will be the short-term effects of the following changes in conditions on the levels of 3-phosphoglycerate and ribulose-1,5-bisphosphate? Explain your answer in each case.

- (a) Carbon dioxide concentration is suddenly reduced 1000-fold.
- (b) Light is restricted to green wavelengths (510–550 nm).
- (c) An inhibitor of photosystem II is added.
- (d) Oxygen concentration is reduced from 20% to 1%.

11-5 Energy Flow in Photosynthesis. A portion of the solar energy that arrives at the surface of a leaf is eventually converted to chemical energy and appears in the chemical bonds of carbohydrates that are generally regarded as the end-products of photosynthesis. In between the photons and the carbohydrate molecules, however, the energy exists in a variety of forms. Trace the flow of energy from photon through ATP to starch molecule, assuming the wavelength of light to be in the absorption range of one of the accessory pigments rather than that of chlorophyll.

11-6 The Mint and the Mouse. Joseph Priestley, a British clergyman, was a prominent figure in the early history of research in photosynthesis. In 1771, Priestley wrote these words:

One might have imagined that since common air is necessary to vegetable as well as to animal life, both plants and animals had affected it in the same manner; and I own that I had that expectation when I first put a sprig of mint into a glass jar standing inverted in a vessel of water; but when it had continued growing there for some months, I found that the air would neither extinguish a candle, nor was it at all inconvenient to a mouse which I put into it.

Explain the basis of Priestley's observations, and indicate their relevance to the early understanding of the nature of photosynthesis.

11-7 Photosynthetic Efficiency. On page 312 we estimated the maximum photosynthetic efficiency for the conversion of red light, carbon dioxide, and water to glyceraldehyde. Under laboratory conditions, a photosynthetic organism *might* convert 31% of the light energy striking it to chemical bond energy of organic molecules. In reality, however, photosynthetic efficiency is far lower, closer to 5% or less. Considering a plant growing in a natural environment, suggest four reasons for this discrepancy.

11-8 Chloroplast Structure. Where in a chloroplast are the following substances or processes localized? Be as specific as possible.

- (a) Ferredoxin-NADP⁺ reductase
- (b) Cyclic electron flow
- (c) Starch synthase
- (d) Light-harvesting complex I
- (e) Plastoquinol
- (f) Proton pumping
- (g) P700
- (h) Reduction of 3-phosphoglycerate
- (i) Carotenoid molecules
- (j) Oxygen-evolving complex

11-9 Metabolite Transport Across Membranes. For each of the following metabolites, indicate whether you would expect it to be in steady-state flux across one or more membranes in a photosynthetically active chloroplast and, if so, indicate which membrane(s) the metabolite must cross.

- | | |
|--------------------------------|--------------------|
| (a) CO ₂ | (f) NADPH |
| (b) P _i | (g) ATP |
| (c) Electrons | (h) O ₂ |
| (d) Starch | (i) Protons |
| (e) Glyceraldehyde-3-phosphate | (j) Pyruvate |

11-10 Crassulacean Acid Metabolism. A CAM plant uses a pathway very similar to the Hatch–Slack cycle for preliminary carbon dioxide fixation. Trace the flow of carbon from the atmosphere to glyceraldehyde-3-phosphate within a CAM plant. How does this minimize water loss by such plants?

11-11 The Endosymbiont Theory. The endosymbiont theory suggests that mitochondria and chloroplasts evolved from ancient bacteria that were ingested by primitive nucleated cells. Biologists have proposed that endosymbiosis led to the evolution of other cellular structures, such as flagella and peroxisomes, as well. Over hundreds of millions of years, the ingested bacteria lost features not essential for survival inside the host cell.

(a) Based on what you have learned about the membrane systems of organelles, for each of the membrane systems found in mitochondria (two systems) and chloroplasts

(three systems), indicate whether it most likely arose from an ingested bacterium or from the nucleated host. Explain your reasoning.

- (b) Describe one structure or metabolic process that purple bacteria might have dispensed with once they became endosymbionts in a eukaryotic cell. How would loss of this feature prevent the bacteria from living outside the host?
- (c) Describe one structure or metabolic process that cyanobacteria might have dispensed with once they became endosymbionts in a eukaryotic cell. How would loss of this feature prevent the bacteria from living outside the host?
- (d) Peroxisomes, unlike mitochondria or chloroplasts, scarcely resemble free-living organisms. Assuming peroxisomes evolved from ingested bacteria, describe three features mitochondria retain but peroxisomes apparently lost over hundreds of millions of years. Describe one advantage peroxisomes might have conferred on ancient nucleated cells.

The Endomembrane System and Peroxisomes

A full appreciation of eukaryotic cells depends on an understanding of the prominent role of intracellular membranes and the compartmentalization of function within organelles—intracellular membrane-bounded compartments that house various cellular activities. Whether we consider the storage and transcription of genetic information, the biosynthesis of secretory proteins, the breakdown of long-chain fatty acids, or any of the numerous other metabolic processes occurring within eukaryotic cells, many of the reactions of a particular pathway occur within a distinct type of organelle. Also, the movement of molecules between organelles, known as trafficking, must be tightly regulated to ensure that each organelle has the correct components for its proper structure and function.

We briefly encountered the major organelles found in eukaryotic cells in Chapter 4, and we then learned more about the mitochondrion and chloroplast in Chapters 10 and 11, respectively. We are now ready to consider several other individual organelles in more detail. We will begin with the rough endoplasmic reticulum, the smooth endoplasmic reticulum, and the Golgi complex, which are sites for protein synthesis, processing, and sorting. Next, we will look at endosomes, organelles that are important for carrying and sorting material brought into the cell. Endosomes help to form lysosomes, which are organelles responsible for digestion of both ingested material and unneeded intracellular components. We will conclude with a look at peroxisomes, which house hydrogen peroxide-generating reactions and perform diverse metabolic functions.

As you study the role of each organelle, keep in mind that the endoplasmic reticulum, the Golgi complex, endosomes, and lysosomes (but not peroxisomes) comprise the **endomembrane system** of the eukaryotic cell, as shown in **Figure 12-1**. (The nuclear envelope, which we will study in Chapter 18, is closely associated with the endomembrane system.) Material flows from the endoplasmic reticulum to and from the Golgi complex, endosomes, and lysosomes by

means of transport vesicles that shuttle between the various organelles. These transport vesicles carry membrane lipids and membrane-bound proteins to their proper destinations in the cell, and they also carry soluble materials destined for secretion. Thus, these organelles and the vesicles connecting them make up a single dynamic system of membranes and internal spaces. Currently, one of the most exciting questions in modern cell biology concerns endomembrane trafficking: How does each of the multitude of proteins and lipids in a cell manage to reach its proper destination at the proper time?

The Endoplasmic Reticulum

The **endoplasmic reticulum (ER)** is a continuous network of flattened sacs, tubules, and associated vesicles that stretches throughout the cytoplasm of the eukaryotic cell. Although the name sounds formidable, it is actually quite descriptive. *Endoplasmic* simply means “within the (cyto)plasm,” and *reticulum* is a Latin word meaning “network.” The membrane-bounded sacs are called **ER cisternae** (singular: **ER cisterna**), and the space enclosed by them is called the **ER lumen** (Figure 12-1). Of the total membrane in a mammalian cell, up to 50–90% surrounds the ER lumen. Unlike more prominent organelles, such as the mitochondrion or chloroplast, however, the ER is not visible by light microscopy unless one or more of its components are stained with a dye or labeled with a fluorescent molecule.

The ER was first observed in the late nineteenth century, when it was noted that some eukaryotic cells, particularly those involved in secretion, contained regions that stained intensely with basic dyes. The significance of these regions remained in doubt until the 1950s, when the resolving power of the electron microscope was improved dramatically. This allowed cell biologists to visualize for the first time the ER’s elaborate network of intracellular membranes and to investigate the role of the ER in cellular processes. This is a common

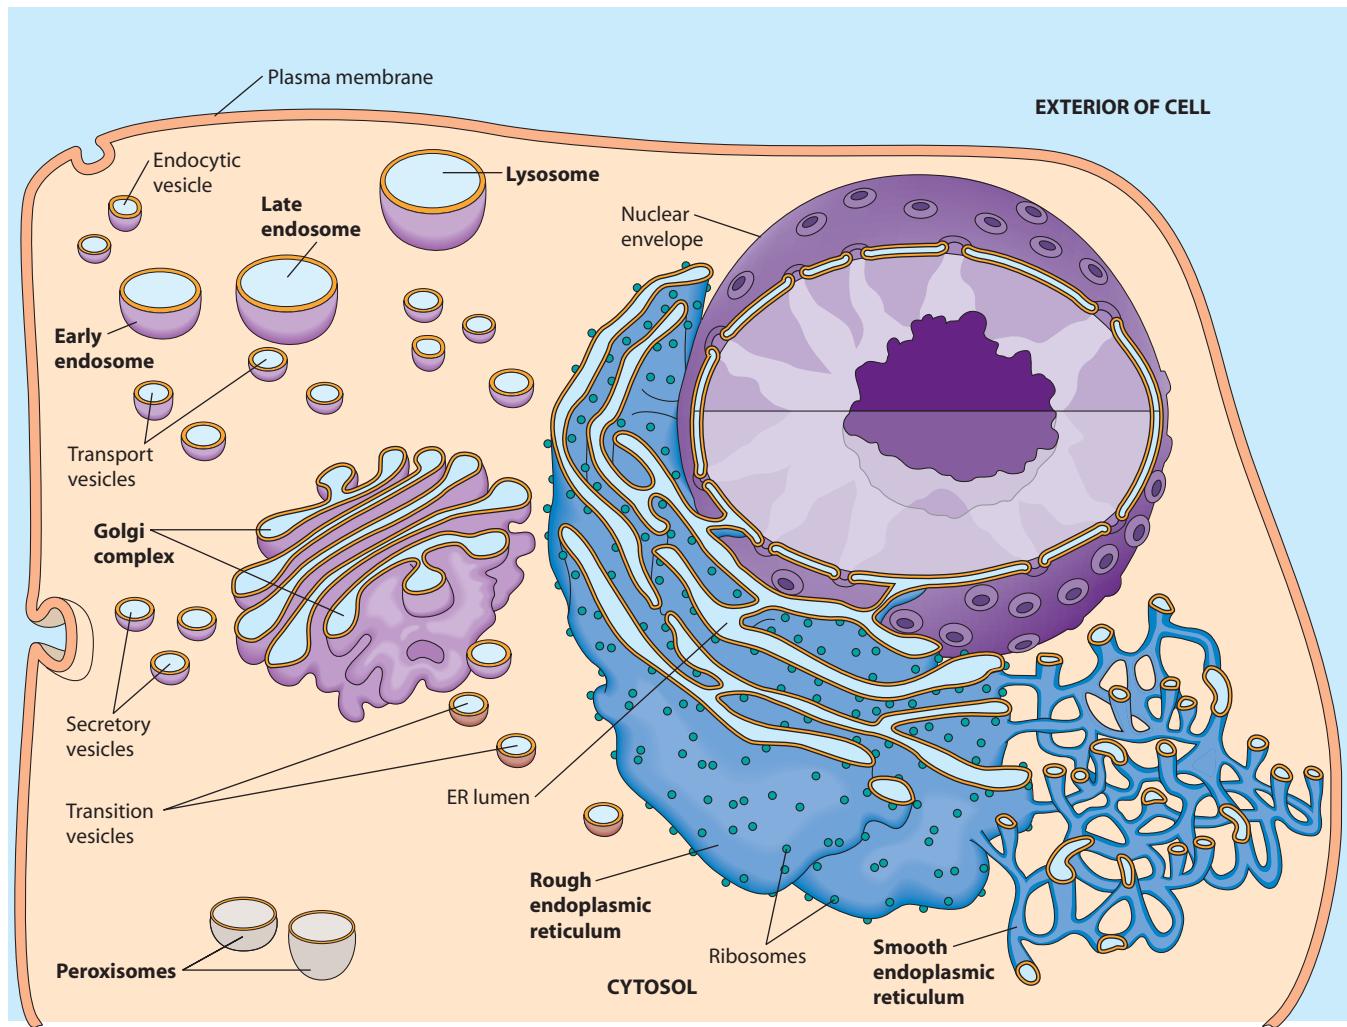

FIGURE 12-1 The Endomembrane System. The endomembrane system of the eukaryotic cell consists of the endoplasmic reticulum (ER), the Golgi complex, endosomes, and lysosomes (but not peroxisomes). It is associated with both the nuclear envelope and the plasma membrane. The ER lumen is linked to the interiors of the Golgi complex, endosomes, and lysosomes by transport vesicles that shuttle material between organelles, as well as to and from the plasma membrane.

theme in scientific discovery—conceptual advances in one field often follow technological advances in a related (or even an unrelated) field.

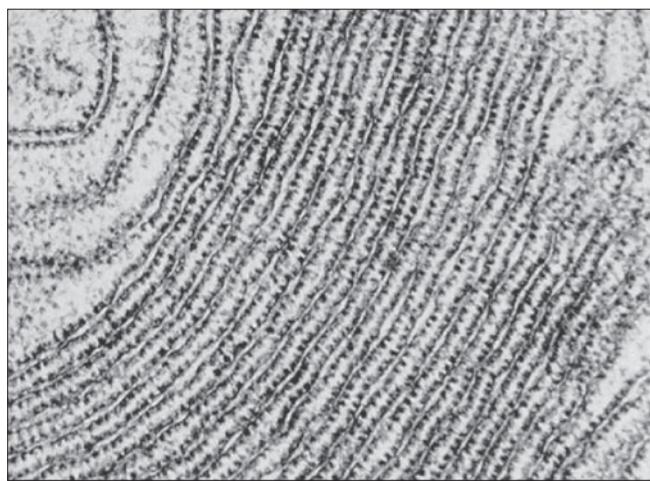

We now know that enzymes associated with the ER are responsible for the biosynthesis of proteins destined for incorporation into the plasma membrane or into organelles of the endomembrane system and for synthesis of proteins destined for export from the cell. The ER also plays a central role in the biosynthesis of lipids, including triacylglycerols, cholesterol, and related compounds. The ER is the source of most of the lipids that are assembled to form intracellular membranes and the plasma membrane.

The Two Basic Kinds of Endoplasmic Reticulum Differ in Structure and Function

The two basic kinds of endoplasmic reticulum typically found in eukaryotic cells are distinguished from one

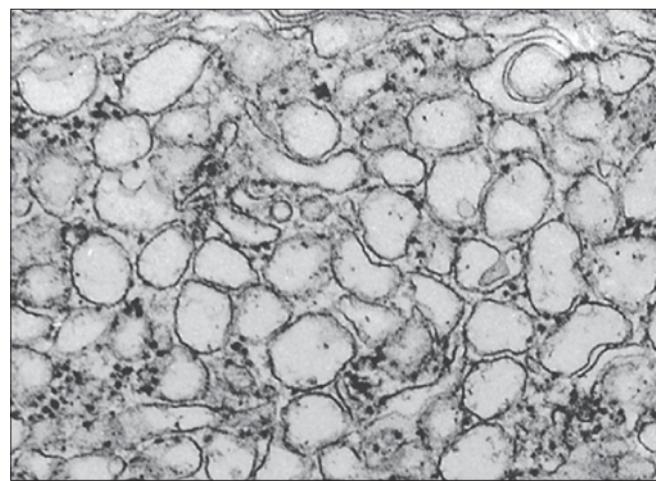

another by the presence or absence of ribosomes attached to the ER membrane (**Figure 12-2**). **Rough endoplasmic reticulum (rough ER)** is characterized by ribosomes attached to the cytosolic side of the membrane (the side that faces away from the ER lumen; Figure 12-2a). Translation by these ribosomes occurs in the cytosol, but the newly-synthesized proteins will enter the ER lumen shortly. Because ribosomes contain RNA, it was this RNA that reacted strongly with the basic dyes originally used to identify the rough ER. A subdomain of rough ER, the **transitional elements (TEs)**, plays an important role in the formation of **transition vesicles** that shuttle lipids and proteins from the ER to the Golgi complex. In contrast, **smooth endoplasmic reticulum (smooth ER)** appears smooth due to the absence of ribosomes attached to the membrane (Figure 12-2b) and has other roles in the cell.

Rough and smooth ER are easily distinguished morphologically. As illustrated in Figure 12-1, rough ER

(a) Rough endoplasmic reticulum

0.25 μm

(b) Smooth endoplasmic reticulum

0.25 μm

FIGURE 12-2 Rough and Smooth Endoplasmic Reticulum. (a) Electron micrograph of endoplasmic reticulum. The rough ER is studded with ribosomes. (b) Electron micrograph of smooth endoplasmic reticulum. The dark spots near the smooth ER appear to be glycogen granules (TEMs).

membranes usually form large flattened sheets, whereas smooth ER membranes generally form tubular structures. The transitional elements of the rough ER are an exception to this rule; they often resemble smooth ER. However, the rough and smooth ER are not separate organelles—electron micrographs and studies in living cells show that their luminal spaces are continuous. Thus, material can travel between the rough and smooth ER without the aid of vesicles.

Both types of ER are present in most eukaryotic cells, but there is considerable variation in the relative amounts of each type, depending on the activities of the particular cell. Cells involved in the biosynthesis of secretory proteins, such as liver cells and cells producing digestive enzymes, tend to have very prominent rough ER networks. On the other hand, cells producing steroid hormones, such as in the testis or ovary, contain extensive networks of smooth ER.

When tissue is homogenized for subcellular fractionation, the ER membranes often break into smaller fragments that spontaneously close to form sealed vesicles known as **microsomes**. Fractions can be isolated with and without attached ribosomes, depending on whether the membrane originated from rough or smooth ER, respectively. Such preparations are tremendously useful for exploring both types of ER. Keep in mind, however, that microsomes do not exist in the cell; they are simply an artifact of the fractionation process. **Box 12A** presents more detailed information about subcellular fractionation by differential centrifugation.

Rough ER Is Involved in the Biosynthesis and Processing of Proteins

The ribosomes attached to the cytosolic side of the rough ER membrane are responsible for synthesizing both membrane-bound and soluble proteins for the endomembrane system. So how do proteins enter the ER lumen and

the endomembrane system from their site of synthesis on the opposite (cytosolic) side of the rough ER membrane? Synthesis of proteins destined for the endomembrane system begins on cytoplasmic ribosomes, which attach to the rough ER via receptor proteins in the ER membrane shortly after translation initiation. Newly-synthesized proteins enter the endomembrane system *cotranslationally*—that is, they are inserted through a pore complex in the ER membrane into the rough ER lumen as the polypeptide is synthesized by the ER-bound ribosome (see Figure 22-16). After biosynthesis, membrane-spanning proteins remain anchored to the ER membrane either by hydrophobic regions of the polypeptide or by covalent attachment to membrane lipids. Soluble proteins, including secretory proteins, are released into the ER lumen.

In addition to its role in the biosynthesis of polypeptide chains, the rough ER is the site for several other processes, including the initial steps of addition and processing of carbohydrate groups to glycoproteins, the folding of polypeptides, the recognition and removal of misfolded polypeptides, and the assembly of multimeric proteins. Thus, ER-specific proteins include a host of enzymes that catalyze cotranslational and posttranslational modifications. These modifications include glycosylation, which is important for sorting of proteins to their proper destinations, and disulfide bond formation, which is essential for proper protein folding. We will discuss the topics of protein biosynthesis, targeting, and folding in more detail in Chapter 22.

The ER is also a site for quality control. In *ER-associated degradation (ERAD)*, proteins improperly modified, folded, or assembled are exported from the ER for degradation by cytosolic *proteasomes* before they can move on to the Golgi complex. Several human diseases, including cystic fibrosis and familial hypercholesterolemia, are associated with defects in these processes.

Centrifugation: An Indispensable Technique of Cell Biology

Centrifugation is a procedure used for the isolation and purification of organelles and macromolecules. This method is based on the fact that when a particle is subjected to centrifugal force by spinning a cellular extract at extremely rapid rates in a laboratory centrifuge, the rate of movement of the particle through a specific solution depends on its size and density, as well as the solution's density and viscosity. The larger or denser a particle is, the higher its **sedimentation rate**, or rate of movement through the solution. Centrifugation is used routinely in labs throughout the world to separate dissolved molecules from cell debris in suspensions of broken cells, to collect precipitated macromolecules such as DNA and proteins from cell suspensions, and to separate different cellular components based on their sedimentation rate.

Because most organelles and macromolecules differ significantly from one another in size and/or density, centrifuging a mixture of cellular components will separate the faster-moving components from the slower-moving ones. This procedure, called **subcellular fractionation**, enables researchers to isolate and purify specific organelles and macromolecules for further manipulation and study *in vitro*.

Albert Claude, George Palade, and Christian de Duve shared a Nobel Prize in 1974 for their pioneering work in centrifugation and subcellular fractionation. Claude played a key role in developing differential centrifugation as a method of isolating organelles. Palade was quick to use this technique in studies of the endoplasmic reticulum and the Golgi complex, establishing the roles of these organelles in the biosynthesis, processing, and secretion of proteins (see Figure 12-10). De Duve, in turn, used centrifugation in his discovery of two entirely new organelles—lysosomes and peroxisomes.

Centrifugation is also routinely used for isolating and purifying DNA and proteins. Following cell lysis, insoluble cell debris and organelles are removed by centrifugation, and the soluble cytoplasmic portion containing the DNA or protein is recovered. Treatment with the appropriate precipitating agent makes the DNA or protein insoluble so that it can be isolated in a second round of centrifugation.

Centrifuges and Sample Preparation

In essence, a **centrifuge** consists of a rotor—often housed in a refrigerated chamber—spun extremely rapidly by an electric motor. The rotor holds tubes containing solutions or suspensions of particles for fractionation. Centrifugation at very high speeds—above 20,000 revolutions per minute (rpm)—requires an **ultracentrifuge** equipped with a vacuum system to reduce friction between the rotor and air. Some ultracentrifuges reach speeds over 100,000 rpm, subjecting samples to forces exceeding 500,000 times the force of gravity (g).

Tissues must first undergo **homogenization**, or disruption, before the cellular components can be separated by centrifugation. To preserve the integrity of organelles, homogenization is usually done in a cold isotonic solution such as 0.25 M sucrose. Disruption can be achieved by grinding tissue in a mortar and pestle, by forcing cells through a narrow orifice (French press) or by subjecting tissue to ultrasonic vibration, osmotic shock, or enzymatic digestion. The resulting **homogenate** is a suspension of organelles, smaller cellular components, membranes, and molecules. If tissue is homogenized gently enough, most organelles and other structures remain intact and retain their original biochemical properties.

Differential Centrifugation

Differential centrifugation separates organelles based on their size and/or density differences. As illustrated in **Figure 12A-1**, particles that are large or dense (purple spheres) sediment rapidly, those that are intermediate in size or density (blue spheres) sediment less rapidly, and the smallest or least dense particles (black spheres) sediment very slowly.

We can express the relative size and/or density of an organelle or macromolecule in terms of its **sedimentation coefficient**, a measure of how rapidly the particle sediments when subjected to centrifugation. Sedimentation coefficients are expressed in **Svedberg units (S)**, in honor of Theodor Svedberg, the Swedish chemist who developed the ultracentrifuge between 1920 and

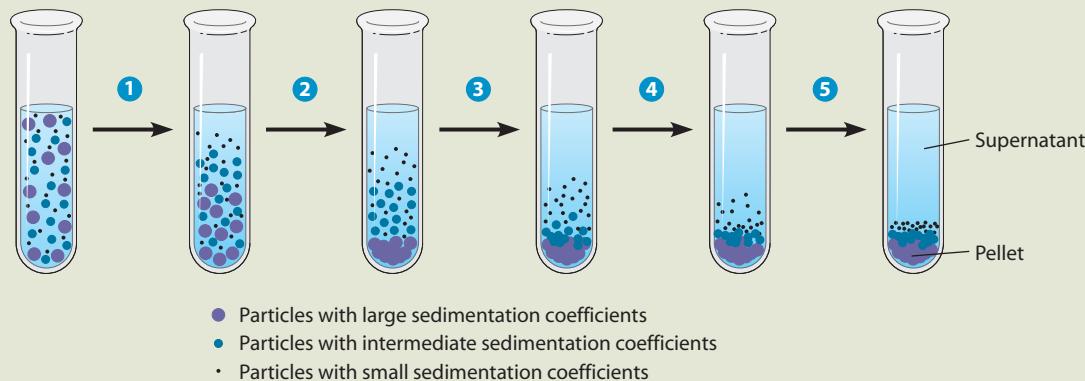

FIGURE 12A-1 Differential Centrifugation. Differential centrifugation separates particles based on differences in sedimentation rate, which reflect differences in size and/or density. The technique is illustrated here for three particles that differ significantly in size. The particles, which are initially part of a homogeneous mixture, are subjected to a fixed centrifugal force for five successive time intervals (circled numbers). Particles that are large or dense (purple spheres) sediment rapidly, those that are intermediate in size or density (blue spheres) sediment less rapidly, and the smallest or least dense particles (black spheres) sediment very slowly. Eventually, all of the particles reach the bottom of the tube, unless the process is interrupted after a specific length of time.

1940. The sedimentation coefficients of some organelles, macromolecules, and viruses are shown in **Figure 12A-2**.

An example of differential centrifugation is illustrated in **Figure 12A-3**. The tissue of interest is first homogenized (step 1). Subcellular fractions are then isolated by subjecting the homogenate and subsequent supernatant fractions to successively higher centrifugal forces and longer centrifugation times (steps 2–5). The **supernatant** is the clarified suspension of homogenate that remains after particles of a given size and density are removed as a **pellet** following each step of the centrifugation process. In each case, the supernatant from one step can be poured off into a new centrifuge tube and then returned to the centrifuge and subjected to greater centrifugal force to obtain the next pellet. In successive steps, the pellets are enriched in nuclei, unbroken cells, and debris (step 2); mitochondria, lysosomes, and peroxisomes (step 3); ER and other membrane fragments (step 4); and free ribosomes and large macromolecules (step 5). The material in each pellet can be resuspended and used for electron microscopy or biochemical studies. The final supernatant consists mainly of soluble cellular components such as DNA and protein.

Each fraction obtained in this way is enriched for the respective organelles but is also likely contaminated with other organelles and cellular components. Often, most of the contaminants in a pellet can be removed by resuspending the pellet in an isotonic solution and repeating the centrifugation procedure.

Density Gradient Centrifugation

In the previous example of differential centrifugation, the particles about to be separated were uniformly distributed throughout the

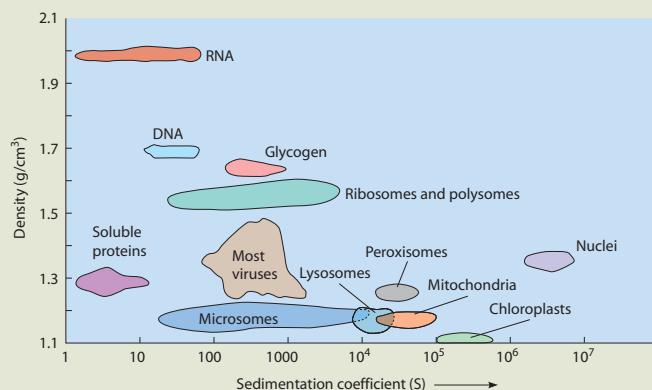

FIGURE 12A-2 Sedimentation Coefficients and Densities of Organelles, Macromolecules, and Viruses. A particle's sedimentation coefficient, expressed in Svedberg units (S), indicates how rapidly it sediments when subjected to a centrifugal force. A higher S value represents more rapid sedimentation. A particle's density (expressed in g/cm³) determines how far it will move during equilibrium density centrifugation.

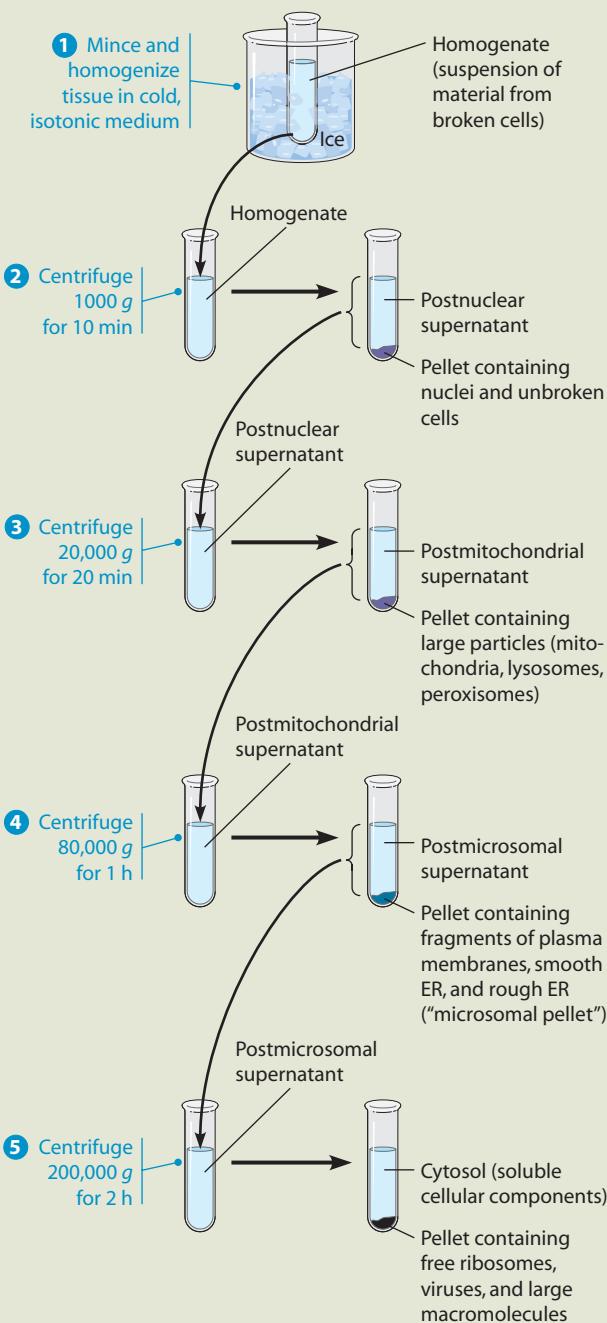

FIGURE 12A-3 Differential Centrifugation and the Isolation of Organelles. To isolate specific cellular components, homogenized tissue is subjected to a series of centrifugation steps. Each step uses the supernatant from the previous step, and subjects it to a higher g force for a longer time.

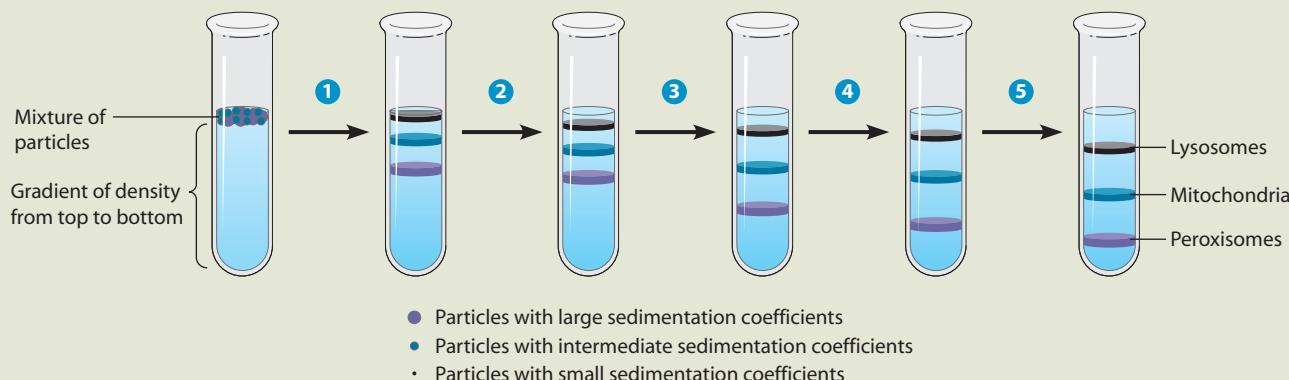

FIGURE 12A-4 Density Gradient Centrifugation. Density gradient centrifugation, like differential centrifugation (see Figure 12A-1), is a technique for separating particles such as organelles based on differences in sedimentation rate. For this centrifugation method, however, the sample for fractionation is placed as a thin layer on top of a gradient of solute that increases in density from the top of the tube to the bottom. The effect is illustrated here for three organelles that differ significantly in size and/or density. Subjected to a fixed centrifugal force for five successive time intervals (circled numbers), the organelles migrate through the gradient as distinct bands.

solution prior to centrifugation. **Density gradient (or rate-zonal) centrifugation** is a variation of differential centrifugation in which the sample for fractionation is placed as a thin layer on top of a *gradient of solute*. The gradient consists of an increasing concentration of solute—and therefore density—from the top of the tube to the bottom. When subjected to a centrifugal force, particles differing in size and/or density move downward as discrete zones, or bands, that migrate at different rates. Due to the gradient of solute in the tube, the particles at the leading edge of each zone continually encounter a slightly denser solution and are thus slightly impeded. As a result, each zone remains very compact, maximizing the ability to separate different particles.

This process is illustrated in **Figure 12A-4**. Particles that are large or dense (purple) move into the gradient as a rapidly sedimenting band, particles that are intermediate in size or density (blue) sediment less rapidly, and the smallest particles (black) move quite slowly. The centrifuge is stopped after the bands of interest have moved far enough into the gradient to be resolved from each other but *before* any of the bands reach the bottom of the tube. Stopping at this point is essential because all of the particles are denser than the solution in the tube, even at the very bottom of the tube. If centrifugation continues too long, the bands will reach the bottom of the tube one after another, piling up and negating the very purpose of the process.

Density gradient centrifugation can be used to separate lysosomes, mitochondria, and peroxisomes, each of which has a slightly different density. The tissue of interest is first homogenized, and a pellet enriched in these organelles is layered over a gradient of solute that increases in concentration and density from the top of

a tube to the bottom. As shown in Figure 12A-4, the dense peroxisomes move into the gradient as a rapidly sedimenting band. The mitochondria, having intermediate density, form a band above the peroxisomes. The lysosomes are the smallest and least dense and form a band nearer the top of the tube. By assaying each fraction for marker enzymes that are unique to each organelle, the fractions containing these organelles can be identified and the extent of cross-contamination can be determined.

Equilibrium Density Centrifugation

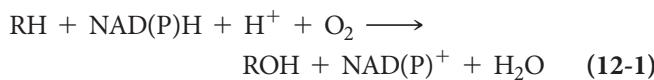

Equilibrium density (or buoyant density) centrifugation is a related method for resolving organelles and macromolecules based on density differences (see Figure 12A-2). Like density gradient centrifugation, this procedure includes a gradient of solute that increases in concentration and density, but in this case the solute is concentrated so that the density gradient spans the range of densities of the organelles or macromolecules about to be separated. Therefore, the material to be purified does not move to the bottom of the tube during centrifugation but instead forms a tight band in a stable equilibrium position where its density is exactly equal to the density of the gradient at that position.

For organelle separation using equilibrium density centrifugation, a gradient of sucrose is often used, and the density range is $1.10\text{--}1.30\text{ g/cm}^3$ ($0.75\text{--}2.3\text{ M}$ sucrose). This method can also be used to separate different forms of DNA and RNA based on their differing densities. It was used to determine the mechanism of replication of DNA in the classic experiments of Meselson and Stahl (see Figure 19-3).

Smooth ER Is Involved in Drug Detoxification, Carbohydrate Metabolism, Calcium Storage, and Steroid Biosynthesis

Drug Detoxification. Drug detoxification often involves enzyme-catalyzed **hydroxylation** because the addition of hydroxyl groups to hydrophobic drugs makes them more soluble and easier to excrete from the body. Hydroxylation of organic acceptor molecules is typically catalyzed by a member of the **cytochrome P-450** family of proteins. These proteins are especially prevalent in the smooth ER of hepatocytes (liver cells), in which many drugs are detoxified.

In the hepatocytes, an electron transport system transfers electrons from NADPH or NADH to a heme group in a cytochrome P-450 protein, which then donates an electron to molecular oxygen. One atom of molecular oxygen gains two electrons and two H⁺, forming H₂O. The other oxygen atom is added to the organic substrate molecule as part of a hydroxyl group. Because one of the two oxygen atoms of O₂ is incorporated into the reaction product, these cytochrome P-450 enzymes are often called *monooxygenases*. The net reaction is shown below, where R represents the organic hydroxyl acceptor:

The elimination of hydrophobic barbiturate drugs, for example, is enhanced by hydroxylation enzymes in the smooth ER. Injection of the sedative phenobarbital into a rat causes a rapid increase in the level of barbiturate-detoxifying enzymes in the liver, accompanied by a dramatic proliferation of smooth ER. However, this means that increasingly higher doses of the drug are necessary to achieve the same sedative effect, an effect known as *tolerance* that is seen in habitual users of phenobarbital. Furthermore, the enzyme induced by phenobarbital can hydroxylate and therefore solubilize a variety of other drugs, including such useful agents as antibiotics, anticoagulants, and steroids. As a result, the chronic use of barbiturates decreases the effectiveness of many other clinically useful drugs.

Another cytochrome P-450 protein found in the smooth ER is part of an enzyme complex called *aryl hydrocarbon hydroxylase*. This complex is involved in metabolizing *polycyclic hydrocarbons*, organic molecules composed of two or more linked benzene rings that are often toxic. Hydroxylation of such molecules is important for increasing their solubility in water, but the oxidized products are often more toxic than the original compounds. Aryl hydrocarbon hydroxylase converts some potential carcinogens into their chemically active forms. Mice synthesizing high levels of this hydroxylase have a higher incidence of spontaneous cancer than normal mice do, whereas mice treated with an inhibitor of aryl hydrocarbon hydroxylase develop few tumors. Significantly, cigarette smoke is a potent inducer of aryl hydrocarbon hydroxylase.

Recent work shows that differences in activities and side effects of certain medications can result from differences in the presence or activity of particular cytochrome P-450 genes in different patients. This has led to a new field of study known as **pharmacogenetics** (also called *pharmacogenomics*), which investigates how inherited differences in genes (and their resulting protein products) can lead to differential responses to drugs and medications.

Carbohydrate Metabolism. The smooth ER of hepatocytes (liver cells) is also involved in the enzymatic breakdown of stored glycogen, as evidenced by the presence of *glucose-6-phosphatase*, a membrane-bound enzyme that is unique to the ER. Thus, its presence is used as a marker to identify the ER during subcellular fractionation or to visualize the ER using fluorescent antibodies. Glucose-6-phosphatase hydrolyzes the phosphate group from glucose-6-phosphate to form free glucose and inorganic phosphate (P_i):

This enzyme is abundant in the liver because a major role of the liver is to keep the level of glucose in the blood relatively constant. The liver stores glucose as glycogen in granules associated with smooth ER (**Figure 12-3a**). When glucose is needed by the body, especially between meals and in response to increased muscular activity, liver glycogen is broken down by phosphorolysis (see Figure 9-10), producing glucose-6-phosphate (Figure 12-3b). Because membranes are generally impermeable to phosphorylated sugars, the glucose-6-phosphate must be converted to free glucose by glucose-6-phosphatase in order to leave the cell and enter the bloodstream. Free glucose then leaves the liver cell via a glucose transporter (GLUT2) and moves into the blood for transport to other cells that need energy. Significantly, glucose-6-phosphatase activity is present in liver, kidney, and intestinal cells but not in muscle or brain cells. Muscle and brain cells retain glucose-6-phosphate and use it to meet their own substantial energy needs.

Calcium Storage. The *sarcoplasmic reticulum* found in muscle cells is an example of smooth ER that specializes in the storage of calcium. In these cells, the ER lumen contains high concentrations of calcium-binding proteins. Calcium ions are pumped into the ER by *ATP-dependent calcium ATPases* and are released in response to extracellular signals to aid in muscle contraction (see Figure 14-12). Binding of neurotransmitter molecules to receptors on the surface of the muscle cell triggers a signal cascade that leads to the release of calcium from the sarcoplasmic reticulum and causes the contraction of muscle fibers. We will discuss nerve impulse transmission and muscle contraction in more detail in Chapters 13 and 16.

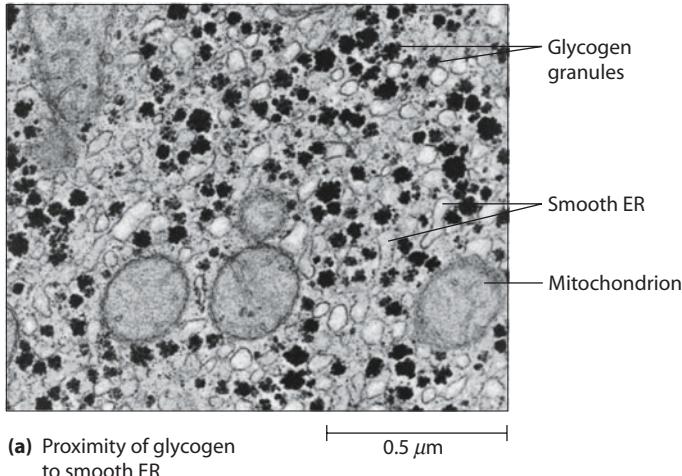

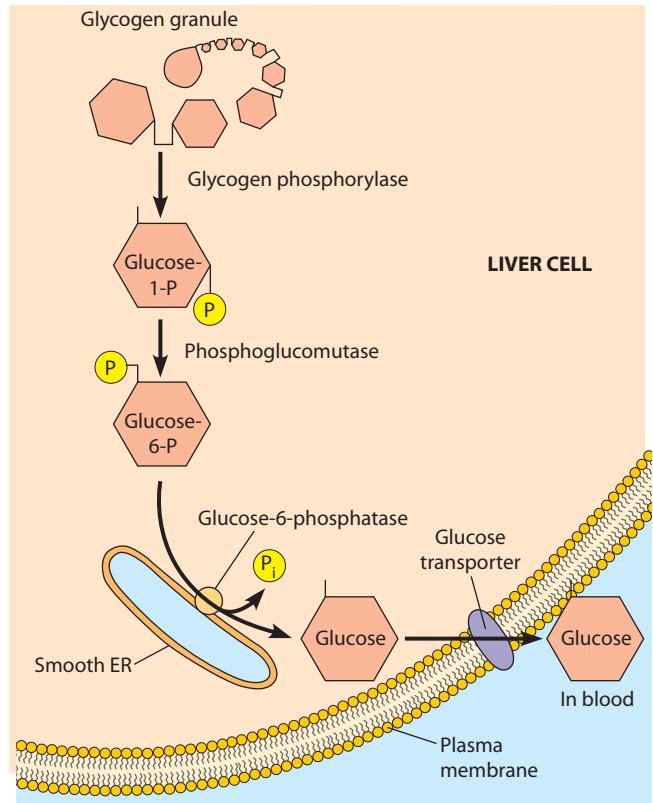

FIGURE 12-3 The Role of the Smooth ER in the Catabolism of Liver Glycogen. (a) This electron micrograph of a monkey liver cell shows numerous granules of glycogen closely associated with smooth ER (TEM). (b) The breakdown of liver glycogen involves the stepwise removal of glucose units as glucose-1-phosphate, followed by the conversion of glucose-1-phosphate to glucose-6-phosphate by enzymes in the cytosol. Removal of the phosphate group depends on glucose-6-phosphatase, an enzyme associated with the smooth ER membrane. Free glucose is then transported out of the liver cell into the blood by a glucose transporter in the plasma membrane.

Steroid Biosynthesis. The smooth ER in certain cells is the site of biosynthesis of cholesterol and steroid hormones such as cortisol, testosterone, and estrogen. Large amounts of smooth ER are found in the cortisol-producing cells of the adrenal gland; the Leydig cells of the testes, which produce testosterone; the cholesterol-producing cells of the liver; and the follicular cells of the ovary, which produce estrogen. Smooth ER has also been found in close association with plastids in some plants, where it may be involved in phytohormone synthesis.

Cholesterol, cortisol, and the male and female steroid hormones just described share a common four-ring structure but differ in the number and arrangement of carbon side chains and hydroxyl groups (see Figure 3-27e and Figure 3-30). *Hydroxymethylglutaryl-CoA reductase* (*HMG-CoA reductase*), the committed step in cholesterol biosynthesis, is present in large amounts in the smooth ER of liver cells. This enzyme is targeted for inhibition by a class of cholesterol-lowering drugs known as *statins*. In addition, the smooth ER contains a number of P-450 monooxygenases that are important not only in the synthesis of cholesterol but also in its conversion into steroid hormones by hydroxylation.

The ER Plays a Central Role in the Biosynthesis of Membranes

In eukaryotic cells, the ER is the primary source of membrane lipids, including phospholipids and cholesterol. Indeed, most of the enzymes required for the biosynthesis of

(b) Process of glycogen breakdown in liver
membrane phospholipids are found nowhere else in the cell. There are, however, important exceptions. Mitochondria synthesize phosphatidylethanolamine by decarboxylating imported phosphatidylserine. Peroxisomes have enzymes to synthesize cholesterol, and chloroplasts contain enzymes for the synthesis of chloroplast-specific lipids.

Biosynthesis of fatty acids for membrane phospholipid molecules occurs in the cytoplasm and incorporation is restricted to the monolayer of the ER membrane facing the cytosol. Cellular membranes, of course, are phospholipid *bilayers*, with phospholipids distributed to both sides. Thus, there must be a mechanism for transferring phospholipids from one layer of the membrane to the other. Because it is thermodynamically unfavorable for phospholipids to flip spontaneously at a significant rate from one side of a bilayer to the other, transfer depends on **phospholipid translocators**, also called **flippases**, which catalyze the translocation of phospholipids through ER membranes (see Figure 7-10).

Phospholipid translocators, like other enzymes, are quite specific and affect only the rate of a process. Therefore, the type of phospholipid molecules transferred across a membrane depends on the particular translocators present, contributing to the *membrane asymmetry* described in Chapter 7. For example, the ER membrane contains a translocator for phosphatidylcholine, and thus it is found in both monolayers of the ER membrane. In contrast, there is no translocator for phosphatidylethanolamine, phosphatidylinositol, or phosphatidylserine, which are therefore confined to the cytosolic monolayer. When vesicles from the ER membrane fuse with other organelles of the

Table 12-1**Composition of the ER and Plasma Membranes of Rat Liver Cells**

Membrane Components	ER Membrane	Plasma Membrane

endomembrane system, the distinct compositions of the cytosolic and luminal monolayers established in the ER are transferred to these other cellular membranes.

Movement of phospholipids from the ER to a mitochondrion, chloroplast, or peroxisome poses a unique problem. Unlike organelles of the endomembrane system, these organelles do not grow by fusion with ER-derived vesicles. Instead, cytosolic **phospholipid exchange proteins** (also called *phospholipid transfer proteins*) convey phospholipid molecules from the ER membrane to the outer mitochondrial and chloroplast membranes. Each exchange protein recognizes a specific phospholipid, removes it from one membrane, and carries it through the cytosol to another membrane. Such transfer proteins also contribute to the movement of phospholipids from the ER to other cellular membranes, including the plasma membrane.

Although the ER is the source of most membrane lipids, the compositions of other cellular membranes vary significantly from the composition of the ER membrane (**Table 12-1**). A striking feature of the plasma membrane of hepatocytes is the relatively low amount of phosphoglycerides and high amounts of cholesterol, sphingomyelin, and glycolipids. Researchers have observed an increasing gradient of cholesterol content from the ER through the compartments of the endomembrane system to the plasma membrane. This correlates with an increasing gradient of membrane thickness. ER membranes are about 5 nm thick, whereas plasma membranes are about 8 nm thick. The observed change in membrane thickness has implications for sorting and targeting integral membrane proteins, which we will discuss after we look at the Golgi complex and its role in protein processing.

The Golgi Complex

We now turn our attention to the Golgi complex, a component of the endomembrane system that is closely linked, both physically and functionally, to the ER. In the Golgi

complex, glycoproteins from the ER undergo further processing and, along with membrane lipids, are sorted and packaged for transport to their proper destinations inside or outside the cell. Thus, the Golgi complex plays a central role in *membrane* and *protein trafficking* in eukaryotic cells.

The **Golgi complex** (or *Golgi apparatus*) derives its name from Camillo Golgi, the Italian biologist who first described it in 1898. He reported that nerve cells soaked in osmium tetroxide showed deposits of osmium in a thread-like network surrounding the nucleus. The same staining reaction was demonstrated with a variety of cell types and other heavy metals. However, no cellular structure could be identified that explained the staining. As a result, the nature—actually, the very existence—of the Golgi complex remained controversial until the 1950s, when its existence was finally confirmed by electron microscopy.

The Golgi Complex Consists of a Series of Membrane-Bounded Cisternae

The Golgi complex is a series of flattened membrane-bounded *cisternae*, disk-shaped sacs that are stacked together as illustrated in **Figure 12-4a**. A series of such cisternae is called a *Golgi stack* and can be visualized by electron microscopy (Figure 12-4b). Usually, there are 3–8 cisternae per stack, though the number and size of Golgi stacks vary with the cell type and with the metabolic activity of the cell. Some cells have one large stack, whereas others—especially active secretory cells—have hundreds or even thousands of Golgi stacks.

The static view of the ER and the Golgi complex presented by electron micrographs such as Figure 12-4b can be misleading. These organelles are actually dynamic structures. Both the ER and Golgi complex are typically surrounded by numerous *transport vesicles* that carry lipids and proteins from the ER to the Golgi complex, between the cisternae of a Golgi stack, and from the Golgi complex to various destinations in the cell, including endosomes, lysosomes, and secretory granules. Thus, the Golgi complex lumen, or *intracisternal space*, is part of the endomembrane system's network of internal spaces (see Figure 12-1).

The Two Faces of the Golgi Stack. Each Golgi stack has two distinct sides, or *faces* (Figure 12-4). The *cis face* is oriented toward the ER. The Golgi compartment closest to the ER is a network of flattened, membrane-bounded tubules referred to as the **cis-Golgi network (CGN)**. Vesicles containing newly synthesized lipids and proteins from the ER continuously arrive at the CGN, where they fuse with CGN membranes. The opposite side of the Golgi complex is called the *trans face*. The compartment on this side of the Golgi complex has similar morphology and is referred to as the **trans-Golgi network (TGN)**. Here, proteins and lipids leave the Golgi in *transport vesicles* that continuously bud from the tips of TGN cisternae. These transport vesicles carry lipids and proteins from the Golgi complex to secretory granules, endosomes, lysosomes, and the plasma membrane. The central sacs between the CGN

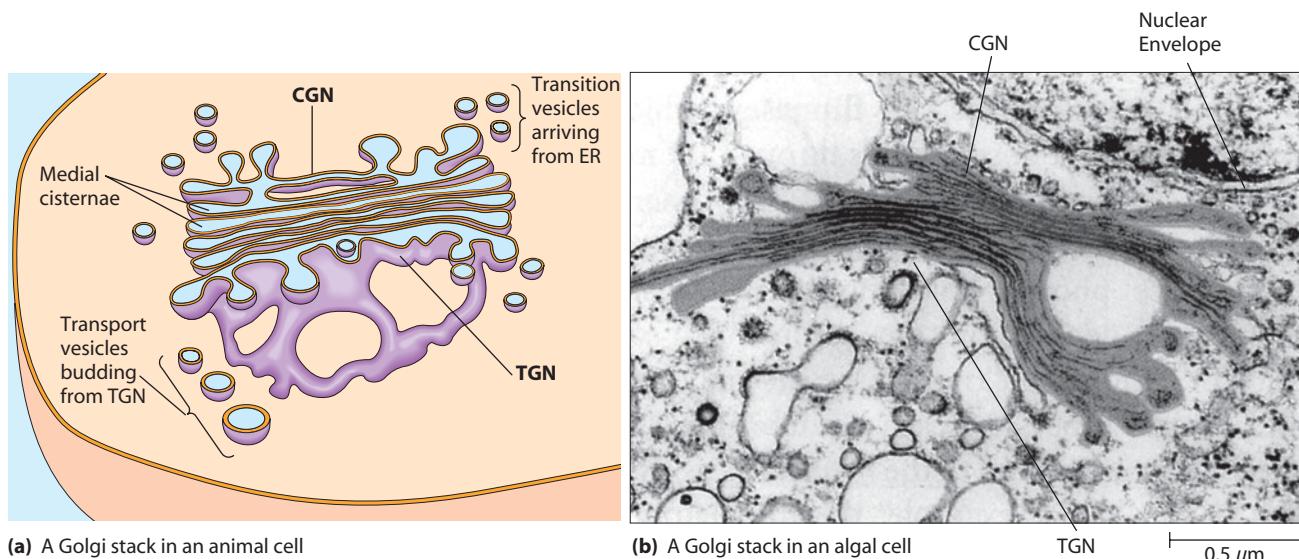

FIGURE 12-4 Golgi Structure. A Golgi stack consists of a small number of flattened cisternae. (a) At the *cis* face, transition vesicles arriving from the ER fuse with membranes of the *cis*-Golgi network (CGN). At the *trans* face, transport vesicles arise by budding from the *trans*-Golgi network (TGN). The transport vesicles carry lipids and proteins to other components of the endomembrane system or form secretory vesicles. (b) This electron micrograph shows a Golgi stack lying next to the nuclear envelope of an algal cell (TEM).

and TGN comprise the **medial cisternae** of the Golgi stack, in which much of the processing of proteins occurs.

The CGN, TGN, and medial cisternae of the Golgi complex are biochemically and functionally distinct. Each compartment contains specific receptor proteins and enzymes necessary for specific steps in protein and membrane processing, as shown by immunological and cytochemical staining techniques. This biochemical *polarity* is illustrated in **Figure 12-5**, which shows a Golgi stack in a rabbit kidney cell. Staining to detect *N-acetylglucosamine transferase I*, an enzyme that modifies carbohydrate side chains of glycoproteins, shows that the enzyme is concentrated in medial cisternae of the Golgi complex.

Two Models Depict the Flow of Lipids and Proteins Through the Golgi Complex

Two models have been proposed to explain the movement of lipids and proteins from the CGN to the TGN via the medial cisternae of the Golgi complex. According to the **stationary cisternae model**, each compartment of the Golgi stack is a stable structure. Trafficking between successive cisternae is mediated by *shuttle vesicles* that bud from one cisterna and fuse with the next cisterna in the *cis*-to-*trans* sequence. Proteins destined for the TGN are simply carried forward by shuttle vesicles, while molecules that belong in the ER and successive Golgi compartments are actively retained or retrieved.

According to the second model, known as the **cisternal maturation model**, the Golgi cisternae are transient compartments that gradually change from CGN cisternae through medial cisternae to TGN cisternae. In this model, transition vesicles from the ER converge to form the CGN, which accumulates specific enzymes for

the early steps of protein processing. Step by step, each *cis* cisterna is transformed first into an intermediate medial cisterna and then into a *trans* cisterna as it acquires additional enzymes. Enzymes that are no longer needed in late compartments return in vesicles to early compartments. In both models, the TGN forms transport vesicles or

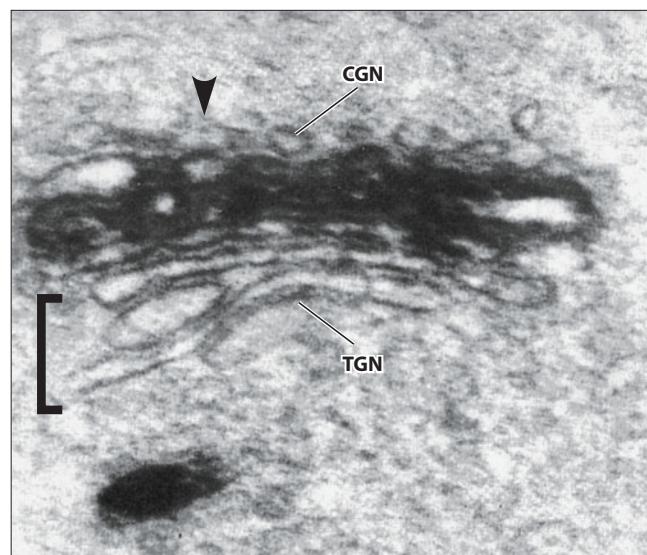

FIGURE 12-5 Immunochemical Staining of a Golgi Complex. This electron micrograph shows a Golgi stack in a rabbit kidney cell. The cell section has been stained to detect the enzyme *N-acetylglucosamine transferase I*, which plays a role in terminal glycosylation of proteins. The arrow and bracket indicate unlabeled cisternae, showing that the enzyme is concentrated in a few medial cisternae close to the *cis* face of the Golgi stack. This indicates that *N-acetylglucosamine* is added to existing oligosaccharides on glycoproteins shortly after the proteins enter the Golgi stack (TEM).

secretory granules containing sorted cargo targeted for various destinations beyond the Golgi complex.

Experimental results suggest that these two models are not necessarily mutually exclusive. It is likely that both apply to some degree, depending on the organism and the role of the cell. While the stationary cisternae model is supported by substantial evidence, some cellular components observed in medial compartments of the Golgi complex are clearly too large to travel by the small shuttle vesicles found in cells. For example, polysaccharide scales produced by some algae first appear in early Golgi compartments. Too large to fit inside transport vesicles, the scales nevertheless reach late Golgi compartments on their way to the plasma membrane for incorporation into the cell wall.

Recently, time-lapse fluorescence microscopy has been used in live yeast cells to study individual Golgi cisternae in real time. Three-dimensional analysis of images supports the cisternal maturation model and suggests that the cisternae mature at a constant rate. In addition, the rate of movement of labeled secretory proteins through the Golgi complex was measured and was shown to match the rate of cisternal maturation.

Anterograde and Retrograde Transport. The movement of material from the ER through the Golgi complex toward the plasma membrane is called **anterograde transport** (*antero* is derived from a Latin word meaning “front,” and *grade* is related to a word meaning “step”). Every time a secretory granule fuses with the plasma membrane and discharges its contents by exocytosis, a bit of membrane that originated in the ER becomes a part of the plasma membrane. To balance the flow of lipids toward the plasma membrane and to ensure a supply of components for forming new vesicles, the cell recycles lipids and proteins no longer needed during the late stages of anterograde transport. This is accomplished by **retrograde transport** (*retro* is a Latin word meaning “back”), the flow of vesicles from Golgi cisternae back toward the ER.

In the stationary cisternae model, retrograde flow facilitates both the recovery of ER-specific lipids and proteins that are passed from the ER to the CGN and the transport of compartment-specific proteins back to distinct medial cisternae of the Golgi stack. Material destined for the TGN continues forward. Whether such retrograde traffic occurs directly from all medial cisternae of the Golgi stack back to the ER or by reverse flow through successive cisternae is not yet clear. In the cisternal maturation model, retrograde flow carries material back toward newly forming compartments after receptors and enzymes are no longer needed in the more mature compartments.

Roles of the ER and Golgi Complex in Protein Glycosylation

Much of the protein processing carried out within the ER and Golgi complex involves **glycosylation**—the addition of carbohydrate side chains to specific amino acid residues

of proteins, forming **glycoproteins**. Subsequent enzyme-catalyzed reactions then modify the oligosaccharide side chain that was attached to the protein. Two general kinds of glycosylation are observed in cells (see Figure 7-25). **N-linked glycosylation** (or **N-glycosylation**) involves the addition of a specific oligosaccharide unit to the *nitrogen* atom on the terminal amino group of certain asparagine residues. **O-linked glycosylation** involves addition of an oligosaccharide to the *oxygen* atom on the hydroxyl group of certain serine or threonine residues. Each step of glycosylation is strictly dependent on preceding modifications. An error at one step, perhaps due to a defective enzyme, can block further modification of a carbohydrate side chain and can lead to disease in the organism.

Initial Glycosylation Occurs in the ER

We will focus here on N-glycosylation. **Figure 12-6** describes the steps of glycosylation that may occur as a glycoprotein travels from the ER to the CGN and through the Golgi complex to the TGN. Note that specific enzymes that catalyze various steps of glycosylation and subsequent modifications are present in specific compartments of the ER and Golgi complex. The initial steps of N-glycosylation take place on the cytosolic surface of the ER membrane and later steps occur in the ER lumen (**Figure 12-7**). Despite the variety of oligosaccharides found in mature glycoproteins, all the carbohydrate side chains added to proteins in the ER initially have a common **core oligosaccharide** consisting of two units of N-acetylglucosamine (GlcNAc, see Figure 3-26a), nine mannose units, and three glucose units.

Glycosylation begins as *dolichol phosphate*, an oligosaccharide carrier, is inserted into the ER membrane (Figure 12-7, step ①). GlcNAc and mannose groups are then added to the phosphate group of dolichol phosphate (step ②). The growing core oligosaccharide is then translocated from the cytosol to the ER lumen by a *flippase* (step ③). Once inside the ER lumen, more mannose and glucose units are added (step ④). The completed core oligosaccharide is then transferred as a single unit from dolichol to an asparagine residue of the recipient protein (step ⑤). Finally, the core oligosaccharide attached to the protein is trimmed and modified (step ⑥).

Usually, the core oligosaccharide is added to the protein as the polypeptide is being synthesized by a ribosome bound to the ER membrane. We know that this **cotranslational glycosylation** helps to promote proper protein folding because experimental inhibition of glycosylation leads to the appearance of misfolded, aggregated proteins. Addition of a single glucose unit allows other ER proteins to interact with the newly synthesized glycoprotein to ensure its proper folding. One of two ER proteins known as **calnexin** (CNX, membrane-bound) and **calreticulin** (CRT, soluble) can bind to the monoglycosylated glycoprotein and promote disulfide bond formation by forming a complex with the glycoprotein and a thiol oxidoreductase known as **ERp57**, which catalyzes disulfide bond formation. The

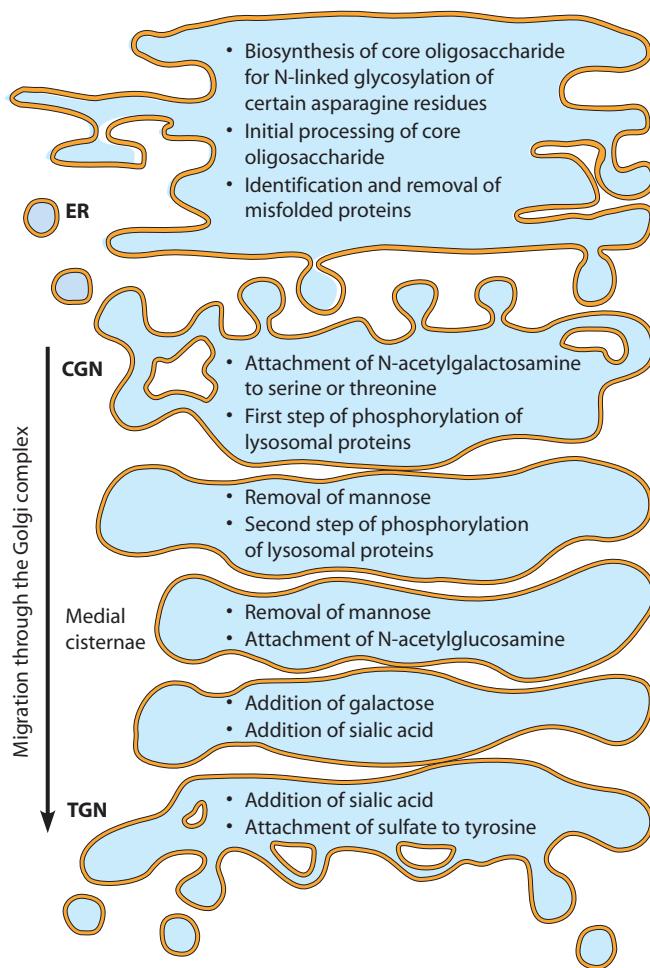

FIGURE 12-6 Compartmentalization of the Steps of Glycosylation and Subsequent Modification of Proteins.

Enzymes that catalyze specific steps of glycosylation and further modification of proteins reside in different compartments of the ER and Golgi complex. Processing occurs sequentially as proteins travel from compartment to compartment. The steps listed in the figure are examples of potential modifications and do not necessarily occur with all glycoproteins.

protein complex then dissociates, and the final glucose unit is removed by an enzyme named *glucosidase II*.

At this point, a specific glucosyl transferase in the ER known as *UGGT (UDP-glucose:glycoprotein glucotransferase)* acts as a sensor for proper folding of the newly synthesized glycoprotein. UGGT binds to improperly folded proteins and adds back a single glucose unit, making the protein a substrate for another round of CNX/CRT binding and disulfide bond formation. Once the proper conformation is achieved, UGGT no longer binds the new glycoprotein, which is then free to exit the ER and move to the Golgi.

Further Glycosylation Occurs in the Golgi Complex

Further processing of N-glycosylated proteins happens in the Golgi complex as the glycoproteins move from the *cis* face through the medial cisternae to the *trans* face of the Golgi stack. These **terminal glycosylations** in the Golgi

show remarkable variability among proteins and account for much of the great diversity in structure and function of protein oligosaccharide side chains.

Terminal glycosylation always includes the removal of a few of the carbohydrate units of the core oligosaccharide. In some cases, no further processing occurs in the Golgi complex. In other cases, more complex oligosaccharides are generated by the further addition of GlcNAc and other monosaccharides, including galactose, sialic acid, and fucose (see Figure 7-26a). Some glycoproteins contain galactose units that are added by *galactosyl transferase*, a marker enzyme unique to the Golgi.

Given the role of the Golgi complex in glycosylation, it is not surprising that two of the most important categories of enzymes present in Golgi stacks are *glucan synthetases*, which produce oligosaccharides from monosaccharides, and *glycosyl transferases*, which attach carbohydrate groups to proteins. The ER and Golgi complex contain hundreds of different glycosyl transferases, which indicates the potential complexity of oligosaccharide side chains. Within the Golgi stack, each cisterna contains a distinctive set of processing enzymes.

Notice in the preceding discussion that the mature oligosaccharides in glycoproteins are found only on the luminal side of the ER and Golgi complex membranes and thus contribute to membrane asymmetry. Because the luminal side of the ER membrane is topologically equivalent to the exterior surface of the cell, it is easy to see why all plasma membrane glycoprotein oligosaccharides are found on the extracellular side of the membrane.

Roles of the ER and Golgi Complex in Protein Trafficking

Membrane-bound and soluble proteins synthesized in the rough ER must be directed to a variety of intracellular locations, including the ER itself, the Golgi complex, endosomes, and lysosomes. Moreover, once a protein reaches an organelle where it is to remain, there must be a mechanism for preventing it from leaving. Other groups of proteins synthesized in the rough ER are destined for incorporation into the plasma membrane or for release to the outside of the cell. Therefore, each protein contains a specific “tag” targeting the protein to a transport vesicle that will carry material from one specific cellular location to another. Depending on the protein and its destination, the tag may be a short amino acid sequence, an oligosaccharide side chain, a hydrophobic domain, or some other structural feature. Tags may also be involved in excluding material from certain vesicles.

Membrane lipids may also be tagged to help vesicles reach their proper destinations. This tag can be one or more phosphate groups attached to positions 3, 4, and/or 5 of a membrane phosphatidylinositol (PI) molecule by a specific kinase. For example, a functional PI 3-kinase is required for proper sorting of vesicles to the vacuole in yeast. In mammalian cells, inhibition of inositol kinases

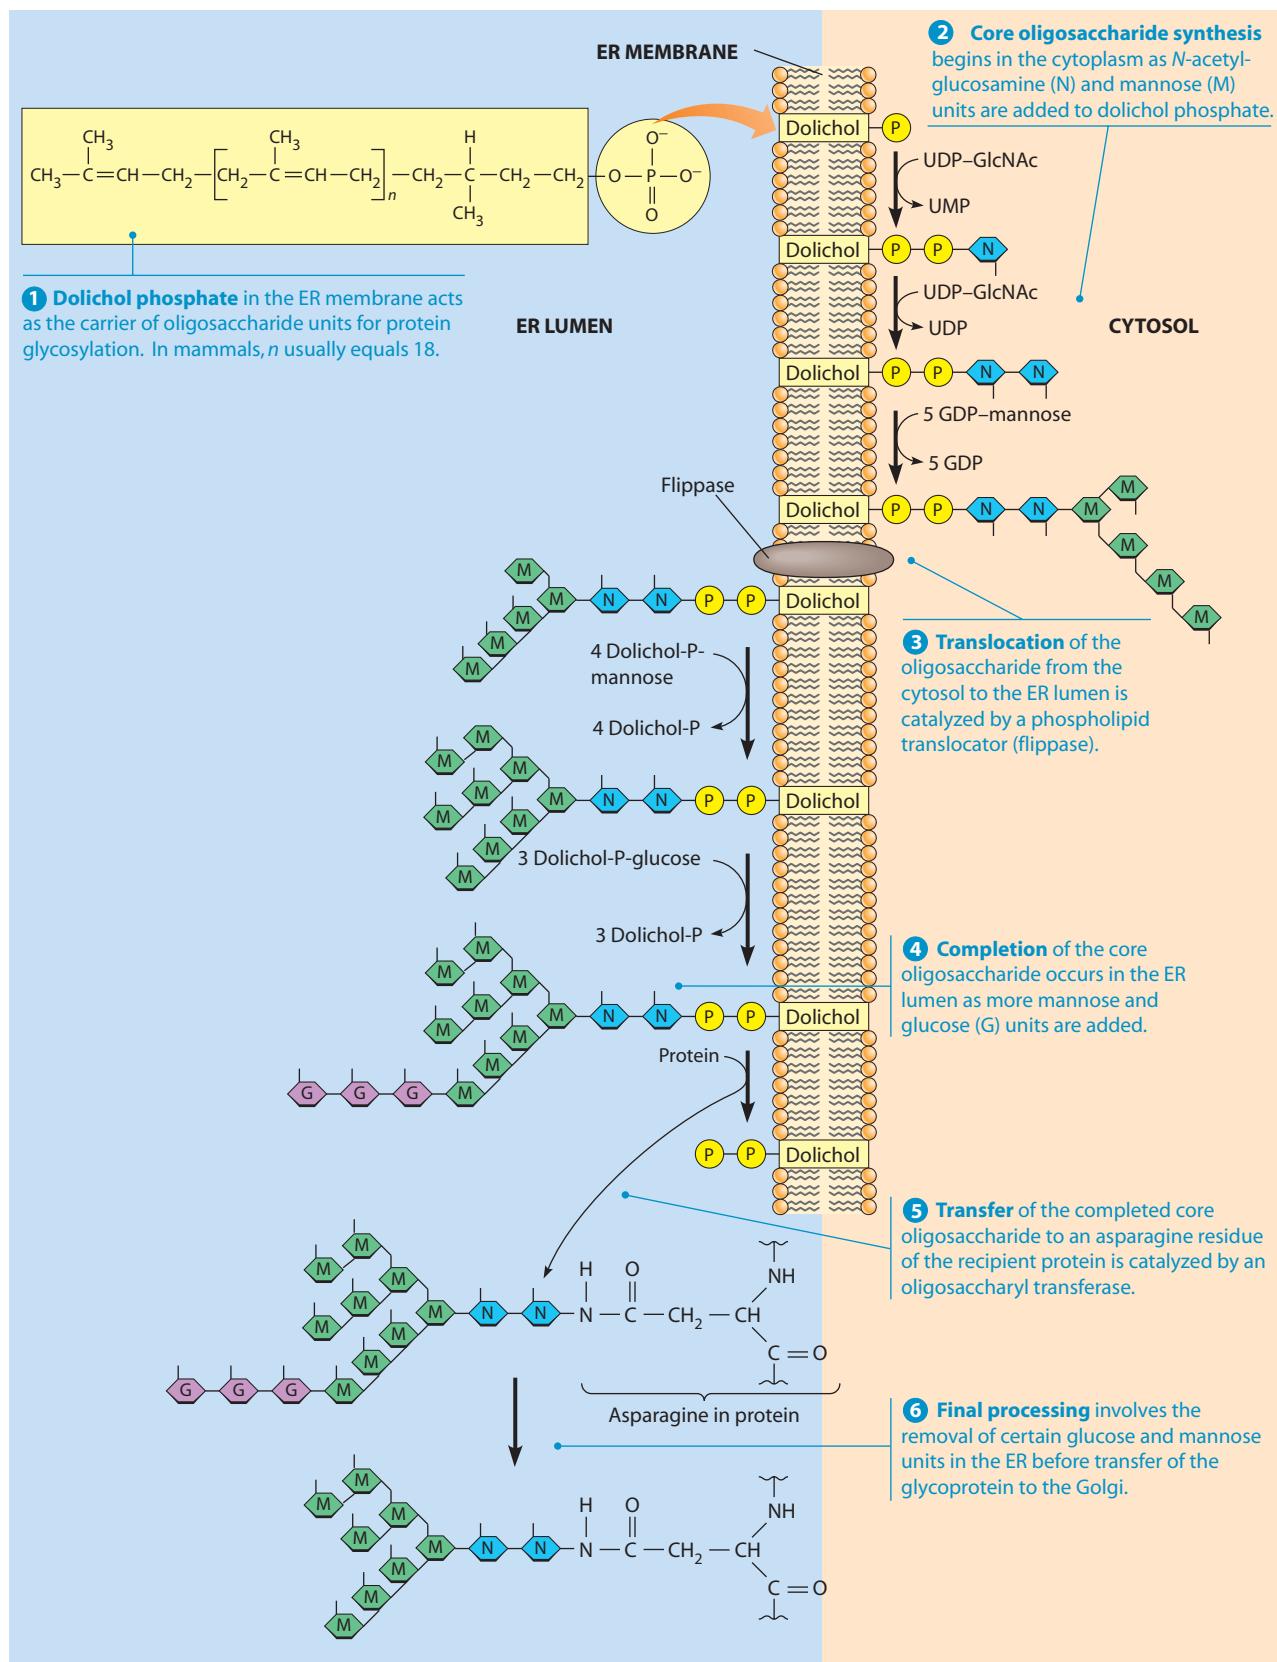

FIGURE 12-7 N-linked Glycosylation of Proteins in the ER. Synthesis of core oligosaccharides begins in the cytoplasm, using a dolichol phosphate molecule as a carrier. The partially synthesized oligosaccharide is translocated to the ER lumen, where additional monosaccharides are added. The completed oligosaccharide is then transferred to the target protein, and several monosaccharide units are removed in final processing.

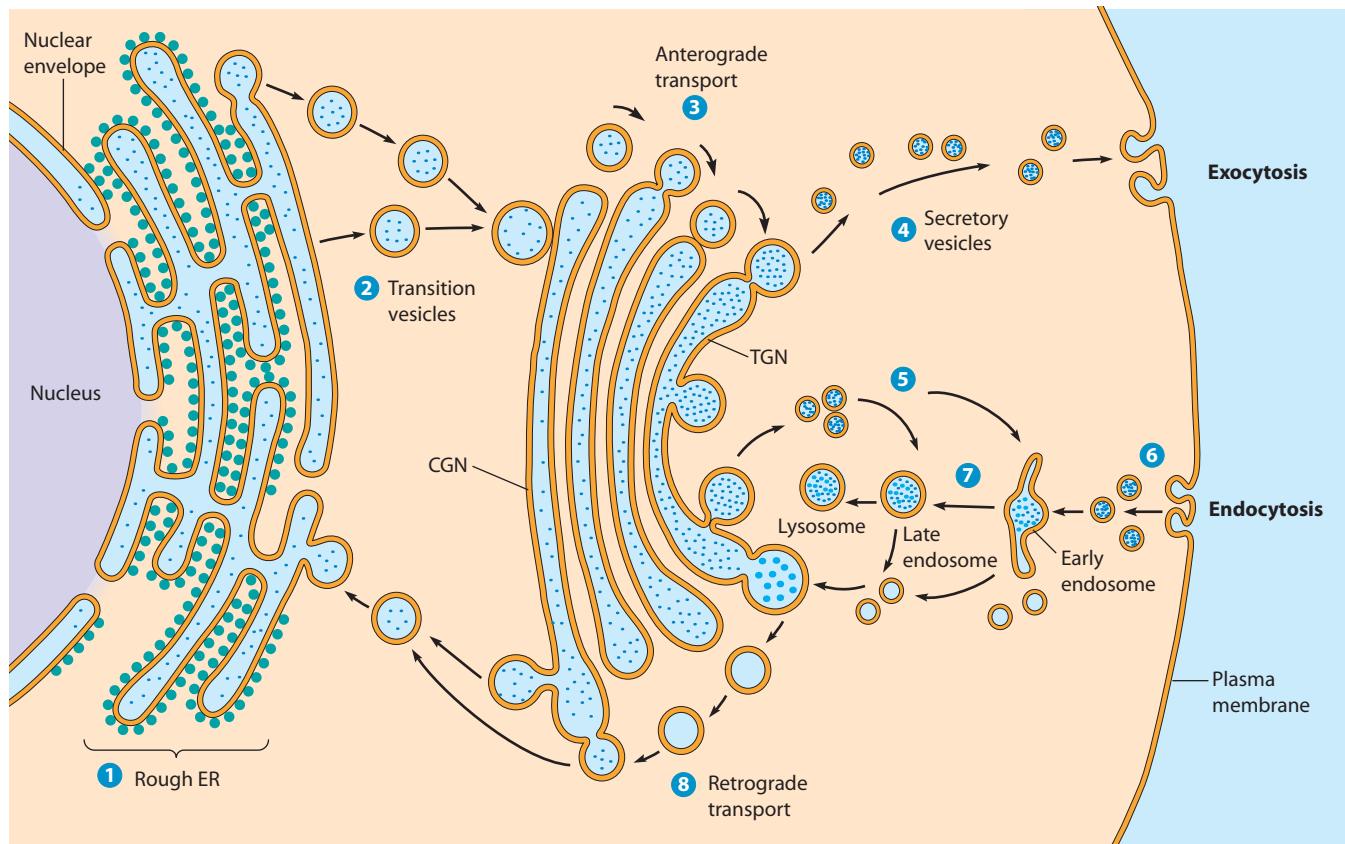

FIGURE 12-8 Trafficking Through the Endomembrane System. Vesicles carry lipids and proteins along several routes from the ER through the Golgi complex to various destinations, including secretory vesicles, endosomes, and lysosomes. ① As ribosomes of the rough ER synthesize proteins, the proteins enter the ER lumen, where initial glycosylation steps occur. ② Transition vesicles carry glycosylated proteins (and newly synthesized lipids) to the CGN. ③ Lipids and proteins move through the cisternae of the Golgi stack via shuttle vesicles and cisternae mature as new enzymes are added via vesicles. ④ At the TGN, some vesicles bud off to form secretory vesicles, which move to the plasma membrane and release their contents by exocytosis. ⑤ Other vesicles bud from the TGN to form endosomes that, in turn, help to make lysosomes. ⑥ Proteins and other materials are taken into the cell by endocytosis, forming endocytic vesicles that fuse with early endosomes. ⑦ Early endosomes containing material for digestion mature to form late endosomes and then lysosomes. ⑧ Retrograde traffic returns compartment-specific proteins to earlier compartments.

 [VIDEOS www.thecellplace.com](http://www.thecellplace.com) ER to Golgi traffic

disrupts vesicle trafficking to the lysosome. Aside from specific tags on some lipids, the length and degree of saturation of certain membrane lipids have also been shown to be important in vesicle trafficking.

An overview of the trafficking involving the ER and Golgi complex is presented in **Figure 12-8**. Sorting of proteins begins in the ER and early compartments of the Golgi stack, which contain mechanisms for retrieving or retaining compartment-specific proteins. This important step preserves the compartment-specific functions needed to maintain the integrity of glycosylation and processing pathways. The final sorting of material that will leave the Golgi complex occurs in the TGN, where lipids and proteins are selectively packaged into distinct populations of transport vesicles that are destined for different locations in the cell. In some cells, the Golgi complex is also involved in the processing of proteins that enter the cell by endocytosis.

ER-Specific Proteins Contain Retention and Retrieval Tags

The protein composition required in the ER is maintained both by preventing some proteins from escaping when vesicles bud from the ER membrane and by retrieving other proteins that have left the ER and reached the CGN. It is not entirely clear how proteins that never leave the ER are retained, but one theory proposes that they form extensive complexes that are physically excluded from vesicles budding from the ER.

Several proteins localized to the ER contain the tripeptide sequence RXR (Arg-X-Arg, where X is any amino acid), which appears to promote retention in the ER. This *retention tag* is also found in some multisubunit proteins that are destined for the plasma membrane. The N-methyl-D-aspartate (NMDA) receptor, which is important in neurotransmission in the mammalian brain, contains such

a tag. But why, you may ask, does this plasma membrane protein have an ER retention signal? It is thought that the tripeptide causes individual subunits of NMDA to be retained in the ER until assembly of the multisubunit complex in the ER is complete. Proper assembly masks the RXR sequence, allowing the assembled complex to leave the ER. Other evidence suggests that phosphorylation of this protein near the RXR sequence promotes ER release.

Retrieval by retrograde flow of vesicles from the CGN to the ER is better understood than retention. Many soluble ER-specific proteins contain *retrieval tags* that bind to specific transmembrane receptors facing the Golgi complex lumen. The tags are short C-terminal amino acid sequences such as KDEL (Lys-Asp-Glu-Leu) or KKXX (where X can be any amino acid) in mammals and HDEL (His-Asp-Glu-Leu) in yeast. When a protein containing such a tag binds to its receptor, the receptor undergoes a conformational change, and the receptor-ligand complex is packaged into a transport vesicle for return to the ER.

Evidence for the importance of retrieval tags comes from experiments involving artificial *chimeric proteins*, also known as *fusion proteins*. They are made by joining the DNA sequences encoding two polypeptide segments from different proteins, allowing a hybrid polypeptide to be produced from the joined DNAs. Proteins normally secreted from the cell were altered in this manner to include amino acids representing an ER retrieval tag, and these proteins were subsequently found in the ER rather than being secreted. Interestingly, some of these chimeric proteins found in the ER had undergone partial processing by enzymes found only in the Golgi complex. This finding indicates that the suspected tag did not simply prevent escape of the protein from the ER but actively promoted the retrieval of ER-specific proteins from the Golgi complex.

Golgi Complex Proteins May Be Sorted According to the Lengths of Their Membrane-Spanning Domains

Like resident proteins required in the ER, some resident proteins of the Golgi complex contain retention or retrieval tags. Moreover, in the Golgi complex as in the ER, the formation of large complexes that are excluded from transport vesicles may play a role in maintaining the protein composition of the Golgi complex. In addition, we will next see that a third, distinctly different mechanism is also likely at work in this organelle—a mechanism involving hydrophobic regions of Golgi proteins.

All known Golgi-specific proteins are integral membrane proteins that have one or more hydrophobic membrane-spanning domains anchoring them to Golgi membranes. The length of the hydrophobic domains may determine into which cisterna of the Golgi complex each membrane-bound protein is incorporated as it moves through the organelle. Recall that the thickness of cellular membranes increases progressively from the ER (about 5 nm) to the plasma membrane (about 8 nm). Among Golgi-specific proteins, there is a corresponding increase in the

lengths of hydrophobic membrane-spanning domains going from the CGN to the TGN. Such proteins tend to move from compartment to compartment until the thickness of the membrane exceeds the length of their membrane-spanning domains, thereby blocking further migration.

Targeting of Soluble Lysosomal Proteins to Endosomes and Lysosomes Is a Model for Protein Sorting in the TGN

During their journey through the ER and early compartments of the Golgi complex, soluble lysosomal enzymes, like other glycoproteins, undergo N-glycosylation followed by removal of glucose and mannose units. Within the Golgi complex, however, mannose residues on the carbohydrate side chain of lysosomal enzymes are phosphorylated, forming an oligosaccharide containing mannose-6-phosphate. This oligosaccharide tag distinguishes soluble lysosomal proteins from other glycoproteins and ensures their delivery to lysosomes (**Figure 12-9**).

The phosphorylation of mannose residues is catalyzed by two Golgi-specific enzymes. The first, located in an early compartment of the Golgi stack, is a phosphotransferase that adds GlcNAc-1-phosphate to carbon atom 6 of mannose. The second, located in a mid-Golgi compartment, removes GlcNAc, leaving behind the mannose-6-phosphate residue.

The interior surface of the TGN membrane has mannose-6-phosphate receptors (MPRs) that bind to the mannose-6-phosphate residues of lysosomal proteins. The pH of the TGN is around 6.4, which favors binding of soluble lysosomal enzymes to these receptors. Following binding of tagged lysosomal proteins to the MPRs, the receptor-ligand complexes are packaged into transport vesicles and conveyed to an endosome. In animal cells, lysosomal enzymes needed for degradation of material brought into the cell by endocytosis are transported from the TGN to organelles known as **late endosomes**. These develop from **early endosomes**, which are formed by the coalescence of vesicles from the TGN and plasma membrane.

As an early endosome matures to form a late endosome, the pH of the lumen decreases to about 5.5, causing the bound lysosomal enzymes to dissociate from the MPRs. This prevents the retrograde movement of these enzymes back to the Golgi along with the receptors that are recycled in vesicles that return to the TGN. Finally, the late endosome either matures to form a new lysosome or delivers its contents to an active lysosome.

Strong support for this model of lysosomal enzyme targeting came from studies of a human genetic disorder called *I-cell disease*. Cultured fibroblast cells from patients with I-cell disease synthesize all the expected lysosomal enzymes but then release most of the soluble proteins to the extracellular medium instead of incorporating them into lysosomes. The distinguishing feature of the misdirected proteins is the absence of mannose-6-phosphate residues on their oligosaccharide side chains. The

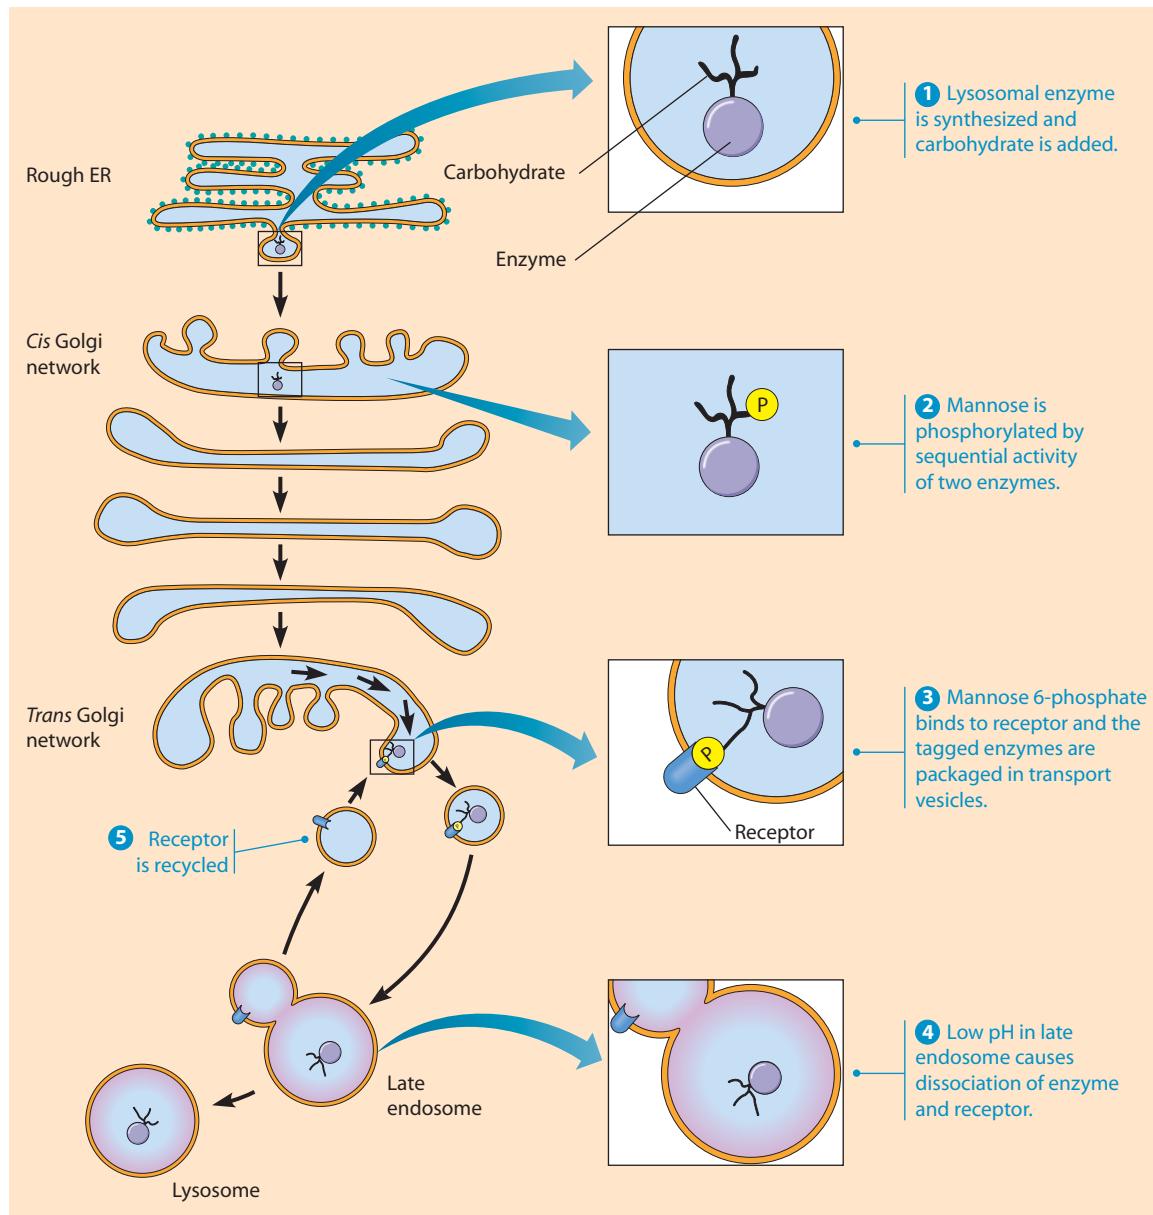

FIGURE 12-9 Targeting of Soluble Lysosomal Enzymes to Endosomes and Lysosomes by a Mannose-6-Phosphate Tag. ① In the ER, soluble lysosomal enzymes undergo *N*-glycosylation followed by removal of glucose and mannose units. ② Within the Golgi complex, mannose residues on the lysosomal enzymes are phosphorylated by two enzymes. The first one adds *N*-acetylglucosamine-1-phosphate to carbon atom 6 of mannose. The second one removes *N*-acetylglucosamine, leaving behind the phosphorylated mannose residue. ③ The tagged lysosomal enzymes bind to mannose-6-phosphate receptors in the TGN and are packaged into coated transport vesicles that convey the enzymes to a late endosome. ④ The acidity of the late endosomal lumen causes the enzymes to dissociate from their receptors. ⑤ The receptors are recycled in vesicles that return to the TGN. The late endosome either matures to form a lysosome or transfers its contents to an active lysosome.

mannose-6-phosphate tag is clearly essential for targeting soluble lysosomal glycoproteins to the lysosome. As you may have guessed, I-cell disease results from a defective phosphotransferase that is needed to add the mannose-6-phosphate to oligosaccharide chains on lysosomal enzymes. However, while mannose-6-phosphate residues are important for directing traffic from the ER to the lysosome, other pathways appear to be involved as well. For example, in patients with I-cell disease, lysosomal acid hydrolases somehow still reach the lysosomes in liver cells.

Secretory Pathways Transport Molecules to the Exterior of the Cell

Integral to the vesicular traffic shown in Figure 12-8 are **secretory pathways** by which proteins move from the ER through the Golgi complex to **secretory vesicles** and **secretory granules**, which then discharge their contents to the exterior of the cell. The concerted roles of the ER and the Golgi complex in secretion were demonstrated in 1967 by James Jamieson and George Palade in secretory

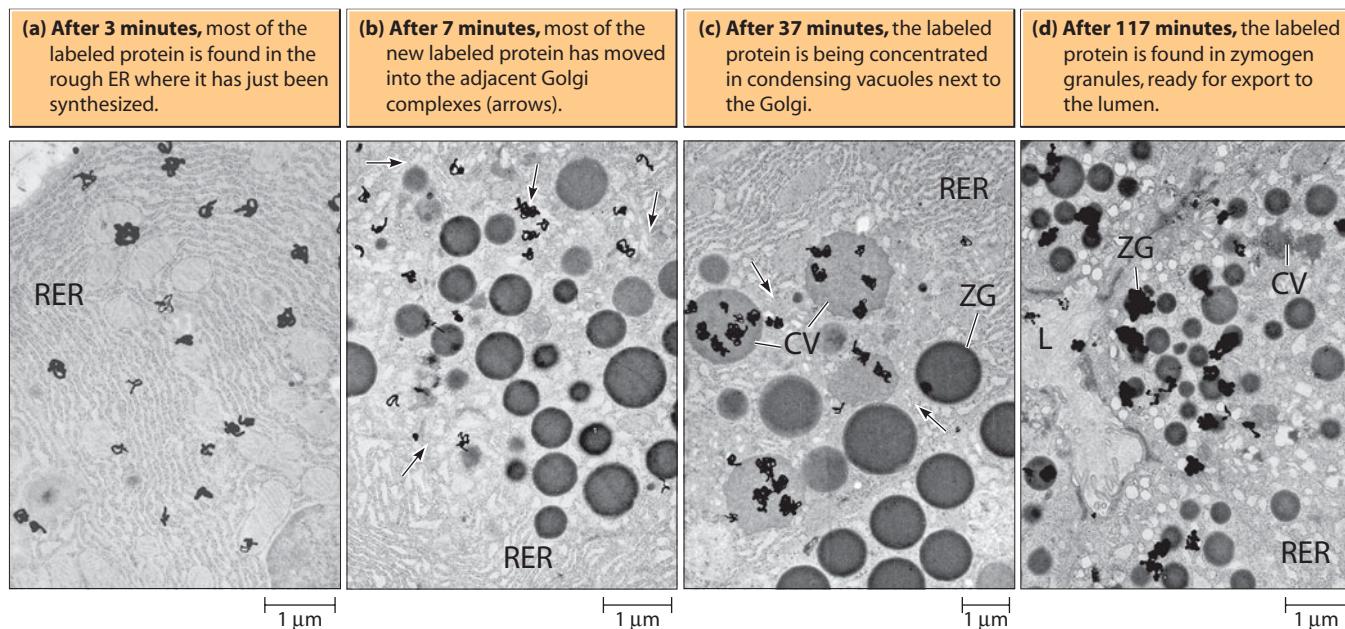

FIGURE 12-10 Autoradiographic Evidence of a Secretory Pathway. To trace the path of newly synthesized proteins through a cell, Jamieson and Palade briefly treated slices of guinea pig pancreatic tissue with a small amount of a radioactive amino acid to pulse label newly synthesized proteins. After washing away unincorporated amino acids, they used microscopic autoradiography to determine the location of radioactively labeled protein in pancreatic secretory cells at several time points following injection (a) to (d) as noted above the panels. Abbreviations: RER, rough endoplasmic reticulum; CV, condensing vacuole; ZG, zymogen granule; L, lumen. Arrows point to the edges of the Golgi complexes (TEMs).

cells from guinea pig pancreatic slices. They used electron microscopic autoradiography to trace the movement of radioactively labeled protein from its place of synthesis in the ER through the Golgi complex to its subsequent packaging in secretory vesicles.

Results from this classic experiment are presented in **Figure 12-10**. Three minutes after brief exposure of tissue slices to a radioactive amino acid, newly synthesized protein labeled with the radioactive amino acid (irregular dark coloration) was found primarily in the rough ER (panel a). A few minutes later, labeled protein began to appear in the Golgi complex (panel b). By 37 minutes, labeled protein was detected in vesicles budding from the Golgi that Jamieson and Palade called *condensing vacuoles* (panel c). After 117 minutes, labeled protein began to accumulate in dense *zymogen granules*, vesicles that discharge secretory proteins to the exterior of the cell (panel d). Some of the radioactively labeled protein was observed in the exterior lumen adjacent to the cell, demonstrating that some of the secretory granules had released their contents from the cell.

Based on this classic experiment and numerous similar studies since then, the secretory pathways shown in Figure 12-8 are now understood in considerable detail. Moreover, we now distinguish two different modes of secretion by eukaryotic cells. *Constitutive secretion* involves the continuous discharge of vesicles at the plasma membrane surface, whereas *regulated secretion* involves controlled, rapid releases that happen in response to an extracellular signal.

Constitutive Secretion. After budding from the TGN, some secretory vesicles move directly to the cell surface, where they immediately fuse with the plasma membrane and release their contents by exocytosis. This unregulated process, which is continuous and independent of specific extracellular signals, occurs in most eukaryotic cells and is called **constitutive secretion**. One example is the continuous release of mucus by cells that line your intestine.

Constitutive secretion was once assumed to be a *default pathway* for proteins synthesized by the rough ER. According to this model, all proteins destined to remain in the endomembrane system must have a tag that diverts them from constitutive secretion. Otherwise, they will move through the endomembrane system and be released outside the cell by default. Support for this model came from studies in which removal of the KDEL retrieval tags on resident ER proteins led to secretion of the modified protein. However, more recent evidence suggests that a variety of short amino acid tags may identify specific proteins for constitutive secretion.

For some proteins, constitutive secretion may require N-glycosylation of the protein, as was recently shown for mouse interleukin-31, a secreted protein involved in extracellular cell-to-cell signaling. Other recent work showed that addition of an N-glycosylation site to the human p53 tumor suppressor protein, a protein that is not normally secreted, caused this altered p53 to be secreted. As you might expect, the secreted protein was N-glycosylated.

Regulated Secretion. While vesicles containing constitutively secreted proteins move continuously and directly from the TGN to the plasma membrane, secretory vesicles involved in **regulated secretion** accumulate in the cell and then fuse with the plasma membrane only in response to specific extracellular signals. An important example is the release of neurotransmitters, which will be described in Chapter 13 (see Figure 13-18). Two additional examples of regulated secretion are the release of insulin from pancreatic β cells in response to glucose and the release of **zymogens**—inactive precursors of hydrolytic enzymes—from pancreatic acinar cells in response to calcium or endocrine hormones.

Regulated secretory vesicles form by budding from the TGN as immature secretory vesicles, which undergo a subsequent maturation process. Maturation of secretory proteins involves concentration of the proteins—referred to as *condensation*—and frequently also some proteolytic processing. The mature secretory vesicles then move close to the site of secretion and remain near the plasma membrane until receiving a hormonal or other chemical signal that triggers release of their contents by fusion with the plasma membrane.

Zymogen granules are a type of mature regulated secretory vesicle that are usually quite large and contain highly concentrated protein, as shown in Figure 12-10 and **Figure 12-11**. Note that the zymogen granules are concentrated in the region of the cell between the Golgi stacks from which they arise and the portion of the plasma

membrane bordering the lumen into which the contents of the granules are eventually discharged.

The information needed to direct a protein to a regulated secretory vesicle is presumably inherent in the amino acid sequence of the protein, though the precise signals and mechanisms are not yet known. Current evidence suggests that high concentrations of secretory proteins in secretory granules promote the formation of large *protein aggregates* that exclude nonsecretory proteins. This could occur in the TGN, where only aggregates would be packaged in vesicles destined for secretory granules, or it could occur in the secretory granule itself. The pH of the TGN and the secretory granule lumens may serve as a trigger favoring aggregation as material leaves the TGN. The soluble proteins that do not become part of an aggregate in the TGN or a secretory granule would be carried by transport vesicles to other locations.

Exocytosis and Endocytosis: Transporting Material Across the Plasma Membrane

Two methods of transporting materials across the plasma membrane are *exocytosis*, the process by which secretory granules release their contents to the exterior of the cell, and *endocytosis*, the process by which cells internalize external materials. Both processes are unique to eukaryotic cells and are also involved in the delivery, recycling, and turnover of membrane proteins. We will first consider exocytosis because it is the final step in a secretory pathway that began with the ER and the Golgi complex.

Exocytosis Releases Intracellular Molecules Outside the Cell

In **exocytosis**, proteins in a vesicle are released to the exterior of the cell as the membrane of the vesicle fuses with the plasma membrane. A variety of proteins are exported from both animal and plant cells by exocytosis. Animal cells secrete peptide and protein hormones, mucus, milk proteins, and digestive enzymes in this manner. Plant and fungal cells secrete enzymes and structural proteins associated with the cell wall, and carnivorous plants secrete hydrolytic enzymes that are used to digest trapped insects.

The process of exocytosis is illustrated schematically in **Figure 12-12a**. Vesicles containing cellular products destined for secretion move to the cell surface (step ①), where the membrane of the vesicle fuses with the plasma membrane (step ②). Fusion with the plasma membrane discharges the vesicle contents to the exterior of the cell (step ③). In the process, the membrane of the vesicle becomes integrated into the plasma membrane, with the *inner* (luminal) surface of the vesicle becoming the *outer* (extracellular) surface of the plasma membrane (step ④). Thus, glycoproteins and glycolipids that were originally formed in the ER and Golgi lumens will face the extracellular space.

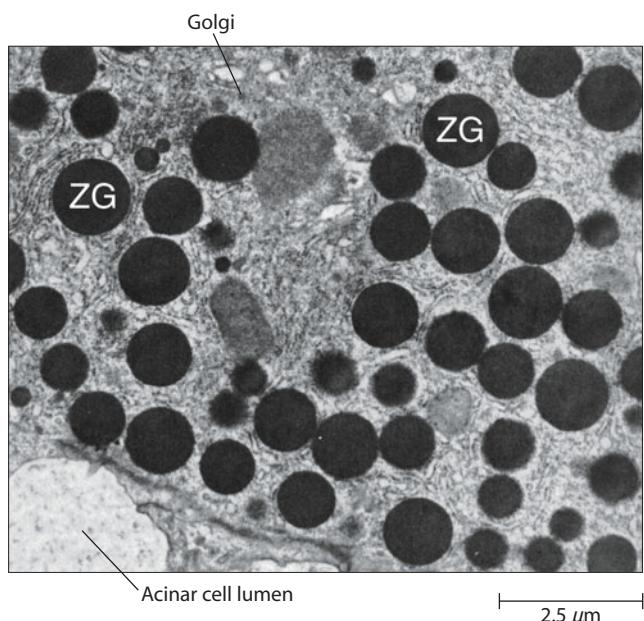

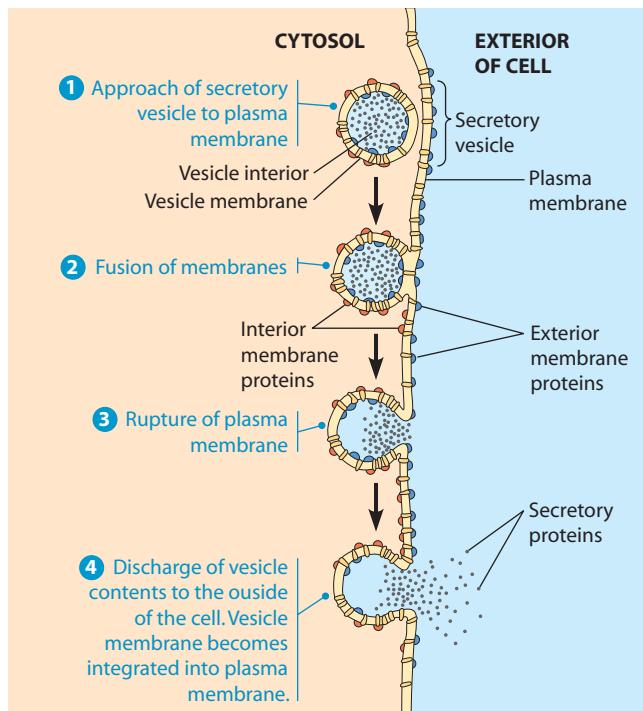

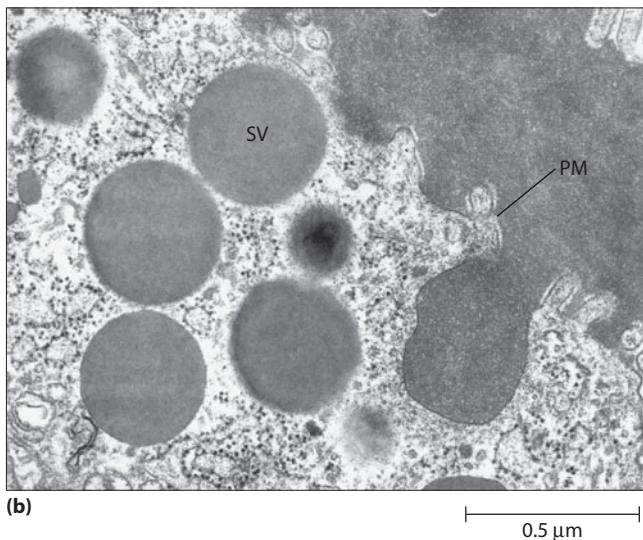

FIGURE 12-11 Zymogen Granules. This electron micrograph of an acinar (secretory) cell from the exocrine pancreas of a rat illustrates the prominence of zymogen granules (ZG), which contain enzymes destined for secretion. They are usually concentrated in the region of the cell between the Golgi complex from which they arise and the portion of the plasma membrane bordering the acinar lumen into which the zymogens will be discharged (TEM).

(a)

(b)

FIGURE 12-12 Exocytosis. (a) This illustration shows how a secretory vesicle approaches the plasma membrane, fuses with it, and releases its contents to the exterior of the cell during exocytosis. (b) In this monkey pancreatic cell, secretory vesicles (SV) approach the plasma membrane (PM), where one vesicle has fused with the membrane and secreted its contents.

The mechanism underlying the movement of exocytic vesicles to the cell surface is not yet clear. Current evidence points to the involvement of microtubules in vesicle movement. For example, in some cells, vesicles appear to move from the Golgi complex to the plasma membrane along “tracks” of microtubules that are oriented parallel to the direction of vesicle movement. Moreover, vesicle movement stops when the cells are treated with *colchicine*, a plant alkaloid that prevents microtubule assembly. We

will discuss the intracellular movement of vesicles along microtubules in Chapter 16.

The Role of Calcium in Triggering Exocytosis. Fusion of regulated secretory vesicles with the plasma membrane is generally triggered by a specific extracellular signal. In most cases, the signal is a hormone or a neurotransmitter that binds to specific receptors on the cell surface and triggers the synthesis or release of a *second messenger* within the cell, as we will see in Chapter 14. During regulated secretion, a transient elevation of the intracellular concentration of calcium ions often appears to be an essential step in the signal cascade leading from the receptor on the cell surface to exocytosis. For example, microinjection of calcium into pancreatic cells induces mature secretory granules to discharge their contents to the extracellular medium. The specific role of calcium is not yet clear, but it appears that an elevation in the intracellular calcium concentration leads to the activation of protein kinases whose target proteins are components of either the vesicle membrane or the plasma membrane.

Polarized Secretion. In many cases, exocytosis of specific proteins is limited to a specific surface of the cell. For example, the secretory cells that line your intestine release digestive enzymes only on the side of the cell that faces the interior of the intestine. This phenomenon, called **polarized secretion**, is also seen in nerve cells, which secrete neurotransmitter molecules only at junctions with other nerve cells (see Figure 13-16). Proteins destined for polarized secretion, as well as lipid and protein components of the two different membrane layers, are sorted into vesicles that bind to localized recognition sites on subdomains of the plasma membrane.

Endocytosis Imports Extracellular Molecules by Forming Vesicles from the Plasma Membrane

Most eukaryotic cells carry out one or more forms of **endocytosis** for uptake of extracellular material. A small segment of the plasma membrane progressively folds inward (Figure 12-13, step ①), and then it pinches off to form an **endocytic vesicle** containing ingested substances or particles (steps ②–④). Endocytosis is important for several cellular processes, including ingestion of essential nutrients by some unicellular organisms and defense against microorganisms by white blood cells.

In terms of membrane flow, exocytosis and endocytosis clearly have opposite effects. Whereas exocytosis adds lipids and proteins to the plasma membrane, endocytosis removes them. Thus, the steady-state composition of the plasma membrane results from a balance between exocytosis and endocytosis. Through endocytosis and retrograde transport, the cell can recycle and reuse molecules deposited in the plasma membrane by secretory vesicles during exocytosis.

The magnitude of the resulting membrane exchange is impressive. For example, the secretory cells in your

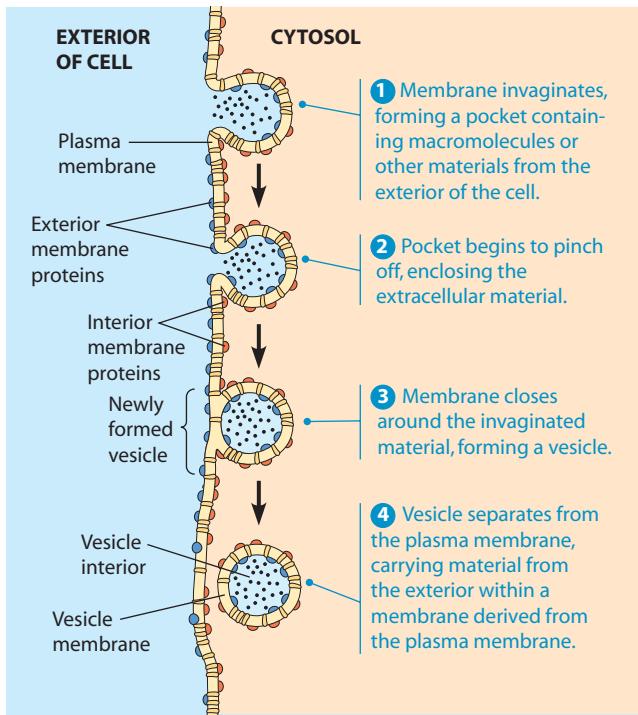

FIGURE 12-13 Endocytosis. This illustration shows the uptake of materials from the exterior of the cell during endocytosis. For clarity, the coat proteins at the site of invagination and around the endocytic vesicle have been omitted from this diagram.

pancreas recycle an amount of membrane equal to the whole surface area of the cell within about 90 minutes. Cultured macrophages (large white blood cells) are even faster, replacing an amount of membrane equivalent to the entire plasma membrane within about 30 minutes!

During endocytosis, the membrane of an endocytic vesicle isolates the internalized substances from the cytosol. Most endocytic vesicles develop into early endosomes, which fuse with vesicles from the TGN, acquiring digestive enzymes and maturing to form new lysosomes. A distinction is usually made between *phagocytosis* (Greek for “cellular eating”), in which large solid particles are ingested, and *pinocytosis* (“cellular drinking”), in which liquids containing soluble or suspended molecules are taken up.

Phagocytosis. The ingestion of large particles ($>0.5 \mu\text{m}$ diameter), including aggregates of macromolecules, parts of other cells, and even whole microorganisms or other cells, is known as **phagocytosis**. For many unicellular eukaryotes, such as amoebas and ciliated protozoa, phagocytosis is a routine means for acquiring food. Phagocytosis is also used by some primitive animals, notably flatworms, coelenterates, and sponges, as a means of obtaining nutrients.

In more complex organisms, however, phagocytosis is usually restricted to specialized cells called **phagocytes**. For example, your body contains two classes of white blood cells—*neutrophils* and *macrophages*—which use phagocytosis for defense rather than nutrition. These cells engulf and digest foreign material or invasive microorganisms found in

the bloodstream or in injured tissues. Macrophages have an additional role as scavengers, ingesting cellular debris and whole damaged cells from injured tissues. Under certain conditions, other mammalian cells engage in phagocytosis. For example, fibroblasts found in connective tissue can take up collagen to allow remodeling of the tissue, and dendritic cells in the mammalian spleen can ingest bacteria as part of an immune response.

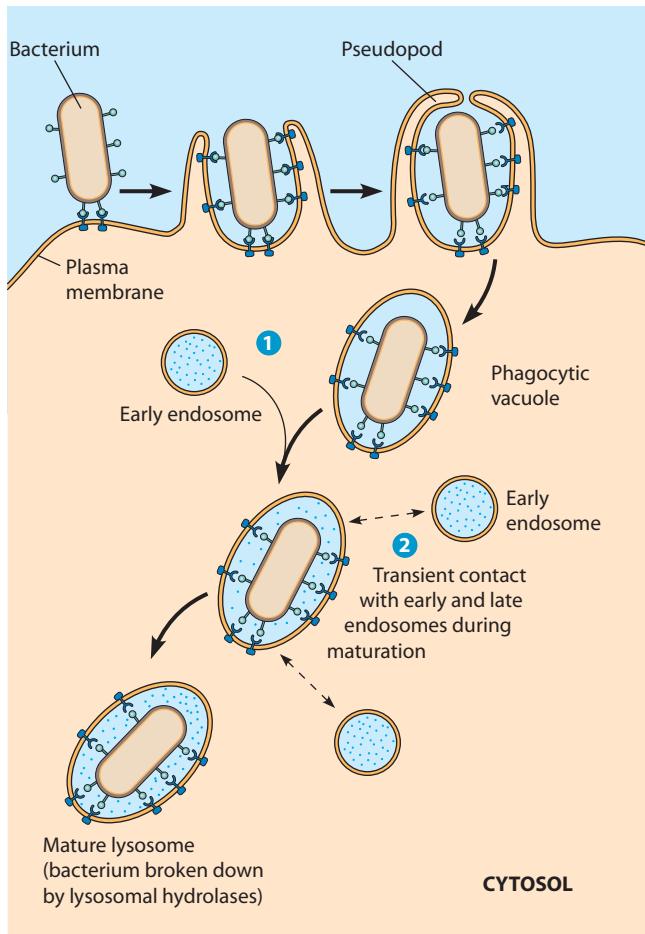

Phagocytosis has been studied most extensively in the amoeba, which uses it for nutrition. Contact with food particles or smaller organisms triggers the onset of phagocytosis, as shown in **Figure 12-14**. Folds of membrane called *pseudopods* gradually surround the object and then meet and engulf the particle, forming an intracellular **phagocytic vacuole**. This endocytic vesicle, also called a *phagosome*, then fuses with a late endosome or matures directly into a lysosome, forming a large vesicle in which the ingested material is digested. As part of their role in the immune system, human phagocytes generate toxic concentrations of hydrogen peroxide, hypochlorous acid, and other oxidants in the phagocytic vacuole to kill microorganisms.

Receptor-Mediated Endocytosis. Cells can acquire certain soluble and suspended materials by a process known as **receptor-mediated endocytosis** (also called **clathrin-dependent endocytosis**). For this process, cells use specific receptors that are found on the outer surface of the plasma membrane. Receptor-mediated endocytosis is the primary mechanism for the specific internalization of most macromolecules by eukaryotic cells. Depending on the cell type, mammalian cells can ingest hormones, growth factors, enzymes, serum proteins, cholesterol, antibodies, iron, and even some viruses and bacterial toxins by this mechanism.

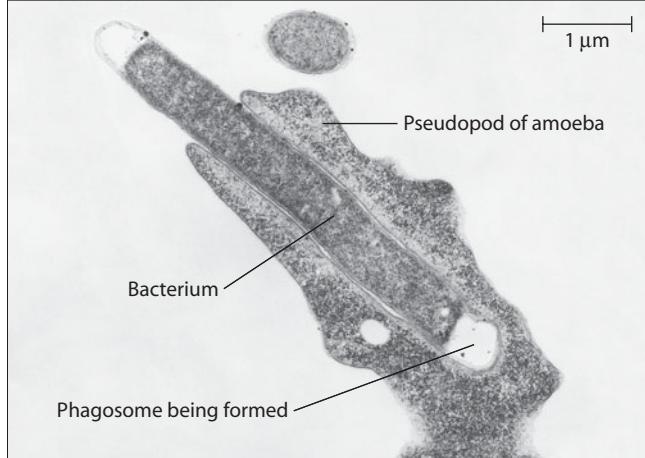

The discovery of receptor-mediated endocytosis and its role in the internalization of *low-density lipoproteins* (*LDL*) is highlighted in **Box 12B** (see p. 346). Receptor-mediated endocytosis of *LDL* carries cholesterol into mammalian cells. An interest in familial hypercholesterolemia, a hereditary predisposition to high blood cholesterol levels and hence to atherosclerosis and heart disease, led Michael Brown and Joseph Goldstein to the discovery of receptor-mediated endocytosis, for which they shared a Nobel Prize in 1986.

Receptor-mediated endocytosis is illustrated in **Figure 12-15**. The process begins with the binding of specific molecules (referred to as *ligands*) to their *receptors*—specific ligand-binding proteins found on the outer surface of the plasma membrane (step ①). As the receptor-ligand complexes diffuse laterally in the membrane, they encounter specialized membrane regions called *coated pits* that serve as sites for the collection and internalization of these complexes (step ②). In a typical mammalian cell, coated pits occupy about 20% of the total surface area of the plasma membrane.

Accumulation of receptor-ligand complexes within the coated pits triggers accumulation of additional proteins on

(a)

(b)

FIGURE 12-14 Phagocytosis. (a) Particles or microorganisms bind to receptors on the cell surface, triggering the onset of phagocytosis. Folds of membrane called *pseudopods* gradually surround the particle. Eventually, the pseudopods meet and engulf the particle, forming a *phagocytic vacuole*. The vacuole then ① fuses with an early endosome or ② forms transient connections (indicated by dashed lines) with early and late endosomes and matures into a lysosome, in which digestion of the internalized material occurs. (b) This micrograph shows a phagosome being formed as an amoeba engulfs a rod-shaped bacterial cell (TEM).

the inner (cytosolic) surface of the plasma membrane. These additional proteins—including *adaptor protein*, *clathrin*, and *dynamin*—are required for promoting membrane curvature and invagination of the pit (step ③). Invagination continues until the pit pinches off from the plasma membrane, forming a **coated vesicle** (step ④). The clathrin coat is released, leaving an uncoated vesicle (step ⑤). The coat proteins and dynamin are then recycled to the plasma membrane, where they become available for forming new vesicles, while the uncoated vesicle is free to fuse with an early endosome (step ⑥).

The speed and scope of receptor-mediated endocytosis are impressive. A coated pit usually invaginates within a minute or so of being formed, and up to 2500 such coated pits invaginate per minute in a cultured fibroblast cell. **Figure 12-16** shows the progressive formation of a coated vesicle from a coated pit as particles of yolk protein are taken up by the maturing oocyte (egg cell) of a chicken.

There are several variations of receptor-mediated endocytosis. Epidermal growth factor (EGF), which stimulates division of epithelial cells, undergoes endocytosis by the mechanism shown in Figure 12-15. Here, endocytosis plays an important role in cell signaling. As EGF receptors are internalized, the cell becomes less responsive to EGF, a process known as *desensitization*. Deficiencies in desensitization caused by defective endocytosis can lead to overstimulation by EGF, resulting in excessive cell growth, cell division, and possible tumor formation.

In another variation of receptor-mediated endocytosis, receptors are concentrated in coated pits independent of formation of receptor-ligand complexes. Binding of ligands to receptors simply triggers internalization. In yet another variation, the receptors are not only constitutively concentrated, but they are also constitutively internalized regardless of whether ligands have bound to the receptors. For example, the LDL receptors described in Box 12B are constitutively internalized.

Following receptor-mediated endocytosis, the uncoated vesicles fuse with vesicles budding from the TGN to form early endosomes in peripheral regions of the cell. *Early endosomes* are sites for the sorting and recycling of extracellular material brought into the cell by endocytosis. Protein molecules essential for new rounds of endocytosis are often—but not always—recycled after separation from the material fated for digestion. The early endosome continues to acquire lysosomal proteins from the TGN and matures to form a late endosome, which then develops into a lysosome. The roles of endosomes in digestion will be discussed in more detail when we examine lysosomes later in the chapter.

Recycling of plasma membrane receptor molecules is facilitated by acidification of the early endosome. The interior of an endocytic vesicle has a pH of about 7.0, whereas the interior of an early endosome has a pH of 5.9–6.5. The lower pH is maintained by an *ATP-dependent proton pump* in the endosomal membrane. The

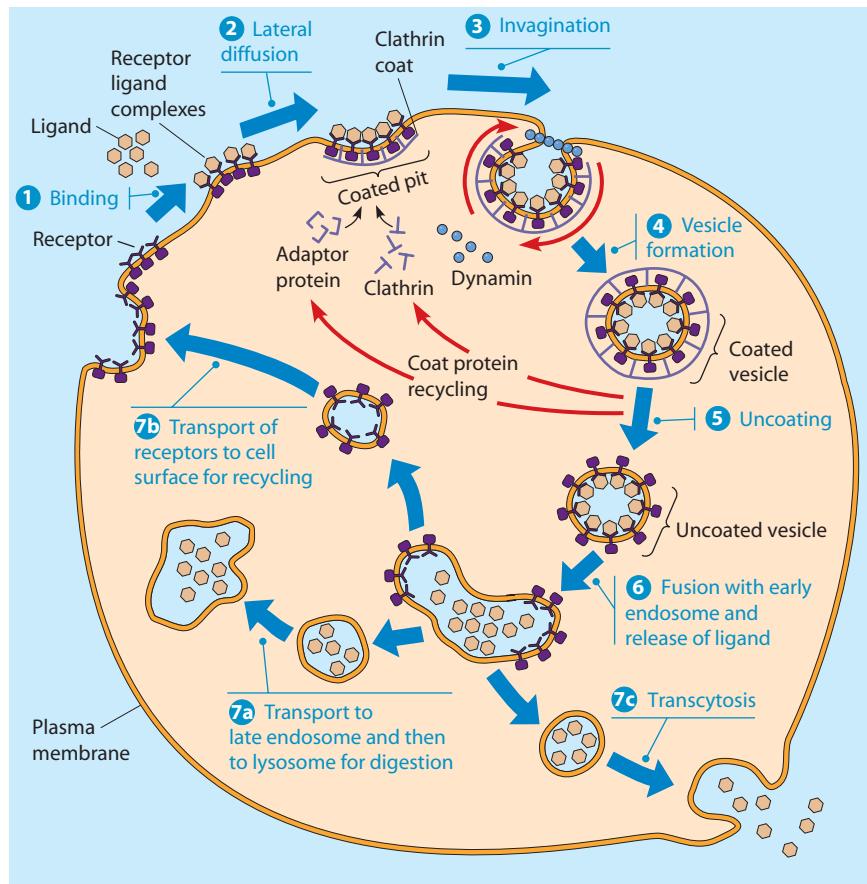

FIGURE 12-15 Receptor-Mediated Endocytosis. During receptor-mediated endocytosis, **1** the molecules that will be internalized bind to specific receptors on the surface of the plasma membrane. **2** Receptor-ligand complexes accumulate in coated pits, where **3** invagination is facilitated by adaptor protein, clathrin, and dynamin on the cytosolic surface of the membrane. The result is **4** an internalized coated vesicle that **5** quickly loses its clathrin coat. The uncoated vesicle is now free to **6** fuse with other intracellular membranes, usually a membrane surrounding an early endosome, where internalized material is sorted. The fate of the receptors and the ingested molecules depends on the nature of the material. Transport vesicles often **7a** carry material to a late endosome for digestion. Alternative pathways include **7b** recycling to the plasma membrane or **7c** transport to another region of the plasma membrane and exocytosis (called transcytosis). For clarity, the nucleus is not shown.

Cholesterol, the LDL Receptor, and Receptor-Mediated Endocytosis

Receptor-mediated endocytosis is a highly efficient pathway for the uptake of specific macromolecules by eukaryotic cells. Many different kinds of macromolecules can be taken up by this means, and each one is recognized by its own specific receptor on the plasma membrane of the appropriate cell types. As we consider the discovery of receptor-mediated endocytosis, we will focus on a specific receptor—and, as it turns out, on a health issue that many of us are concerned about: the level of cholesterol in our blood.

As you may know, one of the primary factors predisposing a person to heart attacks is an abnormally high level of cholesterol in the blood serum, a condition called *hypercholesterolemia*. Because of its insolubility, cholesterol tends to be deposited on the inside walls of blood vessels, forming the *atherosclerotic plaques* that cause *atherosclerosis*, commonly known as hardening of the arteries. Ultimately, the plaques may block the flow of blood through the vessels, causing strokes and heart attacks. Remember, however, that cholesterol is a normal component of healthy animal cell membranes—a moderate level of cholesterol is required for maintenance of these membranes. Therefore, the body will synthesize cholesterol if dietary amounts are inadequate.

Although a high blood cholesterol level is often linked to diet, some people are genetically predisposed to high blood cholesterol levels and hence to atherosclerosis and heart disease. Individuals with this hereditary predisposition, called **familial hypercholesterolemia (FH)**, can have grossly elevated levels of serum cholesterol (about 650–1000 mg/100 mL of blood serum, compared with the normal range of about 130–200 mg/100 mL). They typically develop atherosclerosis early in life and often die from heart disease before the age of 20.

The link between FH and receptor-mediated endocytosis was discovered by Michael Brown and Joseph Goldstein, who began this work in 1972. Their discovery of receptor-mediated endocytosis led to Nobel Prizes for both scientists in 1986. Brown and Goldstein began by culturing fibroblast cells from FH patients in the laboratory and showing that such cells synthesized cholesterol at abnormally high rates compared with normal cells. Their next key observation was that normal cells also synthesized cholesterol at abnormally high rates when they were deprived of the **low-density lipoproteins (LDLs)** that were usually present in the culture medium. LDL is one form in which cholesterol is transported in the blood and taken up into cells.

slightly acidic environment of the early endosome decreases the affinity of most receptor-ligand complexes (for example, LDL and its receptor), thereby freeing receptors to be recycled to the plasma membrane while newly ingested material is diverted to other locations. This is similar to the acid-induced recycling of mannose-6-phosphate receptors from the lysosome back to the TGN that we saw previously.

Sorting receptors and ligands is not always as simple as sending the receptors to the plasma membrane and retaining the ligands in the endosome. Depending on the ligand, some receptor-ligand complexes do not dissociate

LDL is one of several types of *blood lipoprotein particles*, which are classified by density. Another class is the **high-density lipoproteins (HDLs)**, moderately high levels of which are considered healthy. A lipoprotein particle consists of a monolayer of phospholipid and cholesterol molecules and one or more protein molecules, with the lipids oriented so that their polar head groups face the aqueous medium on the outside and their nonpolar tails extend into the interior of the particle, which contains additional cholesterol molecules esterified to long-chain fatty acids (**Figure 12B-1**). LDLs have the highest cholesterol content—more than 50%.

In addition to phospholipids and cholesterol, each LDL particle has a large protein called *apolipoprotein B-100* embedded in its lipid monolayer. This protein is crucial to our understanding of the difference in the response of FH cells and normal cells to the level of LDL in the medium. Normal fibroblasts maintain a low rate of cholesterol synthesis in the presence of LDL, but when deprived of LDL they make cholesterol at abnormally high rates. Since it was known that cholesterol down-regulates its own synthesis, Brown

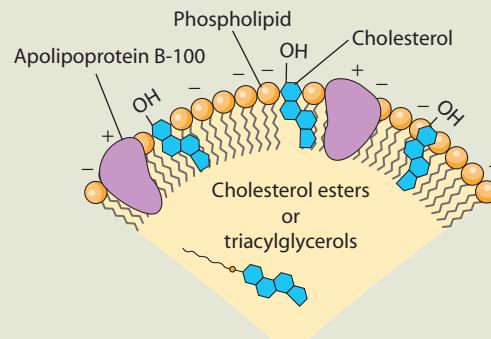

FIGURE 12B-1 LDL Structure. Lipoproteins differ in density depending on the relative amounts of lipid and proteins, with higher lipid amounts resulting in lower density. The low-density lipoprotein (LDL) shown here has a density of 1.02–1.06 g/mL. It contains about 800 phospholipid molecules and 500 free cholesterol molecules in the lipid monolayer plus about 1500 esterified cholesterol molecules in the interior. Apolipoprotein B-100 is embedded in the lipid monolayer and mediates the binding of the LDL to the LDL receptors on the surfaces of cells.

in the early endosome. While dissociated ligands are swept along to their fate in a lysosome, intact receptor-ligand complexes are still subject to sorting and packaging into transport vesicles. There are at least three alternative fates for these complexes: (1) Some receptor-ligand complexes (for example, epidermal growth factor and its receptor) are carried to a lysosome for degradation. (2) Others are carried to the TGN, where they enter a variety of pathways transporting material throughout the endomembrane system. (3) Receptor-ligand complexes can also travel by transport vesicles to a different region of the plasma membrane, where they are secreted as part of a

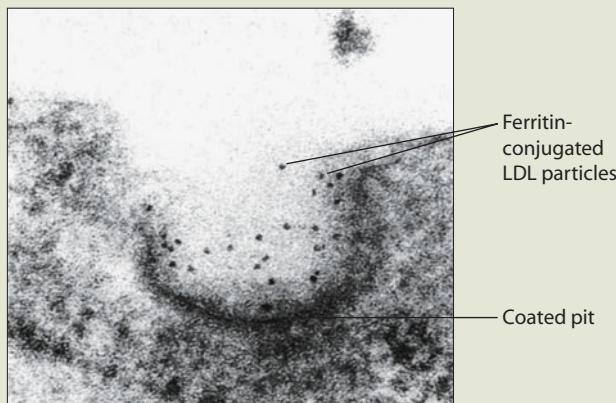

and Goldstein hypothesized that LDL was involved in the transport of cholesterol into the cell. Because FH fibroblasts, on the other hand, synthesized cholesterol at a high rate regardless of whether LDL was present in the medium, they thought that these cells might be defective in LDL-dependent cholesterol uptake.

Based on these observations, Brown and Goldstein postulated that the uptake of cholesterol into cells requires a specific receptor for LDL particles on the cell surface. They then tested whether this receptor is absent or defective in FH patients. In a brilliant series of experiments, these investigators and their colleagues demonstrated the existence of an LDL-specific membrane protein, called the **LDL receptor**, and they showed that it recognizes the apolipoprotein B-100 molecule that is present in every LDL particle. They also showed that the cells from FH patients either lacked the LDL receptor entirely or had defective LDL receptors.

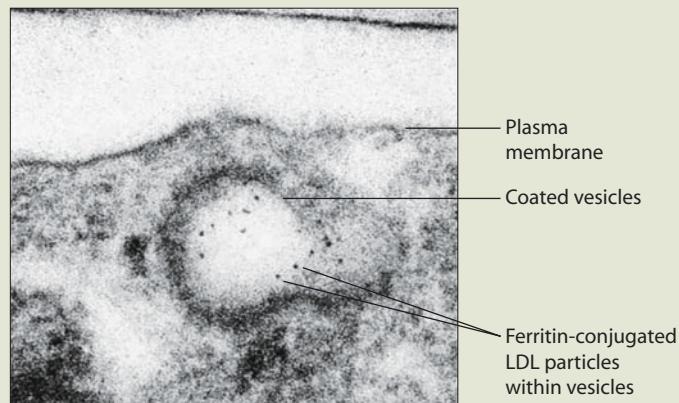

To visualize the LDL particles, these scientists conjugated, or linked, them to molecules of ferritin, a protein that binds iron

atoms. Because iron atoms are electron dense, they appear as dark dots in the electron microscope (**Figure 12B-2**). Using this technique, Brown and Goldstein showed that the ferritin-conjugated LDL particles bound to the surface of the cell and clustered at specific locations (Figure 12B-2a). We now recognize these sites as *coated pits*, which are localized regions of the plasma membrane characterized by the presence of *clathrin* on the cytoplasmic side of the membrane and by the accumulation of membrane-bound receptor-ligand complexes on the exterior of the membrane.

Dark dots were also seen on the inside of vesicles that formed by invagination and pinching off of coated pits (Figure 12B-2b). The receptors, in other words, not only bound the LDL on the cell surface but also were apparently involved in the internalization of LDL within vesicles. In short, these workers had discovered a new mechanism by which cells can take up macromolecules from their environment. And since it was an endocytic process involving specific receptors, Brown and Goldstein gave it the name we know it by today—receptor-mediated endocytosis.

(a) Particles bind to receptors in coated pit

(b) Coated vesicle forms in pit

FIGURE 12B-2 Visualization of LDL Binding. Conjugation of LDL particles with ferritin, an iron-binding protein, allows visualization of the LDL-ferritin complexes by electron microscopy because of the density of the iron atoms bound to the ferritin. (a) LDL-ferritin conjugates, visible as dark dots, bind to receptors concentrated in a coated pit on the surface of a cultured human fibroblast cell. (b) The LDL-ferritin conjugates are internalized when a coated vesicle forms from the coated pit region following invagination of the plasma membrane (TEMs).

process called **transcytosis**. This pathway accommodates the transfer of extracellular material from one side of the cell, where endocytosis occurs, through the cytoplasm to the opposite side, where exocytosis occurs. For example, immunoglobulins are transported across epithelial cells from maternal blood to fetal blood by transcytosis.

Clathrin-Independent Endocytosis. An example of a clathrin-independent endocytic pathway is **fluid-phase endocytosis**, a type of pinocytosis for nonspecific internalization of extracellular fluid. Fluid-phase endocytosis, unlike receptor-mediated endocytosis, does not concen-

trate ingested material. Because the cell engulfs fluid without a mechanism for collecting or excluding particular molecules, the concentration of material trapped in vesicles reflects its concentration in the extracellular environment. In contrast to other forms of endocytosis, fluid-phase endocytosis proceeds at a relatively constant rate in most eukaryotic cells. Because it compensates for the membrane segments that are continuously added to the plasma membrane by exocytosis, it is a means for controlling a cell's volume and surface area. Once inside the cell, fluid-phase endocytic vesicles, like clathrin-dependent endocytic vesicles, are routed to early endosomes.

Coated Vesicles in Cellular Transport Processes

Most of the vesicles involved in lipid and protein transfer are referred to as *coated vesicles* because of the characteristic coats, or layers, of proteins covering their cytosolic surfaces as they form. Coated vesicles are a common feature of most cellular processes that involve the transfer or exchange of substances between specific membrane-bound compartments of eukaryotic cells or between the inside and the outside of a cell.

Coated vesicles were first reported in 1964 by Thomas Roth and Keith Porter, who described their involvement in the selective uptake of yolk protein by developing mosquito oocytes. Since then, coated vesicles have been shown to play vital roles in diverse cellular processes. Coated vesicles are involved in vesicular traffic throughout the endomembrane system, as well as transport during exocytosis and endocytosis. It is probable that such vesicles participate in most, if not all, vesicular traffic connecting the various membrane-bound compartments and the plasma membrane of the eukaryotic cell.

A common feature of coated vesicles is the presence of a layer, or coat, of protein on the cytosolic side of the membrane surrounding the vesicle. The most studied coat proteins are *clathrin*, *COP1*, and *COP2* (COP is an abbreviation for “coat protein.”). Coat proteins participate in several steps of the formation of transport vesicles. The type of coat protein on a vesicle helps in the sorting of molecules that are fated for different destinations in the cell. More general roles for COPs may include forcing nearly flat membranes to form spherical vesicles, preventing premature, nonspecific fusion of a budding vesicle with nearby membranes, and regulating the interactions between budding vesicles and microtubules that are important for moving vesicles through the cell.

The specific set of proteins covering the exterior of a vesicle is an indicator of the origin and destination of the vesicle within the cell (Table 12-2). *Clathrin-coated vesicles* are involved in the selective transport of proteins from the TGN to endosomes and in the endocytosis of receptor-ligand complexes from the plasma membrane. *COP1-coated vesicles*, on the other hand, facilitate retrograde transport of proteins from the Golgi back to the ER, as well as between cisternae of the Golgi complex. *COP2-coated vesicles* are involved in the transport of material from the ER to the Golgi.

A fourth, more recently discovered coat protein is *caveolin*. The precise role of *caveolin-coated vesicles*, called *caveolae*, is still controversial. Caveolae are small invaginations of the plasma membrane characterized by the presence of the protein *caveolin*. They are a type of lipid raft that is rich in cholesterol and sphingolipids, and they may be involved in cholesterol uptake by cells. Mice deficient in caveolin show dramatic abnormalities in the cardiovascular system, which then becomes enriched in cholesterol. Other studies suggest that these cholesterol-carrying caveolae play a role in signal transduction.

Clathrin-Coated Vesicles Are Surrounded by Lattices Composed of Clathrin and Adaptor Protein

Clathrin-coated vesicles are surrounded by coats composed of two multimeric proteins, *clathrin* and *adaptor protein (AP)*. The term *clathrin* comes from *clathratus*, the Latin word for “lattice,” and is well chosen because clathrin and AP assemble to form protein lattices composed of polygons. Flat clathrin lattices are composed entirely of hexagons, whereas curved lattices, which form under coated pits and surround vesicles, are composed of hexagons and pentagons. Use of clathrin to coat vesicles is advantageous to the cell because the unique shape of the clathrin proteins and the way they assemble to form clathrin coats provides the driving force that causes flat membranes to curve and form spherical vesicles.

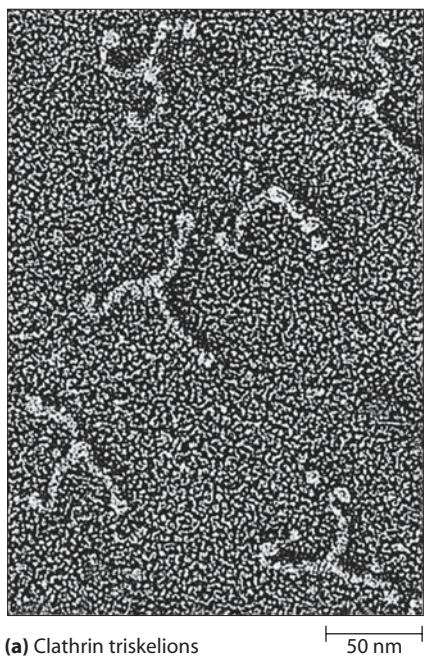

In 1981, Ernst Ungewickell and Daniel Branton visualized the basic structural units of clathrin lattices, three-legged structures called *triskelions* (Figure 12-17a). Each triskelion is a multimeric protein composed of three large polypeptides (heavy chains) and three small polypeptides (light chains) radiating from a central vertex, as illustrated in Figure 12-17b. Antibodies that recognize clathrin light chains bind to the legs of the triskelion near the central vertex, suggesting that the light chains are associated with the inner half of each leg.

By combining information gathered from electron microscopy and X-ray crystallography, researchers have assembled the following model for the organization of triskelions into the characteristic hexagons and pentagons of clathrin-coated pits and vesicles (Figure 12-17c). One clathrin triskelion is located at each vertex of the polygonal lattice. Each polypeptide leg extends along two edges of the

Table 12-2 Coated Vesicles Found Within Eukaryotic Cells

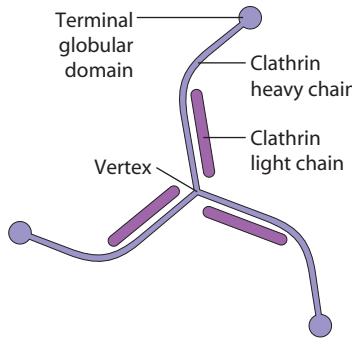

Coated Vesicle	Coat Proteins*	Origin	Destination
Clathrin	Clathrin, AP1, ARF	TGN	Endosomes
Clathrin	Clathrin, AP2	Plasma membrane	Endosomes
COP1	COP1, ARF	Golgi complex	ER or Golgi complex
COP2	COP2 (Sec13/31 and Sec23/24), Sar1	ER	Golgi complex
Caveolin	Caveolin	Plasma membrane	ER?

*ARF designates ADP ribosylation factor 1; AP1 and AP2 designate different adaptor protein complexes (also called assembly protein complexes).

FIGURE 12-17 Clathrin Triskelions. Shown above are (a) a micrograph of clathrin triskelions (SEM), (b) an illustration showing how each triskelion is composed of three clathrin heavy chains and three clathrin light chains, and (c) a model for the assembly of triskelions into the characteristic clathrin pentagons and hexagons found in coated pits and vesicles.

lattice, with the knee of the clathrin heavy chain located at an adjacent vertex. This arrangement of triskelions into overlapping networks ensures extensive longitudinal contact between clathrin polypeptides and may confer the mechanical strength needed when a coated vesicle forms.

The second major component of clathrin coats—**adaptor protein (AP)**—was originally identified simply by its ability to promote the assembly of clathrin coats around vesicles and is sometimes called *assembly protein*. We now know that eukaryotic cells contain at least four types of AP complexes, each composed of four polypeptides—two adaptin subunits, one medium chain, and one small chain. The four polypeptides, which are slightly different in each type of AP complex, bind to different transmembrane receptor proteins and confer specificity during vesicle budding and targeting.

In addition to ensuring that appropriate macromolecules will be concentrated in coated pits, AP complexes mediate the attachment of clathrin to proteins embedded in the plasma membrane. Considering the central role of APs, it is not surprising that AP complexes are sites for regulation of clathrin assembly and disassembly. For example, the ability of AP complexes to bind to clathrin is affected by pH, phosphorylation, and dephosphorylation.

The Assembly of Clathrin Coats Drives the Formation of Vesicles from the Plasma Membrane and TGN

The binding of AP complexes to the plasma membrane and the concentration of receptors or receptor-ligand com-

plexes in coated pits require ATP and GTP—though perhaps only for regulation of the process. The assembly of a clathrin coat on the cytosolic side of a membrane appears to provide part of the driving force for formation of a vesicle at the site. Initially, all clathrin units are hexagonal and form a planar, two-dimensional structure (**Figure 12-18a, c**). As more clathrin triskelions are incorporated into the growing lattice, a combination of hexagonal and pentagonal units allows the new clathrin coat to curve around the budding vesicle (**Figure 12-18b, d**).

As clathrin accumulates around the budding vesicle, at least one more protein—**dynamin**—participates in the process. Dynamin is a cytosolic GTPase required for coated pit constriction and closing of the budding vesicle. This essential protein was first identified in *Drosophila*, a fruit fly used extensively as a genetic model organism. Flies expressing a temperature-sensitive form of dynamin were instantly paralyzed after a temperature shift disrupted the dynamin function. Further investigation revealed an accumulation of coated pits in the membranes of neuromuscular junctions in the affected flies. Formation of the closed vesicle occurs as dynamin forms helical rings around the neck of the coated pit. As GTP is hydrolyzed, the dynamin rings tighten and separate the fully sealed endocytic vesicle from the plasma membrane.

Some mechanism is also required to *uncoat* clathrin-coated membranes. Moreover, uncoating must be done in a regulated manner because, in most cases, the clathrin coat remains intact as long as the membrane is part of a coated pit or budding vesicle but dissociates rapidly once the vesicle is fully formed. Like assembly, dissociation of the clathrin coat

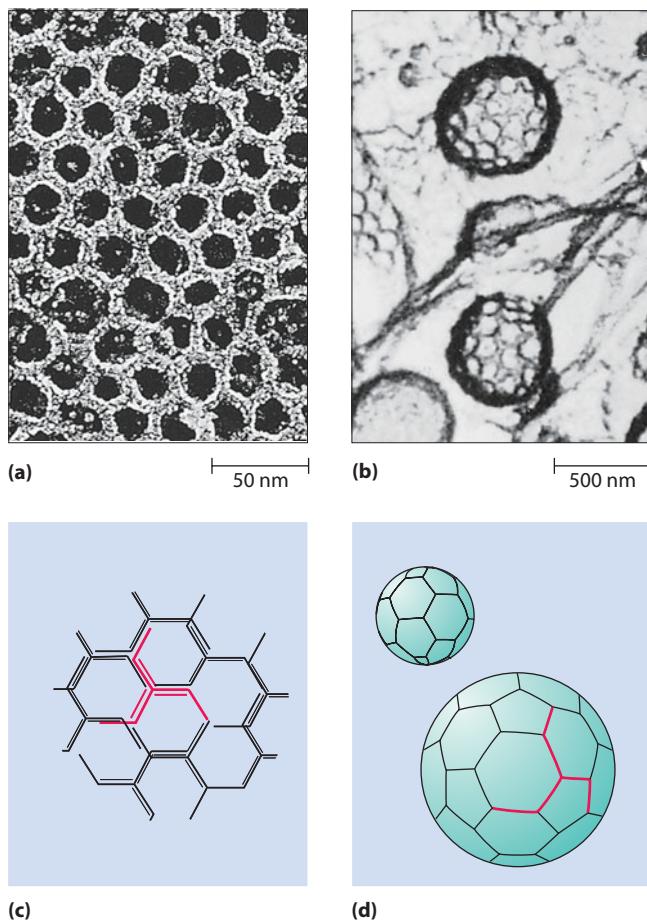

FIGURE 12-18 Clathrin Lattices. Each vesicle is surrounded by a cage of overlapping clathrin complexes. (a) Freeze-etch electron micrograph of a clathrin lattice in a human carcinoma cell. This flat lattice is composed of hexagonal units. (b) Electron micrograph of clathrin cages isolated from a calf brain. Cages include both pentagonal and hexagonal units (TEMs). (c) and (d) Interpretive drawings of the lattice and clathrin cages shown in (a) and (b).

 [VIDEOS](http://www.thecellplace.com) www.thecellplace.com Clathrin-coated vesicle formation

is an energy-consuming process, accompanied by the hydrolysis of about three ATP molecules per triskelion. At least one protein, an *uncoating ATPase*, is essential for this process, though the uncoating ATPase releases only the clathrin triskelions from the APs. The factors responsible for releasing APs from the membrane have not yet been identified.

Clathrin-coated vesicles readily dissociate into soluble clathrin complexes, adaptor protein complexes, and uncoated vesicles that can spontaneously reassemble under appropriate conditions. In a slightly acidic solution containing calcium ions, clathrin complexes will reassemble independently of adaptor protein and membrane-bounded vesicles, resulting in empty shells called *clathrin cages*. Assembly occurs remarkably fast—within seconds, under favorable conditions. Ease of assembly and disassembly is an important feature of the clathrin coat because fusion of the underlying membrane with the membrane of another structure appears to require partial or complete uncoating of the vesicle.

COPI- and COPII-Coated Vesicles Travel Between the ER and Golgi Complex Cisternae

COPI-coated vesicles have been found in all eukaryotic cells examined, including mammalian, insect, plant, and yeast cells. They are involved in retrograde transport from the Golgi complex back to the ER as well as bidirectional transport between Golgi complex cisternae. COPI-coated vesicles are surrounded by coats composed of **COPI** protein and **ADP ribosylation factor** (ARF), a small GTP-binding protein. The major component of the coat, COPI, is a protein multimer composed of seven subunits.

Assembly of a COPI coat is mediated by ARF. In the cytosol, ARF occurs as part of an ARF-GDP complex. However, when ARF encounters a specific *guanine nucleotide exchange factor* associated with the membrane (from which a new coated vesicle is about to form), the GDP is exchanged for GTP. This induces a conformational change in ARF that exposes its hydrophobic N-terminal region, which attaches to the lipid bilayer of the membrane. Once firmly anchored, ARF binds to COPI multimers, and assembly of the coat drives the formation and budding of a new vesicle. After the formation of a free vesicle, a protein in the donor membrane triggers hydrolysis of GTP, and the resulting ARF-GDP releases the coat proteins for another cycle of vesicle budding. Our knowledge of COP-mediated vesicle transport has been aided considerably by using the fungal toxin *brefeldin A*, which inhibits this process by interfering with the ability of the guanine nucleotide exchange factor to produce ARF-GTP from ARF-GDP.

COPII-coated vesicles were first discovered in yeast, where they have a role in transport from the ER to the Golgi complex. Mammalian and plant homologues of some of the components of COPII coats have been identified, and the COPII-mediated mechanism of ER export appears to be highly conserved between organisms as different as yeast and humans. The COPII coat found in yeast is assembled from two protein complexes—called *Sec13/31* and *Sec23/24*—and a small GTP-binding protein called *Sar1*, which is similar to ARF. By a mechanism resembling formation of a COPI coat, a Sar1 molecule with GDP bound to it approaches the membrane from which a vesicle is about to form. A peripheral membrane protein then triggers exchange of GTP for GDP, enabling Sar1 to bind to Sec13/31 and Sec23/24. After the formation of a free vesicle, a component of the COPII coat triggers GTP hydrolysis, and Sar1 releases Sec13/31 and Sec23/24.

SNARE Proteins Mediate Fusion Between Vesicles and Target Membranes

Much of the intracellular traffic mediated by coated vesicles is highly specific. As we have seen, the final sorting of proteins synthesized in the ER occurs in the TGN when lipids and proteins are packaged into vesicles for transport to various destinations. Recall that when clathrin-coated vesicles form from the TGN, the adaptor complexes include two adaptin subunits. The two adaptin subunits are partly

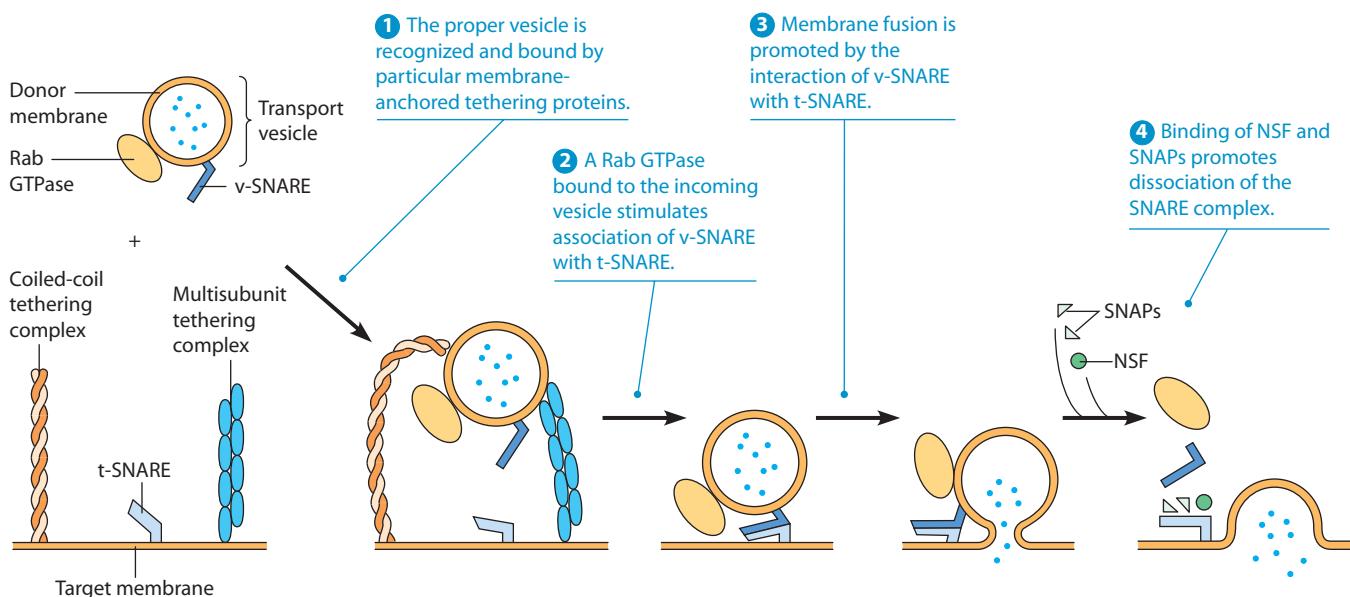

FIGURE 12-19 The SNARE Hypothesis for Transport Vesicle Targeting and Fusion. The basic molecular components that mediate sorting and targeting of vesicles in eukaryotic cells include tethering proteins, v-SNAREs on transport vesicles, t-SNAREs on target membranes, Rab GTPase, NSF, and several SNAPS. The exact timing of GTP or ATP hydrolysis is still unclear, but it most likely occurs after vesicle fusion.

responsible for the specificity displayed when receptors are concentrated for inclusion in a budding vesicle.

Once a vesicle forms, however, additional proteins are needed to ensure delivery of the vesicle to the appropriate destination. Therefore, there must be a mechanism to keep the various vesicles in the cell from accidentally fusing with the wrong membrane. The **SNARE hypothesis** provides a working model for this important sorting and targeting step in intracellular transport (Figure 12-19).

According to the SNARE hypothesis, the proper sorting and targeting of vesicles in eukaryotic cells involves two families of **SNARE (SNAP receptor) proteins**: the **v-SNAREs (vesicle-SNAP receptors)** found on transport vesicles and the **t-SNAREs (target-SNAP receptors)** found on target membranes. The v-SNAREs and t-SNAREs are complementary molecules that, along with additional tethering proteins, allow a vesicle to recognize and fuse with a target membrane. Both v-SNAREs and t-SNAREs were originally investigated because of their role in neuronal exocytosis. Since their discovery in brain tissue, both families of proteins have also been implicated in transport from the ER to the Golgi complex in yeast and other organisms.

When a vesicle reaches its destination, a third family of proteins, the **Rab GTPases**, comes into play. Rab GTPases are also specific: Vesicles fated for different destinations have distinct members of the Rab family associated with them. As illustrated in Figure 12-19, the affinity of complementary v-SNAREs and t-SNAREs for one another enables them to form a stable complex. This ensures that, when these proteins collide, they will remain in contact long enough for a Rab protein associated with the vesicle to lock the complementary t-SNARE and v-SNARE together, facilitating membrane fusion.

Following vesicle fusion, **N-ethylmaleimide-sensitive factor (NSF)** and a group of **soluble NSF attachment proteins (SNAPS)** mediate release of the v- and t-SNAREs of the donor and target membranes. ATP hydrolysis may be involved at this step, but its precise role is unclear. NSF and SNAPS are involved in fusion between a variety of cellular membranes, indicating they are not responsible for specificity during targeting.

SNARE proteins are required for the fusion of neurotransmitter-containing vesicles with the plasma membrane of nerve cells. This fusion event releases the neurotransmitter by exocytosis, leading to an electrical impulse that will initiate muscle contraction. Botulinum toxin (Botox), produced by the bacterium *Clostridium botulinum*, is a protease that cleaves a SNARE protein that is required for this fusion. Thus, the toxin interferes with muscle contraction and can cause paralysis. Although it is one of the most potent biological toxins known, in very small doses Botox can be used therapeutically to control muscle spasms or correct crossed eyes. It is also used cosmetically to remove wrinkles caused by muscle contractions in the skin. Currently, it is being investigated for possible use as a treatment for migraine headaches.

Recent research suggests that SNARE proteins alone cannot account for the specificity observed in vesicle targeting. A different class of proteins known as **tethering proteins** acts over longer distances and provides specificity by connecting vesicles to their target membranes prior to v-SNARE/t-SNARE interaction (Figure 12-19). We know this because experimental toxin-induced cleavage of SNARE proteins *in vivo* can block SNARE complex formation without blocking vesicle association with the target membrane. Also, in an *in vitro* reconstituted

system, ER-derived vesicles can attach to Golgi membranes without addition of SNARE proteins.

Two main groups of tethering proteins are known at present—*coiled-coil proteins* and *multisubunit complexes*. Coiled-coil proteins such as the **golgins** are important in the initial recognition and binding of COPI- or COPII-coated vesicles to the Golgi. The golgins are anchored by one end to the Golgi membrane and use the other end to contact the appropriate passing vesicle. We know that these proteins are also important in connecting Golgi cisternae to each other because antibodies directed against certain golgins block the action of the golgins and disrupt the structure of the Golgi medial cisternae.

The second class of tethering proteins consists of several families of multisubunit protein complexes containing four to eight or more individual polypeptides. For example, the *exocyst* complex of yeast and mammals is important for protein secretion, binding both to the plasma membrane and to vesicles from the TGN whose contents are destined for export. Other types of multisubunit tethering complexes such as the *COG* (*conserved oligomeric Golgi*) complex, the *GARP* (*Golgi-associated retrograde protein*) complex, and the *TRAPP* (*transport protein particle*) complex are implicated in the initial recognition and specificity of vesicle–target membrane interaction. Most of the proteins in these complexes are highly conserved among organisms as different as yeast and humans. Identifying the functions of these complexes and the roles of their individual subunits is currently one of the most intriguing frontiers of modern cell biology.

Lysosomes and Cellular Digestion

The **lysosome** is an organelle of the endomembrane system that contains digestive enzymes capable of degrading all the major classes of biological macromolecules—lipids, carbohydrates, nucleic acids, and proteins. These hydrolytic enzymes degrade extracellular materials brought into the cell by endocytosis and digest intracellular structures and macromolecules that are damaged or no longer needed. We will first look at the organelle itself and then consider lysosomal digestive processes, as well as some of the diseases that result from lysosomal malfunction.

Lysosomes Isolate Digestive Enzymes from the Rest of the Cell

As we learned in Chapter 4, lysosomes were discovered in the early 1950s by Christian de Duve and his colleagues (see Box 4B, page 92). Differential centrifugation led the researchers to realize that an acid phosphatase initially thought to be located in the mitochondrion was in fact associated with a class of particles that had never been reported before. Along with the acid phosphatase, the new organelle contained several other hydrolytic enzymes, including β -glucuronidase, a deoxyribonuclease, a ribonuclease, and a protease. Because of its apparent role in cellular lysis, de Duve called this newly discovered organelle a *lysosome*.

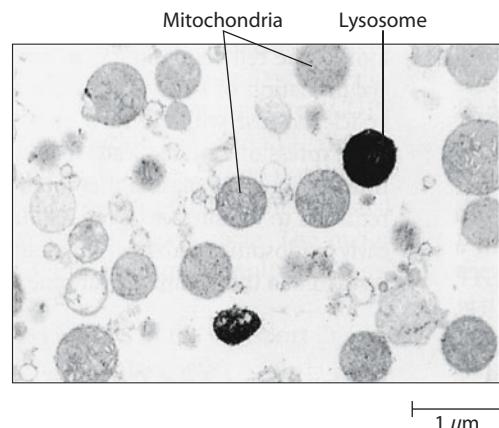

FIGURE 12-20 Cytochemical Localization of Acid Phosphatase, a Lysosomal Enzyme.

Phosphatase, a Lysosomal Enzyme. Tissue was incubated in a medium containing soluble lead nitrate and β -glycerophosphate, which is cleaved by acid phosphatase, producing free glycerol and phosphate anions. The phosphate anions react with lead ions to form insoluble lead phosphate, which precipitates at the site of enzyme activity and reveals the location of acid phosphatase within the cell. The darkly stained organelles shown here are lysosomes highlighted by deposits of the electron-dense lead phosphate. They are surrounded by mitochondria, which lack acid phosphatase and do not become electron dense (TEM).

Only after the lysosome's existence had been predicted, its properties described, and its enzyme content specified was the organelle actually observed by electron microscopy and recognized as a normal constituent of most animal cells. Final confirmation came from cytochemical staining reactions capable of localizing the acid phosphatase and other lysosomal enzymes to specific structures that can be seen by electron microscopy (Figure 12-20).

Lysosomes vary considerably in size and shape but are generally about $0.5\text{ }\mu\text{m}$ in diameter. Like the ER and Golgi complex, the lysosome is bounded by a single membrane. This membrane protects the rest of the cell from the hydrolytic enzymes in the lysosomal lumen. The luminal side of lysosomal membrane proteins is highly glycosylated, forming a nearly continuous carbohydrate coating that appears to protect membrane proteins from lysosomal proteases. ATP-dependent proton pumps in the membrane maintain an acidic environment (pH 4.0–5.0) within the lysosome. This favors enzymatic digestion of macromolecules both by activating acid hydrolases and by partially denaturing the macromolecules targeted for degradation. The products of digestion are then transported across the membrane to the cytosol, where they enter various synthetic pathways or are exported from the cell.

The list of lysosomal enzymes has expanded considerably since de Duve's original work, but all have the common property of being *acid hydrolases*—hydrolytic enzymes with a pH optimum around 5.0. The list includes at least 5 phosphatases, 14 proteases and peptidases, 2 nucleases, 6 lipases, 13 glycosidases, and 7 sulfatases. Taken together, these lysosomal enzymes can digest all the major classes of biological molecules. No wonder, then,

that they are sequestered from the rest of the cell, where they cannot quickly destroy the cell itself.

Lysosomes Develop from Endosomes

Lysosomal enzymes are synthesized by ribosomes attached to the rough ER and are translocated through a pore in the ER membrane into the ER lumen before transport to the Golgi complex. After modification and processing in the ER and Golgi complex compartments, the lysosomal enzymes are sorted from other proteins in the TGN. Earlier in the chapter, we described the addition of a unique mannose-6-phosphate tag to soluble lysosomal enzymes. Distinctive sorting signals are also present on membrane-bound lysosomal proteins. The lysosomal enzymes are packaged in clathrin-coated vesicles that bud from the TGN, lose their protein coats, and travel to one of the endosomal compartments (see Figure 12-9).

Lysosomal enzymes are delivered from the TGN to endosomes in transport vesicles, as shown in **Figure 12-21**. Recall that early endosomes are formed by the coalescence of vesicles from the TGN and vesicles from the plasma membrane. Over time, the early endosome matures to form a late endosome, an organelle having a full complement of acid hydrolases but not engaged in digestive activity. As the pH of the early endosomal lumen drops from about 6.0 to 5.5, the organelle loses its capacity to fuse with endocytic vesicles. The late endosome is essentially a collection of newly synthesized digestive enzymes as well as extracellular

and intracellular material fated for digestion, packaged in a way that protects the cell from hydrolytic enzymes.

The final step in lysosome development is the activation of the acid hydrolases, which occurs as the enzymes and their substrates encounter a more acidic environment. There are two ways eukaryotic cells accomplish this step. ATP-dependent proton pumps may lower the pH of the late endosomal lumen to 4.0–5.0, transforming the late endosome into a lysosome, thereby generating a new organelle. Alternatively, the late endosome may transfer material to the acidic lumen of an existing lysosome.

Lysosomal Enzymes Are Important for Several Different Digestive Processes

Lysosomes are important for cellular activities as diverse as nutrition, defense, recycling of cellular components, and differentiation. We can distinguish the digestive processes that depend on lysosomal enzymes by the site of their activity and by the origin of the material that is digested, as shown in Figure 12-21. Usually, the site of activity is intracellular. In some cases, though, lysosomes may release their enzymes to the outside of the cell by exocytosis. The materials to be digested are often of extracellular origin, although there are also important processes known to involve lysosomal digestion of internal cellular components.

To distinguish between mature lysosomes of different origins, we refer to those containing substances of extracellular origin as **heterophagic lysosomes**, whereas those with

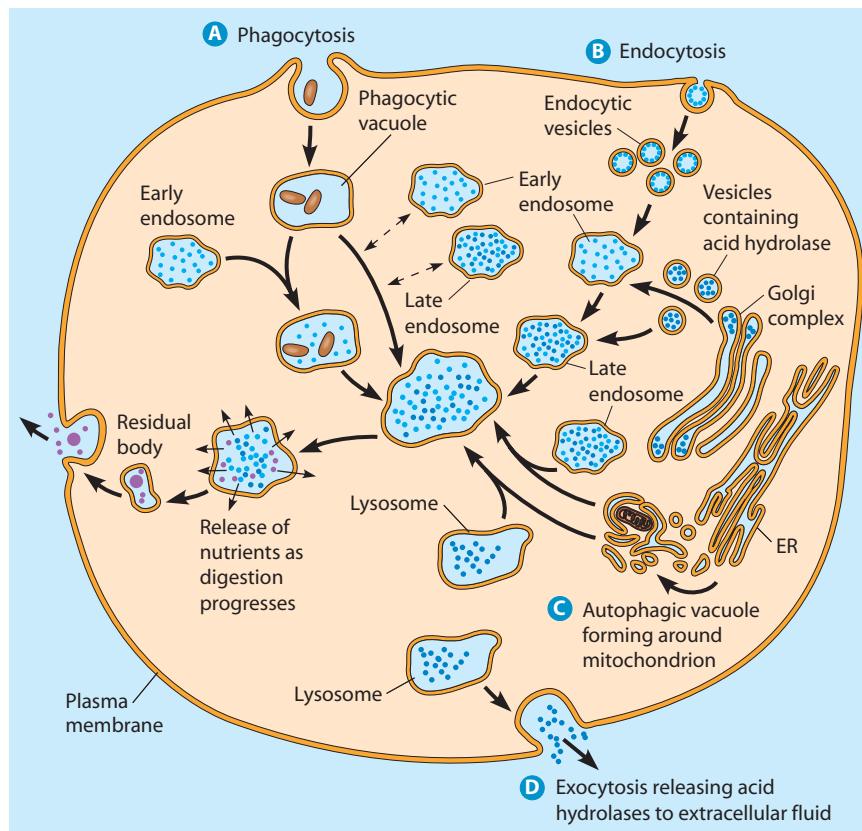

FIGURE 12-21 The Formation of Lysosomes and Their Roles in Cellular Digestive Processes. Illustrated in this composite cell are the major processes in which lysosomes are involved. The pathways depicted are **A** phagocytosis, **B** receptor-mediated endocytosis, **C** autophagy, and **D** extracellular digestion. For clarity, the nucleus is not shown.

materials of intracellular origin are called **autophagic lysosomes**. The specific processes in which lysosomal enzymes are involved are *phagocytosis*, *receptor-mediated endocytosis*, *autophagy*, and *extracellular digestion*. These are illustrated in Figure 12-21 as pathways **A**, **B**, **C**, and **D**, respectively.

Phagocytosis and Receptor-Mediated Endocytosis: Lysosomes in Defense and Nutrition. One of the most important functions of lysosomal enzymes is the degradation of foreign material brought into eukaryotic cells by *phagocytosis* and *receptor-mediated endocytosis* (see Figures 12-14 and 12-15). Phagocytic vacuoles are transformed into lysosomes by fusing with early endosomes (Figure 12-21, pathway **A**). Depending on the material ingested, these lysosomes can vary considerably in size, appearance, content, and stage of digestion. Vesicles containing material brought into a cell by receptor-mediated endocytosis also form early endosomes (pathway **B** of Figure 12-21). As early endosomes fuse with vesicles from the TGN containing acid hydrolases, they mature to form late endosomes and lysosomes, in which the ingested material is digested.

Soluble products of digestion, such as sugars, amino acids, and nucleotides, are then transported across the lysosomal membrane into the cytosol and are used as a source of nutrients by the cell. Some may cross by facilitated diffusion, whereas others undergo active transport. The acidity of the lysosomal lumen contributes to an electrochemical proton gradient across the lysosomal membrane, which can provide energy for driving transport to and from the cytosol.

Eventually, however, only indigestible material remains in the lysosome, which becomes a **residual body** as digestion ceases. In protozoa, residual bodies routinely fuse with the plasma membrane and expel their contents to the outside by exocytosis, as illustrated in Figure 12-21. In vertebrates, residual bodies may accumulate in the cytoplasm. This accumulation of debris is thought to contribute to cellular aging, particularly in long-lived cells such as those of the nervous system.

Certain white blood cells of the immune system, however, use this residual material. After neutrophils digest invading microorganisms via phagocytosis and lysosome action, they release the debris, which is picked up by scavenging macrophages. These macrophages transport the debris to the lymph nodes and present it to other immune system cells (B and T lymphocytes) to “educate” them regarding what foreign material has been found in the body. This process causes the lymphocytes to form memory cells that will quickly respond in case the same microorganism is encountered in the future.

Autophagy: A Biological Recycling System. A second important task for lysosomes is the breakdown of cellular structures and components that are damaged or no longer needed. Most cellular organelles are in a state of dynamic flux, with new organelles continuously being synthesized while old organelles are destroyed. The digestion of old or unwanted organelles or other cell structures is called

FIGURE 12-22 Autophagic Digestion. Early and late stages of autophagic digestion are shown here in a rat liver cell. At the top, an autophagic vacuole is formed as a mitochondrion is sequestered by a membrane derived from the ER. At the bottom are several autophagic vacuoles containing remnants of mitochondria (TEM). Most old organelles are eliminated through autophagic digestion.

autophagy, which is Greek for “self-eating.” Autophagy is illustrated as pathway **C** in Figure 12-21.

There are two types of autophagy—*macrophagy* and *microphagy*. **Macrophagy** begins when an organelle or other structure becomes wrapped in a double membrane derived from the ER. The resulting vesicle is called an **autophagic vacuole** (or **autophagosome**). It is often possible to see identifiable remains of cellular structures in these vacuoles, as shown in **Figure 12-22**. **Microphagy** involves formation of a much smaller autophagic vacuole, surrounded by a single phospholipid bilayer

that encloses small bits of cytoplasm rather than whole organelles.

Autophagy occurs at varying rates in most cells under most conditions, but it is especially prominent in red blood cell development. As a red blood cell matures, virtually all of the intracellular content is destroyed, including all of the mitochondria. This destruction is accomplished by autophagic digestion. A marked increase in autophagy is also noted in cells stressed by starvation. Presumably, the process represents a desperate attempt by the cell to continue providing for its energy needs, even if it has to consume its own structures to do so.

It has long been suspected that some cancer cells may be deficient in autophagy, but recent work suggests a direct link between autophagy and cancer. The human version of a gene required for autophagy in yeast cells has been shown to be frequently deleted in human breast and ovarian tumors. Knocking out the function of this gene in mice caused a decrease in autophagy and an increase in the number of breast and lung tumors. However, some oncogenes that promote cancer suppress autophagy during tumor development. Clearly, more research is needed.

Extracellular Digestion. While most digestive processes involving lysosomal enzymes occur intracellularly, in some cases lysosomes discharge their enzymes to the outside of the cell by exocytosis, resulting in **extracellular digestion** (Figure 12-21, pathway D). One example of extracellular digestion occurs during fertilization of animal eggs. The head of the sperm releases lysosomal enzymes capable of degrading chemical barriers that would otherwise keep the sperm from penetrating the egg surface. Certain inflammatory diseases, such as rheumatoid arthritis, may result from the inadvertent release of lysosomal enzymes by white blood cells in the joints, damaging the joint tissue. The steroid hormones cortisone and hydrocortisone are thought to be effective anti-inflammatory agents because of their role in stabilizing lysosomal membranes and thereby inhibiting enzyme release.

Lysosomal Storage Diseases Are Usually Characterized by the Accumulation of Indigestible Material

The essential role of lysosomes in the recycling of cellular components is clearly seen in disorders caused by deficiencies of specific lysosomal proteins. Over 40 such **lysosomal storage diseases** are known, each characterized by the harmful accumulation of specific substances, usually polysaccharides or lipids (see Box 4A, page 86). In most cases, the substances accumulate because digestive enzymes are defective or missing, but they sometimes accumulate because the proteins that transport degradation products from the lysosomal lumen to the cytosol are defective. In either case, the cells in which material accumulates are severely impaired or destroyed. Skeletal deformities, muscle weakness, and mental retardation commonly result, and are often fatal. Unfortunately, most lysosomal storage diseases are not yet treatable.

The first storage disease to be understood was *type II glycogenesis*, in which young children accumulate excessive amounts of glycogen in the liver, heart, and skeletal muscles and die at an early age. The problem turned out to be a defective form of the lysosomal enzyme α -1,4-glucosidase, which catalyzes glycogen hydrolysis in normal cells. Although glycogen metabolism occurs predominantly in the cytosol, a small amount of glycogen can enter the lysosome through autophagy and will accumulate to a damaging level if not broken down to glucose.

Two of the best-known lysosomal storage diseases are *Hurler syndrome* and *Hunter syndrome*. Both arise from defects in the degradation of glycosaminoglycans, which are the major carbohydrate components of the extracellular matrix (see Chapter 17). The defective enzyme in a patient with Hurler syndrome is α -L-iduronidase, which is required for the degradation of glycosaminoglycans. Electron microscopic observation of sweat gland cells from a patient with Hurler syndrome reveals large numbers of atypical vacuoles that stain for both acid phosphatase and undigested glycosaminoglycans. These vacuoles are apparently abnormal late endosomes filled with indigestible material.

Mental retardation is a common feature of lysosomal storage diseases. It can occur due to the impaired metabolism of glycolipids, which are important components of brain tissue and the sheaths of nerve cell axons. One particularly well-known example is *Tay-Sachs disease*, a condition inherited as a recessive trait. Afflicted children show rapid mental deterioration after about six months of age, followed by paralysis and death within three years. The disease results from the accumulation in nervous tissue of a particular glycolipid called a *ganglioside*. The missing lysosomal enzyme in this case is β -N-acetylhexosaminidase, which is responsible for cleaving the terminal N-acetylgalactosamine from the carbohydrate portion of the ganglioside. Lysosomes from children afflicted with Tay-Sachs disease are filled with membrane fragments containing undigested gangliosides.

The Plant Vacuole: A Multifunctional Organelle

Plant cells contain acidic membrane-enclosed compartments called vacuoles that resemble the lysosomes found in most animal cells but generally serve additional roles. The biogenesis of a vacuole parallels that of a lysosome. Most of the components are synthesized in the ER and transferred to the Golgi complex, where proteins undergo further processing. Coated vesicles then convey lipids and proteins destined for the vacuole to a **provacuole**, which is analogous to an endosome. The provacuole eventually matures to form a functional vacuole that can fill as much as 90% of the volume of a plant cell.

In addition to confining hydrolytic enzymes, plant vacuoles have various other essential functions. Most of these functions reflect the plant's lack of mobility and consequent susceptibility to changes in the surrounding environment. As mentioned in Chapter 4, a major role of the vacuole is to

maintain *turgor pressure*, the osmotic pressure that prevents plant cells from collapsing. Turgor pressure prevents a plant from wilting, and it can drive the expansion of cells. During development, softening of the cell wall—accompanied by higher turgor pressure—allows the cell to expand.

Another role of the plant vacuole is the regulation of cytosolic pH. ATP-dependent proton pumps in the vacuolar membrane can compensate for a decline in cytosolic pH (perhaps due to a change in the extracellular environment) by transferring protons from the cytosol to the lumen of the vacuole.

The vacuole also serves as a storage compartment. Seed storage proteins are generally synthesized by ribosomes attached to the rough ER and cotranslationally inserted into the ER lumen. Some of the storage proteins remain in the ER while others are transferred to vacuoles, either by autophagy of vesicles budding from the ER or by way of the Golgi. When the seeds germinate, the storage proteins are available for hydrolysis by vacuolar proteases, thereby releasing amino acids for the biosynthesis of new proteins needed by the growing plant.

Other substances found in vacuoles include malate stored in CAM plants (Chapter 11), the anthocyanins that impart color to flowers, toxic substances that deter predators, inorganic and organic nutrients, compounds that shield cells from ultraviolet light, and residual indigestible waste. Storage of soluble as well as insoluble waste is an important function of plant vacuoles. Unlike animals, most plants do not have a mechanism for excreting soluble waste from the organism. The large vacuoles found in plant cells enable the cells to accumulate solutes to a degree that would inhibit or restrict metabolic processes if the material were to remain in the cytosol.

Peroxisomes

Peroxisomes, like the Golgi complex, endosomes, and lysosomes, are bounded by single membranes. However, they are not derived from the endoplasmic reticulum and are therefore not part of the endomembrane system that includes the other organelles discussed in this chapter. Peroxisomes are found in all eukaryotic cells but are especially prominent in mammalian kidney and liver cells, in algae and photosynthetic cells of plants, and in germinating seedlings of plant species that store fat in their seeds. Peroxisomes are somewhat smaller than mitochondria, though there is considerable variation in size, depending on their function and the tissue where they are found.

Regardless of location or size, the defining characteristic of a peroxisome is the presence of *catalase*, an enzyme essential for the degradation of hydrogen peroxide (H_2O_2). Hydrogen peroxide is a potentially toxic compound that is formed by a variety of oxidative reactions catalyzed by *oxidases*. Both catalase and the oxidases are confined to peroxisomes. Thus, the generation and degradation of H_2O_2 occur within the same organelle, thereby protecting other parts of the cell from exposure to this harmful compound. Before discussing the functions of peroxisomes

further, let us look at how peroxisomes were discovered and how they are distinguished from other organelles when viewed by electron microscopy.

The Discovery of Peroxisomes Depended on Innovations in Equilibrium Density Centrifugation

Christian de Duve and his colleagues discovered not only lysosomes, but also peroxisomes. During the course of their early studies on lysosomes, they encountered at least one enzyme, *urate oxidase*, that was associated with lysosomal fractions but was not an acid hydrolase. By using a gradient of sucrose concentration, the researchers found that urate oxidase from rat liver was recovered in a region of the gradient having a slightly higher density than that of other organelles, such as lysosomes and mitochondria (see Figure 12A-4).

Once separation of this new organelle was achieved, additional enzymes were identified in the fractions containing urate oxidase, including catalase and *D-amino acid oxidase*. Catalase, as we have seen, degrades H_2O_2 . Like urate oxidase, *D*-amino acid oxidase generates H_2O_2 . Because of its apparent involvement in hydrogen peroxide metabolism, the new organelle became known as a *peroxisome*. Other peroxisomal enzymes have since been identified, and it is now clear that the enzyme complement of the organelle varies significantly from species to species, from organ to organ, and in some cases from one developmental stage to another within the same organ. However, the presence of catalase and one or more hydrogen peroxide-generating oxidases remains a distinguishing characteristic of all peroxisomes.

Once peroxisomes had been identified and isolated biochemically, the existence of organelles with the expected properties was confirmed by electron microscopy. Peroxisomes turned out to be the functional equivalents of organelles that had been seen earlier in electron micrographs of both animal and plant cells. Because their function was not known at the time, these organelles were simply called *microbodies*. In both plant and animal cells, peroxisomes are usually about 0.2–2.0 μm in diameter, are surrounded by a single membrane, and generally have a finely granular or crystalline interior.

As seen in **Figure 12-23**, animal peroxisomes often contain a distinct crystalline core, which usually consists of a crystalline form of urate oxidase. Crystalline cores consisting of catalase may be present in the peroxisomes of plant leaves (see Figure 4-20). When such crystals are present, it is easy to identify peroxisomes, since urate oxidase and catalase are two of the enzymes by which peroxisomes are defined. In the absence of a crystalline core, however, it is not always easy to spot peroxisomes ultrastructurally.

A useful technique in such cases is a cytochemical test for catalase called the *diaminobenzidine (DAB) reaction*. Catalase oxidizes DAB to a polymeric form that causes deposition of electron-dense osmium atoms when the tissue is treated with osmium tetroxide. The resulting electron-dense deposits can be readily seen in cells from

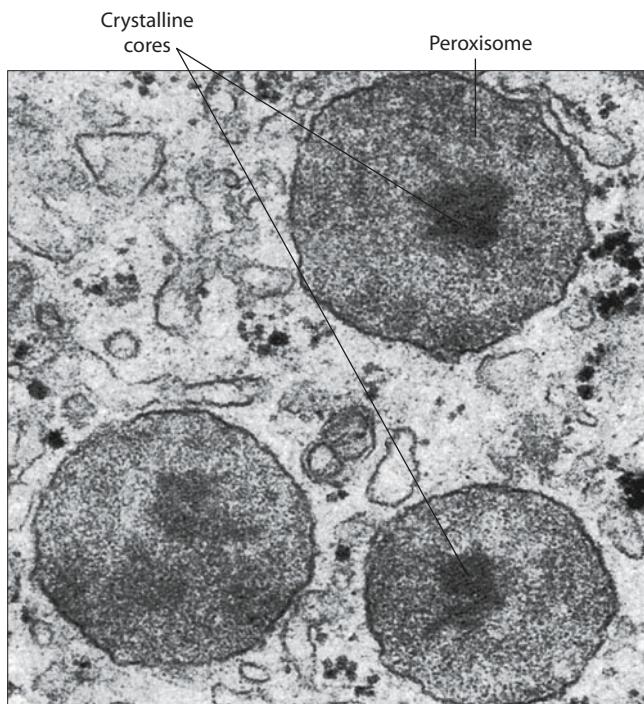

FIGURE 12-23 Peroxisomes in Animal Cells. This electron micrograph shows several peroxisomes (microbodies) in the cytoplasm of a rat liver cell. A crystalline core is readily visible in each microbody. In animal microbodies, the cores are almost always crystalline urate oxidase (TEM).

stained tissue. In animal peroxisomes, the entire internal space often stains intensely with DAB, indicating that catalase exists as a soluble enzyme uniformly distributed throughout the matrix of the organelle. Similarly, in plant leaf peroxisomes lacking a crystalline core of catalase, DAB staining is observed through the entire peroxisome (Figure 12-24). Because catalase is the single enzyme present in all peroxisomes and does not routinely occur in any other organelle, the DAB reaction is a reliable and specific means of identifying organelles as peroxisomes.

Most Peroxisomal Functions Are Linked to Hydrogen Peroxide Metabolism

Peroxisomes occur widely in animals, plants, algae, and some fungi. In animals, peroxisomes are most prominent in liver and kidney tissue. The essential roles of peroxisomes in eukaryotic cells have become more apparent in recent years, stimulating new research into the metabolic pathways and the disorders arising from defective components of the pathways found in these organelles. There are at least five general categories of peroxisomal functions that we will discuss in the sections below: hydrogen peroxide metabolism, detoxification of harmful compounds, oxidation of fatty acids, metabolism of nitrogen-containing compounds, and catabolism of unusual substances.

Hydrogen Peroxide Metabolism. A significant role of peroxisomes in eukaryotic cells is the detoxification of

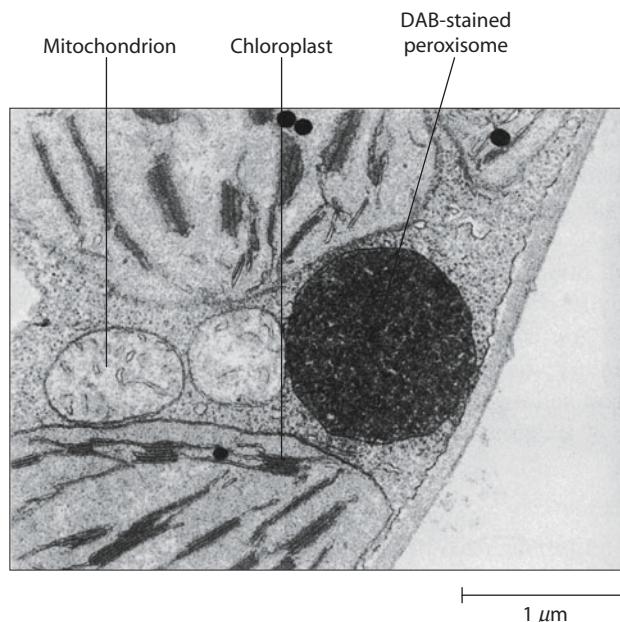

FIGURE 12-24 Cytochemical Localization of Catalase in Plant Peroxisomes. Shown here is a tobacco leaf cell similar to the one shown in Figure 4-20, but stained by diaminobenzidine (DAB). The principle of this assay is similar to that of the cytochemical test for acid phosphatase described in Figure 12-20. Catalase oxidizes DAB to a polymeric form that causes the deposition of electron-dense osmium atoms in tissue treated with osmium tetroxide (OsO_4). The DAB technique reveals that the deposition of osmium is confined to peroxisomes and thus that catalase is a component of the crystalline core (TEM).

H_2O_2 by catalase, which can comprise up to 15% of the total protein in the peroxisome. The oxidases that generate H_2O_2 in peroxisomes transfer electrons plus hydrogen ions (hydrogen atoms) from their substrates to molecular oxygen (O_2), reducing it to H_2O_2 . Using RH_2 to represent an oxidizable substrate, the general reaction catalyzed by oxidases can be written as

The hydrogen peroxide formed in this manner is broken down by catalase in one of two ways. Usually, catalase functions by detoxifying two molecules of H_2O_2 simultaneously—one is oxidized to oxygen, and a second is reduced to water:

Alternatively, catalase can function as a *peroxidase*, in which electrons derived from an organic donor are used to reduce hydrogen peroxide to water:

(The prime on the R group simply indicates that this substrate is likely to be different from the substrate in Reaction 12-3.)

The result is the same in either case: Hydrogen peroxide is degraded without ever leaving the peroxisome. Given the toxicity of hydrogen peroxide (which is the main active ingredient in a variety of disinfectants), it

makes good sense for the enzymes responsible for peroxide generation to be compartmentalized together with the catalase that catalyzes its degradation.

Detoxification of Harmful Compounds. As a peroxidase (Reaction 12-5), catalase can use a variety of toxic substances as electron donors, including methanol, ethanol, formic acid, formaldehyde, nitrites, and phenols. Because all of these compounds are harmful to cells, their oxidative detoxification by catalase may be a vital peroxisomal function. The prominent peroxisomes of liver and kidney cells are thought to be important in such detoxification reactions.

In addition, peroxisomal enzymes are important in the detoxification of **reactive oxygen species** such as H_2O_2 , superoxide anion (O_2^-), hydroxyl radical ($\text{OH}\cdot$ where the dot signifies an unpaired, highly reactive electron), and organic peroxide conjugates. These reactive oxygen species can be formed in the presence of molecular oxygen during normal cellular metabolism, and if they accumulate the cell can suffer from *oxidative stress*. Peroxisomal enzymes such as *superoxide dismutase*, catalase, and peroxidases detoxify these reactive oxygen species, preventing their accumulation and subsequent oxidative damage to cellular components.

Oxidation of Fatty Acids. Peroxisomes found in animal, plant, and fungal cells contain enzymes necessary for oxidizing fatty acids via β oxidation to provide energy for the cell. About 25–50% of fatty acid oxidation in animal tissues occurs in peroxisomes, with the remainder localized in mitochondria. In plant and yeast cells, on the other hand, all β oxidation occurs in peroxisomes.

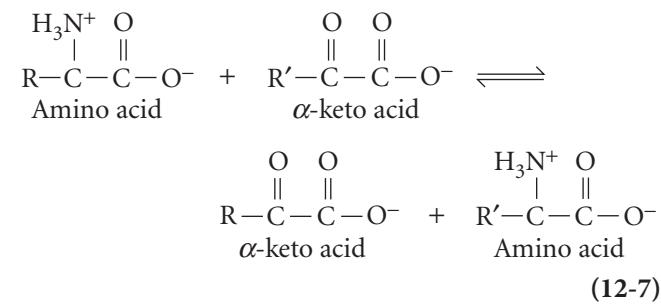

In animal cells, peroxisomal β oxidation is especially important for degrading long-chain (16–22 carbons), very long-chain (24–26 carbons), and branched fatty acids. The primary product of β oxidation, acetyl-CoA, is then exported to the cytosol, where it enters biosynthetic pathways or the TCA cycle. Once fatty acids are shortened to fewer than 16 carbons, further oxidation usually occurs in the mitochondria. Thus, in animal cells, the peroxisome is important for shortening fatty acids in preparation for subsequent metabolism in the mitochondrion rather than completely breaking them down to acetyl-CoA. In plants and yeast, on the other hand, peroxisomes are essential for the complete catabolism of all fatty acids to acetyl-CoA.

Metabolism of Nitrogen-Containing Compounds. Except for primates, most animals require *urate oxidase* (also called *uricase*) to oxidize urate, a purine that is formed during the catabolism of nucleic acids and some proteins. Like other oxidases, urate oxidase catalyzes the direct transfer of hydrogen atoms from the substrate to molecular oxygen, generating H_2O_2 :

As noted earlier, the H_2O_2 is immediately degraded in the peroxisome by catalase. The allantoin is further metabolized and excreted by the organism, either as allantoic acid or—in the case of crustaceans, fish, and amphibians—as urea.

Additional peroxisomal enzymes involved in nitrogen metabolism include *aminotransferases*. Members of this collection of enzymes catalyze the transfer of amino groups ($-\text{NH}_3^+$) from amino acids to α -keto acids:

Such enzymes play important roles in the biosynthesis and degradation of amino acids by moving amino groups from one molecule to another (see Figure 10-12).

Catabolism of Unusual Substances. Some of the substrates for peroxisomal oxidases are rare compounds for which the cell has no other degradative pathways. Such compounds include D-amino acids, which are not recognized by enzymes capable of degrading the L-amino acids found in polypeptides. In some cells, the peroxisomes also contain enzymes that break down unusual substances called **xenobiotics**, chemical compounds foreign to biological organisms. This category includes *alkanes*, short-chain hydrocarbon compounds found in oil and other petroleum products. Fungi containing enzymes capable of metabolizing such xenobiotics may turn out to be useful for cleaning up oil spills that would otherwise contaminate the environment.

Peroxisomal Disorders. Considering the variety of metabolic pathways found in peroxisomes, it is not surprising that a large number of disorders arise from defective peroxisomal proteins (see Box 4A, page 86). The most common peroxisomal disorder is *X-linked adrenoleukodystrophy*. The defective protein causing this disorder is an integral membrane protein that may be responsible for transporting very long-chain fatty acids into the peroxisome for β oxidation. Accumulation of these long-chain fatty acids in body fluids destroys the myelin sheath in nervous tissues.

Plant Cells Contain Types of Peroxisomes Not Found in Animal Cells

In plants and algae, peroxisomes are involved in several specific aspects of cellular energy metabolism, which we discussed in Chapters 10 and 11. Here, we will simply introduce several plant-specific peroxisomes and briefly describe their functions.

Leaf Peroxisomes. Cells of leaves and other photosynthetic plant tissues contain characteristic large, prominent **leaf peroxisomes**, which often appear in close contact with chloroplasts and mitochondria (see Figure 12-24; see also

Figure 4-20). The spatial proximity of the three organelles probably reflects their mutual involvement in the *glycolate pathway* (see Figure 11-15), also called the *photorespiratory pathway* because it involves the light-dependent uptake of O₂ and release of CO₂. Several enzymes of this pathway, including a peroxide-generating oxidase and two amino-transferases, are confined to leaf peroxisomes.

Glyoxysomes. Another functionally distinct type of plant peroxisome occurs transiently in seedlings of plant species that store carbon and energy reserves in the seed as fat (primarily triacylglycerols). In such species, stored triacylglycerols are mobilized and converted to sucrose during early postgerminative development by a sequence of events that includes β oxidation of fatty acids as well as a pathway known as the *glyoxylate cycle*. All of the enzymes needed for these processes are localized to specialized peroxisomes called **glyoxysomes** (see Box 10A, page 268).

Glyoxysomes are found only in the tissues where the fat is stored (endosperm or cotyledons, depending on the species) and are present only for the relatively short period of time required for the seedling to deplete its supply of stored fat. Once they fulfill their role in the seedling, the glyoxysomes are converted to peroxisomes. Glyoxysomes have been reported to appear again in the senescing (aging) tissues of some plant species, presumably to degrade lipids derived from the membranes of the senescent cells. However, the importance of their involvement in senescence is not yet clear.

Other Kinds of Plant Peroxisomes. In addition to their presence in tissues that carry out either photorespiration or β oxidation of fatty acids, peroxisomes are found in other plant tissues. For example, another kind of specialized peroxisome is present in *nodules*, the structures on plant roots in which plant cells and certain bacteria cooperate in the fixation of atmospheric nitrogen (that is, the conversion of N₂ into organic form). The peroxisomes in these cells are involved in the processing of fixed nitrogen.

Peroxisome Biogenesis Occurs by Division of Preexisting Peroxisomes

Like other organelles, peroxisomes increase in number as cells grow and divide. This proliferation of organelles is called *biogenesis*, and the peroxisomal proteins required for this process are known as *peroxins*. Biogenesis of endosomes and lysosomes occurs by fusion of vesicles budding from the Golgi complex, and peroxisomes were once thought to form from vesicles in a similar manner. Later, most investigators believed that peroxisome biogenesis occurred solely from the division of preexisting peroxisomes. Recent evidence suggests that new peroxisomes can be formed by either of these two methods, or perhaps by a combination of the two. Either way, their biogenesis raises two important questions.

First, where do the lipids that make up the newly synthesized peroxisomal membrane come from? We know that some of the lipids are synthesized by peroxisomal enzymes whereas others are synthesized in the ER and

carried to the peroxisome by phospholipid exchange proteins. However, there is some evidence that these exchange proteins may not always be efficient enough to account for the rapid incorporation of new lipids and that some direct transfer from ER-derived vesicles may be involved.

Second, where are the new enzymes and other proteins that are present in the peroxisomal membrane and matrix synthesized? Proteins destined for peroxisomes are synthesized on free cytosolic ribosomes and are incorporated into preexisting peroxisomes posttranslationally. This passage of polypeptides across the peroxisomal membrane is an ATP-dependent process mediated by specific membrane peroxins, although the precise role of ATP is unclear.

Figure 12-25 illustrates both the incorporation of membrane components, matrix enzymes, and enzyme cofactors from the cytosol into a peroxisome (steps 1–3) and the formation of new peroxisomes by division of a preexisting organelle (step 4). The protein depicted in the figure is catalase, a tetrameric protein with a heme group bound to each subunit. The subunits are synthesized

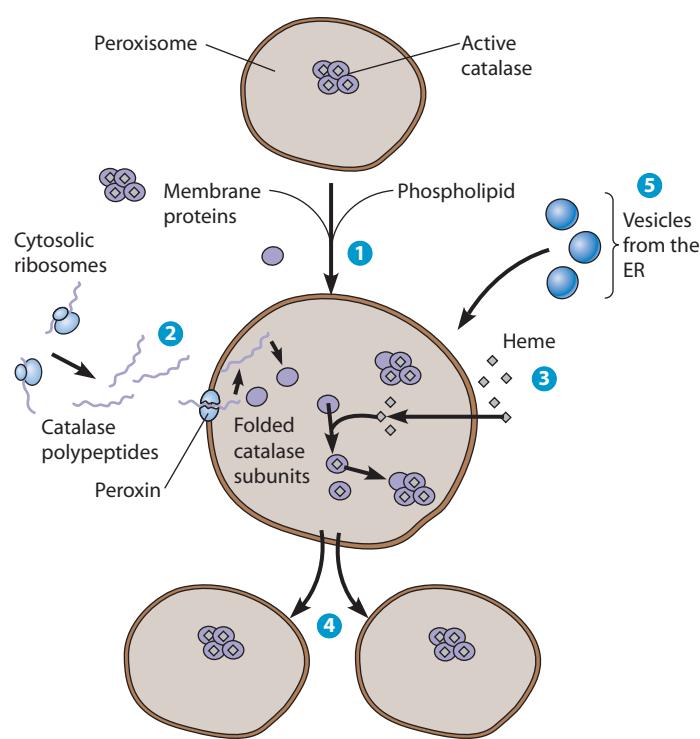

FIGURE 12-25 Biogenesis of Peroxisomes and Protein Import.

Import. New peroxisomes typically arise by the division of existing peroxisomes rather than by fusion of vesicles from the Golgi complex. ① Lipids and membrane proteins can be added to existing peroxisomes via cytosolic sources. ② Polypeptides for peroxisomal matrix enzymes are synthesized on cytosolic ribosomes and are threaded through the membrane via a transmembrane peroxin transport protein. The enzyme shown here is catalase, a tetrameric protein that requires a heme cofactor. ③ Heme enters the peroxisomal lumen via a separate pathway, and the catalase polypeptides are folded and assembled with heme to form the active tetrameric protein. ④ After lipids and protein are added, new peroxisomes are formed by the division of the existing peroxisomes. ⑤ Some researchers believe that peroxisomes can obtain proteins or form de novo from protoperoxisomal vesicles that are derived from the ER.

individually on cytosolic ribosomes, imported into the peroxisome, refolded, and then assembled, along with heme, into the active tetrameric enzyme. Peroxisomes can also import not only single, unfolded polypeptides but also larger, folded polypeptides and even native oligomeric proteins.

Recent work suggests that some peroxins are synthesized in the cytosol but then travel to the ER in vesicles before being incorporated into peroxisomes (step 5). Evidence for this route includes the presence on certain peroxins of N-linked oligosaccharides typical of ER-synthesized proteins. Additionally, treatment of yeast cells with the toxin brefeldin A, which prevents formation of ER-derived vesicles, causes accumulation of the peroxin *Pex3p* in the ER.

Similarly, in plant cells, ascorbate peroxidase appears to be routed to a subdomain of the ER after being synthesized in the cytosol but before being incorporated into the peroxisome. This proposed subdomain of the ER, presumably involved in sorting of cytosolic proteins destined for the peroxisome, has been termed the *peroxisomal ER* (*pER*), although its existence is still controversial. Likewise, the existence of the *protoperoxisome*, an ER-derived vesicle considered by some researchers to be capable of developing directly into a peroxisome, is currently the subject of much debate.

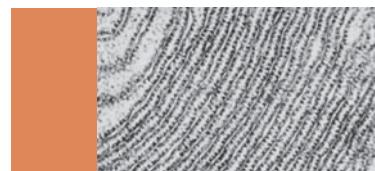

For posttranslational import to work, each protein destined for a specific organelle must have some sort of tag or signal that directs, or targets, the protein to the correct organelle. Such a signal functions by recognizing specific receptors or other features on the surface of the appropriate membrane. The signal in each case is a sequence of amino acids that differs in sequence, length, and location for proteins targeted to different organelles. The signal that targets at least some peroxisomal proteins to their destination consists of just three amino acids and is found at or near the carboxyl terminus of the molecule. For example, the most common sequence is SKL (Ser-Lys-Leu), though a limited

number of other amino acids are possible at each of the three locations.

This C-terminal tripeptide, known as *PTS-1 (peroxisomal targeting signal-1)*, is recognized and bound by the cytosolic peroxin *Pex5p*. A second peroxisomal targeting signal known as *PTS-2* is an N-terminal sequence recognized by the peroxin *Pex7p*. These PTS-binding peroxins deliver the PTS-containing proteins to the peroxisome for import by a mechanism that is not yet fully understood. At the peroxisomal membrane, *Pex5p* and *Pex7p* interact with one or more membrane-bound *docking proteins*. Then they are believed to enter the peroxisome carrying their cargo, which they release before they are exported from the peroxisome back to the cytosol to participate in subsequent transport cycles.

Suresh Subramani and others have shown that a protein normally targeted to the peroxisome by PTS-1 will remain in the cytosol if its SKL sequence is removed. Conversely, the addition of an SKL sequence to a cytosolic protein will direct the chimeric protein to the peroxisome. Thus the SKL sequence, or one of the acceptable variants, is both *necessary* and *sufficient* to direct proteins to peroxisomes. Moreover, a peroxisomal targeting sequence identified in one species often functions in other species, even when the organisms are as evolutionarily diverse from one another as plants, yeast, insects, and animals.

In one striking example, the gene for *luciferase*, a peroxisomal enzyme that enables fireflies to emit flashes of light, was transferred into plant cells from which whole plants were then grown. When cells of the genetically transformed plant were carefully examined, the luciferase was found in peroxisomes, the same organelle in which it is located in fireflies. Knowledge of peroxisomal import mechanisms and the identification of numerous peroxins conserved between yeast and humans, coupled with the powerful genetic methods available in yeast model systems, will help us to understand and better treat human diseases caused by faulty peroxisome biogenesis or protein import.

SUMMARY OF KEY POINTS

The Endoplasmic Reticulum

- Especially prevalent within most eukaryotic cells is the endomembrane system, an elaborate array of membrane-bounded organelles derived from the endoplasmic reticulum (ER). The ER itself is a network of sacs, tubules, and vesicles surrounded by a single membrane that separates the ER lumen from the surrounding cytosol.
- The rough ER has ribosomes that synthesize proteins destined for the plasma membrane, for secretion, or for various organelles of the endomembrane system—the nuclear envelope, Golgi complex, endosomes, and

lysosomes. Both the rough and smooth ER synthesize lipids for cellular membranes. The smooth ER is also the site of drug detoxification, carbohydrate metabolism, calcium storage, and steroid biosynthesis in some cells.

The Golgi Complex

- The Golgi complex plays an important role in the glycosylation of proteins and in the sorting of proteins for transport to other organelles, for transport to the plasma membrane, or for secretion.

- Transition vesicles that bud from the ER fuse with the *cis*-Golgi network (CGN), delivering lipids and proteins to the Golgi complex. Proteins then move through the Golgi cisternae toward the *trans*-Golgi network (TGN).

Roles of the ER and Golgi Complex in Protein Glycosylation

- Before proteins leave the ER in transition vesicles, they undergo the first few steps of protein modification. ER-specific proteins catalyze core glycosylation and folding of polypeptides, elimination of misfolded proteins, and the assembly of multimeric proteins.
- During their journey through the Golgi complex, proteins are further modified as oligosaccharide side chains are trimmed or further glycosylated in the Golgi lumen.

Roles of the ER and Golgi Complex in Protein Trafficking

- Some ER-specific proteins have a retention signal that prevents them from leaving the ER as vesicles move from the ER to the CGN. Other ER proteins have a retrieval tag that allows them to return to the ER in vesicles that return from the CGN.
- Numerous transport vesicles bud from the TGN Golgi network and carry the processed proteins to their final destinations. The tag that identifies a particular protein and its destination may be a short amino acid sequence, an oligosaccharide side chain, or some other structural feature.
- Hydrolytic enzymes destined for the lysosome are phosphorylated on a mannose residue. Vesicles containing specific receptors for this mannose phosphate group carry these enzymes to the lysosome. During acidification in the lysosome, the enzymes are released from the receptors, which are then recycled back to the TGN.

Exocytosis and Endocytosis

- Exocytosis adds lipids and proteins to the plasma membrane when secretory granules release their contents to the extracellular medium by fusing with the plasma membrane. This addition of material to the plasma membrane is balanced by endocytosis, which removes lipids and proteins from the plasma membrane as extracellular material is internalized in vesicles.
- Phagocytosis is a type of endocytosis involving the ingestion of extracellular particles through invagination of the plasma membrane. Receptor-mediated endocytosis depends on highly specific binding of ligands to corresponding receptors on the cell surface. In both cases, after sorting of receptors and other necessary proteins back to the plasma membrane, ingested material is sent to lysosomes for digestion or to other locations for reuse.

Coated Vesicles in Cellular Transport Processes

- Transport vesicles carry material throughout the endomembrane system. Coat proteins—which include clathrin, COPI, COPII, and caveolin—participate in the sorting of molecules fated for different destinations as well as in the formation of vesicles.

- The specific coat proteins covering a vesicle indicate its origin and help determine its destination within the cell. Clathrin-coated vesicles deliver material from the TGN or plasma membrane to endosomes. COPII-coated vesicles carry materials from the ER to the Golgi, while COPI-coated vesicles transport material from the Golgi back to the ER.

- Once a transport vesicle nears its destination, it is recognized and bound by tethering proteins attached to the target membrane. At this point the v-SNAREs in the transport vesicle membrane and the t-SNAREs in the target membrane interact physically, helping to promote membrane fusion.

Lysosomes and Cellular Digestion

- Extracellular material obtained from phagocytosis or receptor-mediated endocytosis is sorted in early endosomes, which mature to form late endosomes and lysosomes as they fuse with vesicles containing inactive hydrolytic enzymes packaged in the TGN.
- The late endosomal membrane contains ATP-dependent proton pumps that lower the pH of the endosomal lumen and help to transform the late endosome into a lysosome. Then, latent acid hydrolases capable of degrading most biological molecules become active due to the low pH.
- Lysosomes also function in autophagy, the turnover and recycling of cellular structures that are damaged or no longer needed. In some cells, extracellular material is digested by enzymes that lysosomes discharge out of the cell by exocytosis.

The Plant Vacuole: A Multifunctional Organelle

- The plant vacuole is an acidic compartment resembling the animal lysosome. In addition to having hydrolytic enzymes for digestion of macromolecules, it helps the plant cell maintain positive turgor pressure and serves as a storage compartment for a variety of plant metabolites.

Peroxisomes

- Peroxisomes, which are not part of the endomembrane system, appear to increase in number by the division of preexisting organelles rather than by the coalescence of vesicles from the ER or Golgi. However, there is currently a debate concerning the existence of protoperoxisomes, vesicles that some researchers believe bud off from the ER and develop into new peroxisomes.
- Some peroxisomal membrane lipids are synthesized by peroxisomal enzymes, while others are carried from the ER by phospholipid exchange proteins. Most peroxisomal proteins are synthesized by cytosolic ribosomes and are imported posttranslationally. Others are believed to travel via a proposed subdomain of the ER known as the peroxisomal ER (pER).
- The defining enzyme of a peroxisome is catalase, an enzyme that degrades the toxic hydrogen peroxide that is generated by various oxidases in the peroxisome. Animal cell peroxisomes are important for detoxification of harmful substances, oxidation of fatty acids, and metabolism of nitrogen-containing compounds. In plants, peroxisomes play distinctive roles in the conversion of stored lipids into carbohydrate by glyoxysomes and in photorespiration by leaf peroxisomes.

MAKING CONNECTIONS

Now that we are halfway through our studies of cell biology, you should be familiar with many of the basic properties of cells and their components. As in many fields of biology, structure often determines function, and an understanding of cell chemistry and the macromolecules that make up cell structures and organelles is essential. You have learned how enzymes function and how cells get energy from the sun or from organic food molecules. In this chapter, you have used your knowledge of membrane structure and function to understand the movement of materials throughout the cell via the

endomembrane system. The second half of the text will focus on more specific aspects of cell biology. Among other things, you will learn how cells respond to external electrical and hormonal signals, how materials move inside cells, how cells themselves move, and how muscle cells contract. We will study how the extracellular matrix in animals and the cell wall in plants join cells together to form specialized tissues. Then we will focus on the roles of DNA and RNA in cell growth and reproduction, on the expression of genetic information, and, finally, on the defects in cell metabolism that can lead to cancer.

PROBLEM SET

More challenging problems are marked with a •.

12-1 Compartmentalization of Function. Each of the following processes is associated with one or more specific eukaryotic organelles. In each case, identify the organelle or organelles, and suggest one advantage of confining the process to the organelle or organelles.

- (a) β oxidation of long-chain fatty acids
- (b) Biosynthesis of cholesterol
- (c) Biosynthesis of insulin
- (d) Biosynthesis of testosterone or estrogen
- (e) Degradation of damaged organelles
- (f) Glycosylation of membrane proteins
- (g) Hydroxylation of phenobarbital
- (h) Sorting of lysosomal proteins from secretory proteins

12-2 Endoplasmic Reticulum. For each of the following statements, indicate if it is true of the rough ER only (R), of the smooth ER only (S), of both rough and smooth ER (RS), or of neither (N).

- (a) Contains less cholesterol than does the plasma membrane.
- (b) Has ribosomes attached to its outer (cytosolic) surface.
- (c) Is involved in the detoxification of drugs.
- (d) Is involved in the breakdown of glycogen.
- (e) Is the site for biosynthesis of secretory proteins.
- (f) Is the site for the folding of membrane-bound proteins.
- (g) Tends to form tubular structures.
- (h) Usually consists of flattened sacs.
- (i) Visible only by electron microscopy.

12-3 Biosynthesis of Integral Membrane Proteins. In addition to their role in cellular secretion, the rough ER and the Golgi complex are also responsible for the biosynthesis of integral membrane proteins. More specifically, these organelles are the source of glycoproteins commonly found in the outer phospholipid monolayer of the plasma membrane.

(a) In a series of diagrams, depict the synthesis and glycosylation of glycoproteins of the plasma membrane.

(b) Explain why the carbohydrate groups of membrane glycoproteins are always found on the outer surface of the plasma membrane.

(c) What assumptions did you make about biological membranes in order to draw the diagrams in part a and answer the question in part b?

12-4 Coated Vesicles in Intracellular Transport. For each of the following statements, indicate for which coated vesicle the statement is true: clathrin- (C), COPI- (I), or COPII-coated (II). Each statement may be true for one, several, or none (N) of the coated vesicles discussed in this chapter.

- (a) Binding of the coat protein to an LDL receptor is mediated by an adaptor protein complex.
- (b) Fusion of the vesicle (after dissociation of the coat) with the Golgi membrane is facilitated by specific t-SNARE and Rab proteins.
- (c) Has a role in bidirectional transport between the ER and Golgi complex.
- (d) Has a role in sorting proteins for intracellular transport to specific destinations.
- (e) Has a role in transport of acid hydrolases to late endosomes.
- (f) Is essential for all endocytic processes.
- (g) Is important for retrograde traffic through the Golgi complex.
- (h) Is involved in the movement of membrane lipids from the TGN to the plasma membrane.
- (i) The basic structural component of the coat is called a triskelion.
- (j) The protein coat dissociates shortly after formation of the vesicle.
- (k) The protein coat always includes a specific small GTP-binding protein.

12-5 Interpreting Data. Each of the following statements summarizes the results of an experiment related to exocytosis or endocytosis. In each case, explain the relevance of the experiment and its result to our understanding of these processes.

- (a) Addition of the drug colchicine to cultured fibroblast cells inhibits movement of transport vesicles.
- (b) Certain pituitary gland cells secrete laminin continuously but secrete adrenocorticotropic hormone only in response to specific signals.
- (c) Certain adrenal gland cells can be induced to secrete epinephrine when their intracellular calcium concentration is experimentally increased.
- (d) Cells expressing a temperature-sensitive form of dynamin do not display receptor-mediated endocytosis after a temperature shift, yet they continue to ingest extracellular fluid (at a reduced level initially, and then at a normal level within 30–60 minutes).
- (e) Brefeldin A inhibits cholesterol efflux in adipocytes (fat cells) without affecting the rate of cellular uptake and resecretion of apolipoprotein A-I in adipocytes.

12-6 Cellular Digestion. For each of the following statements, indicate the specific digestion process or processes of which the statement is true: phagocytosis (P), receptor-mediated endocytosis (R), autophagy (A), or extracellular digestion (E). Each statement may be true of one, several, or none (N) of these processes.

- (a) Can involve exocytosis.
- (b) Can involve fusion of vesicles or vacuoles with a lysosome.
- (c) Digested material is of extracellular origin.
- (d) Digested material is of intracellular origin.
- (e) Essential for sperm penetration of the egg during fertilization.
- (f) Important for certain developmental processes.
- (g) Involves acid hydrolases.
- (h) Involves fusion of endocytic vesicles with an early endosome.
- (i) Involves fusion of lysosomes with the plasma membrane.
- (j) Occurs within lysosomes.
- (k) Serves as a source of nutrients within the cell.

12-7 Peroxisomal Properties. For each of the following statements, indicate whether it is true of all (A), some (S), or none (N) of the various kinds of peroxisomes described in this chapter, and explain your answer.

- (a) Acquires proteins from the ER and Golgi complex.
- (b) Capable of catabolizing fatty acids.
- (c) Contains acid hydrolases.
- (d) Contains catalase.
- (e) Contains peroxide-generating chemical reactions.
- (f) Contains the genes coding for luciferase.
- (g) Contains urate oxidase.
- (h) Is a source of dolichol.
- (i) Is surrounded by a lipid bilayer.

12-8 Lysosomal Storage Diseases. Despite a bewildering variety of symptoms, lysosomal storage diseases have several properties in common. For each of the following statements, indicate if you would expect the property to be common to most lysosomal storage diseases (M), to be true of a specific lysosomal storage disease (S), or not to be true of any lysosomal storage diseases (N).

- (a) Impaired metabolism of glycolipids causes mental deterioration.
- (b) Leads to accumulation of degradation products in the lysosome.
- (c) Leads to accumulation of excessive amounts of glycogen in the lysosome.
- (d) Results from an inability to regulate the synthesis of glycosaminoglycans.
- (e) Results from an absence of functional acid hydrolases.
- (f) Results in accumulation of lysosomes in the cell.
- (g) Symptoms include muscle weakness and mental retardation.
- (h) Triggers proliferation of organelles containing catalase.

12-9 Sorting Proteins. Specific structural features tag proteins for transport to various intracellular and extracellular destinations. Several examples were described in this chapter including: (1) the short peptide Lys-Asp-Glu-Leu, (2) characteristic hydrophobic membrane-spanning domains, and (3) mannose-6-phosphate residues attached to oligosaccharide side chains. For each structural feature, answer the following questions:

- (a) Where in the cell is the tag incorporated into the protein?
- (b) How does the tag ensure that the protein reaches its destination?
- (c) Where would the protein likely go if you were to remove the tag?

• **12-10 Silicosis and Asbestosis.** *Silicosis* is a debilitating miner's disease that results from the ingestion of silica particles (such as sand or glass) by macrophages in the lungs. *Asbestosis* is a similarly serious disease caused by inhalation of asbestos fibers. In both cases, the particles or fibers are found in lysosomes, and fibroblasts, which secrete collagen, are stimulated to deposit nodules of collagen fibers in the lungs, leading to reduced lung capacity, impaired breathing, and eventually death.

- (a) How do you think the fibers get into the lysosomes?
- (b) What effect do you think fiber or particle accumulation has on the lysosomes?
- (c) How might you explain the death of silica-containing or asbestos-containing cells?
- (d) What do you think happens to the silica particles or asbestos fibers when such cells die? How can cell death continue almost indefinitely, even after prevention of further exposure to silica dust or asbestos fibers?
- (e) Cultured fibroblast cells will secrete collagen and produce connective tissue fibers after the addition of material from a culture of lung macrophages that have been exposed to silica particles. What does this tell you about the deposition of collagen nodules in the lungs of silicosis patients?

- **12-11 What's Happening?** Researchers have discovered a group of plant proteins that are related to the exocyst proteins in yeast (*The Plant Cell* 20 (2008): 1330). Explain how the following observations made by these researchers suggest that these plant proteins form a tethering complex similar to the exocyst complex of yeast and mammals.
- (a) Following size fractionation of plant protein extracts, antibodies recognizing each of several different plant exocyst proteins bind to the same high-molecular-weight protein fraction.
- (b) Mutations in four of the proteins each causes defective pollen germination.
- (c) Plants lacking more than one of these proteins have more serious defects in pollen germination than plants lacking only one.
- (d) The exocyst proteins all co-localize at the growing tip of elongating pollen cells.
- (e) Pollen cells of plants with mutations in exocyst genes are defective in tip growth or germinating pollen cells.

Signal Transduction Mechanisms: I. Electrical and Synaptic Signaling in Neurons

In Chapter 8 we saw that a key property of cell membranes is the ability to regulate the flow of ions between the interior of the cell and the outside environment. Since ions are charged solutes, cells can, in effect, regulate the flow of electric current through their membranes as well as the electrical potentials across them. The most dramatic example of regulation of the electrical properties of cells is the functioning of the main cellular component of the nervous system of animals: the nerve cell, or neuron.

In this chapter, we will examine the cellular mechanisms that allow neurons to transmit signals at remarkably high speeds throughout the body, and we will consider the ways neurons connect with one another. By studying neurons, we will gain important insights into how cells in general regulate their electrical properties and how cells can send signals to one another. In the first part of this chapter, we will see that although virtually all cells maintain electrical potentials across their plasma membranes, nerve cells have special mechanisms for using this potential to transmit information over long distances. In the second part of the chapter, we will focus on the processes by which the information is passed between neurons and other cells, such as other nerve cells, glands, or muscle cells.

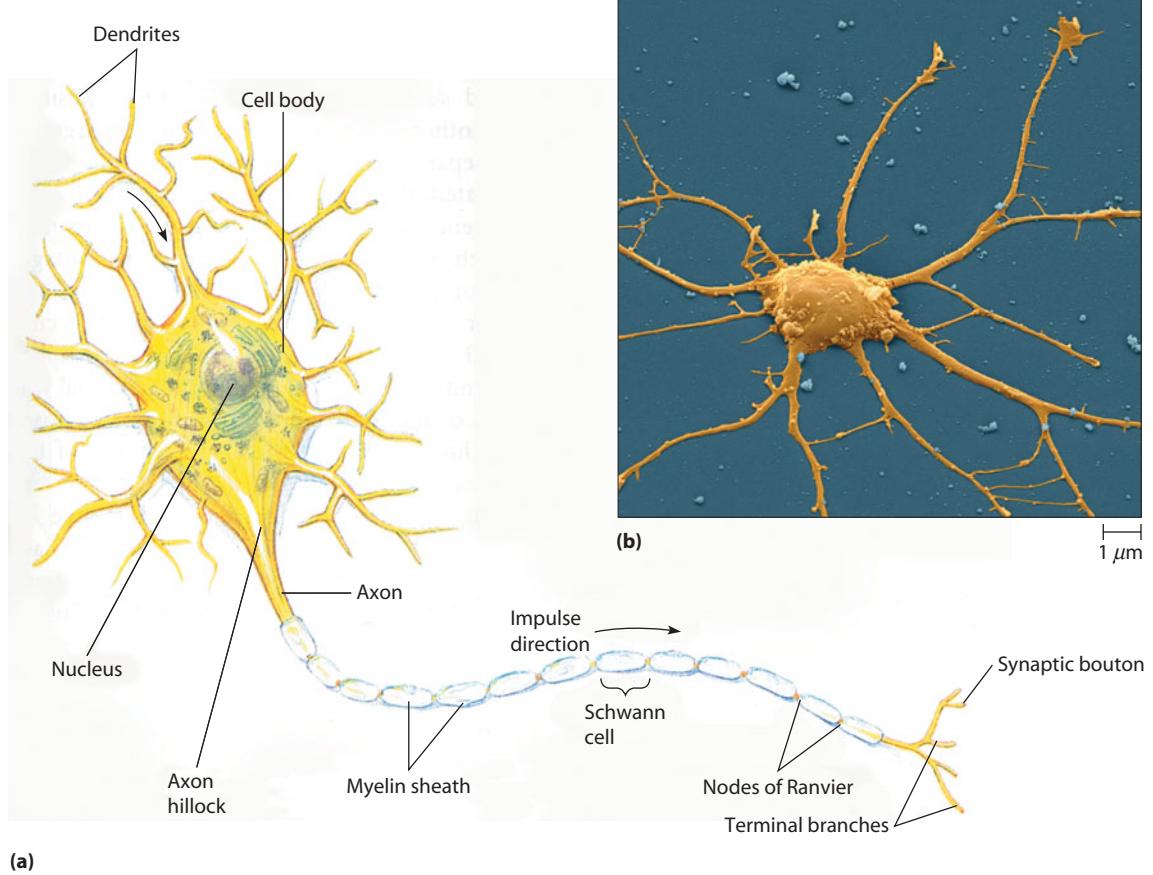

Neurons

Almost all animals have a *nervous system* in which electrical impulses are transmitted along the specialized plasma membranes of nerve cells. In the case of vertebrates, the nervous system has two main components: the *central nervous system (CNS)*, which consists of the brain and spinal cord, and the *peripheral nervous system (PNS)*, which comprises other sensory and motor components. Cells that make up the nervous system can be broadly divided into

two groups: neurons and glial cells. All **neurons** send or receive electrical impulses. Neurons can be subdivided into three basic types based on function: sensory neurons, motor neurons, and interneurons. *Sensory neurons* are a diverse group of cells specialized for the detection of various types of stimuli; they provide a continuous stream of information from various sensory receptors to the brain about the state of the body and its environment. *Motor neurons* transmit signals from the CNS to the muscles or glands they *innervate*—that is, the tissues with which they make synaptic connections. *Interneurons* process signals received from other neurons and relay the information to other parts of the nervous system.

The term *glial cell* (from *glia*, the Greek word for “glue”) encompasses a variety of cell types. Glial cells are by far the most abundant types of cells in the CNS. *Microglia* are phagocytic cells that fight infections and remove debris. *Oligodendrocytes* and *Schwann cells* form the insulating *myelin sheath* around neurons of the CNS and those of the peripheral nerves, respectively. *Astrocytes* control access of blood-borne components into the extracellular fluid surrounding nerve cells, thereby forming the *blood-brain barrier*.

Intricate networks of neurons make up the complex tissues of the brain that are responsible for coordinating nervous function—in humans, about 10 billion neurons. Each neuron can receive input from thousands of other neurons, so the brain's connections number well into the trillions. Rather than discussing the overall functioning of the nervous system, our purpose here is to examine the cellular mechanisms by which these electrical signals, called *nerve impulses*, are spread. In addition to understanding the functions of nerve cells specifically, we will acquire a better appreciation for several general aspects of membrane function, of which nerve cells present a specialized, highly developed example.

(a)

FIGURE 13-1 The Structure of a Typical Motor Neuron. (a) A diagram of a typical motor neuron. The cell body contains the nucleus and most of the usual organelles. Dendrites conduct signals inward to the cell body; starting near the axon hillock, the axon transmits signals outward (the black arrows indicate direction of transmission). At the end of the axon are many synaptic boutons. Some, though not all, neurons have a discontinuous myelin sheath around their axons to insulate them electrically. Each segment of the sheath consists of a concentric layer of membranes wrapped around the axon by a Schwann cell (or an oligodendrocyte in the CNS). Breaks in the myelin sheath, called nodes of Ranvier, are concentrated regions of electrical activity. (b) A scanning electron micrograph of the cell body and dendrites of a neuron. The neuron has been colored orange. Schwann cells are not visible.

 [ACTIVITIES](http://www.thecellplace.com) www.thecellplace.com Neuron structure

Neurons Are Specially Adapted for the Transmission of Electrical Signals

The structure of a typical motor neuron is shown schematically in **Figure 13-1**. The **cell body** of the neuron is similar to that of other cells and includes the nucleus and many components of the endomembrane system, which you learned about in Chapter 12. Neurons also contain extensions, or branches, called *processes*. Transporting components to and from these extensions is a special challenge for neurons, which we will discuss in Chapter 15. There are two types of processes: Those that receive signals and combine them with signals received from other neurons are called **dendrites**, and those that conduct signals, sometimes over long distances, are called **axons**. The cytosol within an axon is commonly referred to as **axoplasm**. Many vertebrate axons are surrounded by a discontinuous **myelin sheath**, which insulates the segments of axon separating the **nodes of Ranvier**. Axons

can be very long—up to several thousand times longer than the diameter of the cell body. For example, a motor neuron that innervates your foot has its cell body in your spinal cord, and its axon extends approximately a meter down your leg! A **nerve** is simply a tissue composed of bundles of axons.

As Figure 13-1 illustrates, a motor neuron has multiple, branched dendrites and a single axon leading away from the cell body. The axon of a typical neuron is much longer than the dendrites and forms multiple branches. The branches terminate in structures called **synaptic boutons** (also called *terminal bulbs* or *synaptic knobs*; the French word *bouton* means “button”). The boutons are responsible for transmitting the signal to the next cell, which may be another neuron or a muscle or gland cell. In each case, the junction is called a **synapse**. For neuron-to-neuron junctions, synapses usually occur between an axon and a dendrite, but they can occur between two dendrites. Typically, neurons make synapses with many other

neurons. They can do so not only at the ends of their axons but at other points along their length as well.

Neurons display tremendous structural variability. Some sensory neurons have only one process, which conducts signals both toward and away from the cell body. Moreover, the structure of the processes is not random; many different classes of neurons in the CNS can be identified by structure alone.

Understanding Membrane Potential

Recall from Chapter 8 that **membrane potential** is a fundamental property of all cells. It results from an excess of negative charge on one side of the plasma membrane and an excess of positive charge on the other side. Cells at rest normally have an excess of negative charge inside and an excess of positive charge outside the cell; the resulting electrical potential is called the **resting membrane potential**, denoted V_m . A great technical advance in understanding how membrane potential changes as nerve signals are transmitted came with the discovery in the 1930s of very large axons in some nerve fibers of squid. These nerve fibers stimulate the explosive expulsion of water from the mantle cavity of the squid, enabling it to propel itself quickly backward to escape predators (**Figure 13-2**). The **squid giant axon** has a diameter of about 0.5–1.0 mm, allowing the easy insertion of tiny electrodes, or *microelectrodes*, to measure and control electrical potentials and ionic currents across the axonal membrane. The *resting membrane potential* can be measured by placing one microelectrode inside the cell and another outside the cell (**Figure 13-3a**); its value is generally given in millivolts (mV). (Do not confuse the potential

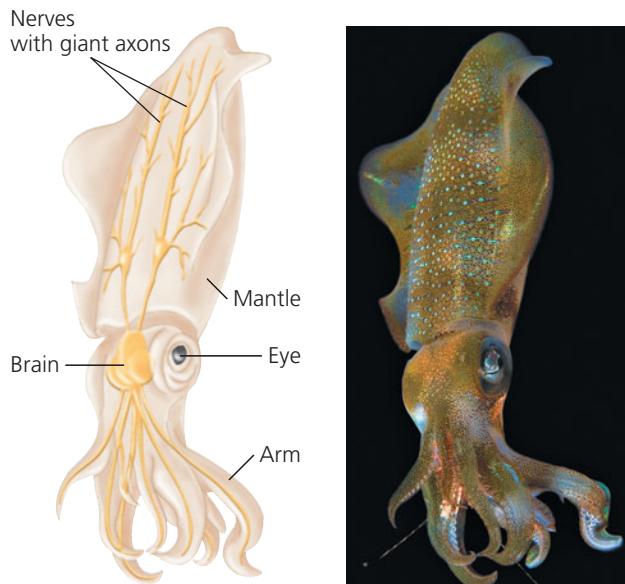

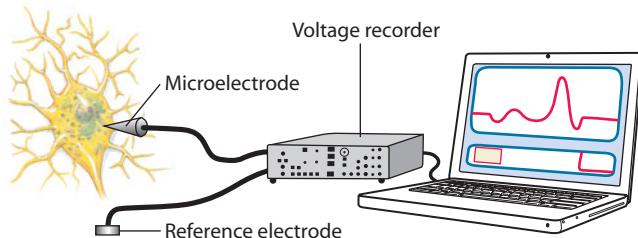

FIGURE 13-2 Squid Giant Axons. The squid nervous system includes motor nerves that control swimming movements. The nerves contain giant axons (fibers) with diameters ranging up to 1 mm, providing a convenient system for studying resting and action potentials in a biological membrane.

V_m and the unit mV.) The electrodes compare the ratio of negative to positive charge inside the cell and outside the cell. Because the inside of a cell typically has an excess of negative charge, we say that the cell has a negative resting membrane potential. For example, the resting membrane potential is approximately –60 mV for the squid giant axon.

Nerve, muscle, and certain other cell types such as the islet cells of the pancreas of vertebrates exhibit a special property called **electrical excitability**. In electrically excitable cells, certain types of stimuli trigger a rapid sequence of changes in membrane potential known as an **action potential**. During an action potential, the membrane potential changes from negative to positive values and then back to negative values again, all in as little as a

(a) Measuring the resting membrane potential. Differences in potential between the recording and reference electrodes are amplified by a voltage amplifier and displayed on a voltmeter, an oscilloscope, or a computer monitor.

(b) Measuring an action potential in a squid axon. The stimulating electrode is connected to a pulse generator, which delivers a pulse of current to the axon when the switch is momentarily closed. The nerve impulse this generates is propagated down the axon and can be detected a few milliseconds later by the recording electrode.

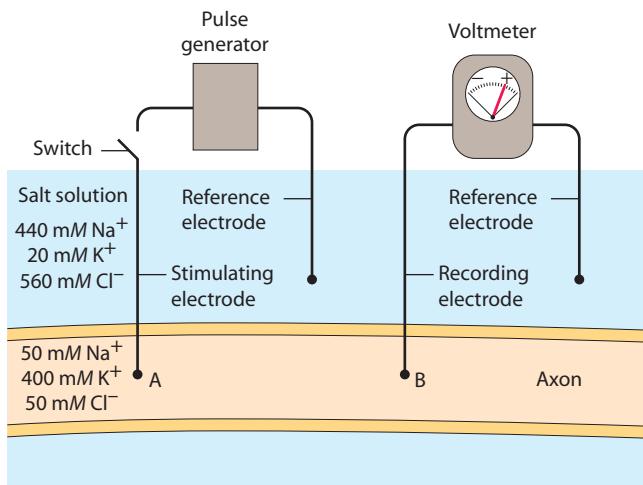

FIGURE 13-3 Measuring Membrane Potentials. (a) Measurement of the resting membrane potential requires two electrodes, one inserted inside the axon (the recording electrode) and one placed in the fluid surrounding the cell (the reference electrode). (b) Measurement of an action potential requires four electrodes, one in the axon for stimulation, another in the axon for recording, and two in the fluid surrounding the cell for reference.

few milliseconds. In addition to measuring resting potential, microelectrodes can also be used to measure these dynamic changes in membrane potential. An electrode called the *stimulating electrode* is connected to a power source and inserted into the axon some distance from the recording electrode (see Figure 13-3b). A brief impulse from this stimulating electrode depolarizes the membrane by about 20 mV (i.e., from -60 to about -40 mV), bringing the neuron beyond the threshold potential. This triggers an action potential that propagates away from the stimulating electrode. As the action potential passes the recording electrode, the voltmeter or oscilloscope will display a characteristic pattern of membrane potential changes. Alan Hodgkin and Andrew Huxley used microelectrodes and the squid giant axon to learn how action potentials are generated; for their work, they received a share of the Nobel Prize in 1963. To understand how nerve cells use action potentials to transmit signals, we must first examine how cells generate a resting membrane potential and how the membrane potential changes during an action potential.

The Resting Membrane Potential Depends on Differing Concentrations of Ions Inside and Outside the Neuron and on the Selective Permeability of the Membrane

The resting membrane potential develops because the cytosol of the cell and the extracellular fluid contain different compositions of cations and anions. Extracellular fluid contains dissolved salts, including sodium chloride and lesser amounts of potassium chloride. The cytosol contains potassium rather than sodium as its main cation because of the action of the Na^+/K^+ pump (described in Chapter 8). The anions in the cytosol consist largely of trapped macromolecules such as proteins, RNA, and a variety of other molecules that are not present, or much less abundant, outside the cell. These negatively charged macromolecules cannot pass through the plasma membrane and therefore remain inside the cell. The concentrations of important ions for two types of well-studied neurons, the squid axon and one type of mammalian axon, are shown in **Table 13-1**.

To understand how a membrane potential forms, we need to recall a few basic physical principles. First, all

Table 13-1 Ionic Concentrations Inside and Outside Axons and Neurons

Ion	Squid Axon		Mammalian Neuron (cat motor neuron)	
	Outside (mM)	Inside (mM)	Outside (mM)	Inside (mM)
Na^+	440	50	145	10
K^+	20	400	5	140
Cl^-	560	50	125	10

substances tend to diffuse from an area where they are more highly concentrated to an area where they are less concentrated. Cells normally have a high concentration of potassium ions inside and a low concentration of potassium ions outside. We refer to this uneven distribution of potassium ions as a *potassium ion gradient*. Given the large potassium concentration gradient, potassium ions will tend to diffuse out of the cell.

The second basic principle is that of *electroneutrality*. When ions are in solution, they are always present in pairs, one positive ion for each negative ion, so that there is no net charge imbalance. For any given ion, which we will call A, there must be an oppositely charged ion B in the solution; therefore, we refer to B as the *counterion* for A. In the cytosol, potassium ions (K^+) serve as counterions for the trapped anions. Outside the cell, sodium (Na^+) is the main cation and chloride (Cl^-) is its counterion.

Although a solution must have an equal number of positive and negative charges overall, these charges can be locally separated so that one region has more positive charges while another region has more negative charges. It takes work to separate charges; even after they have been separated, they tend to move back toward each other. The tendency of oppositely charged ions to flow back toward each other is called an **electrical potential or voltage**. When negative or positive ions are actually moving, one toward the other, we say that **current** is flowing; this current is measured in amperes (A). Given these principles, we can understand how a resting membrane potential will form as a result of the ionic compositions of the cytosol and the extracellular fluid, as well as the characteristics of the plasma membrane.

The plasma membrane is normally permeable to potassium due to the leakiness of some types of potassium channels, which permits potassium ions to diffuse out of the cell. There are no channels for negatively charged macromolecules, however. As potassium leaves the cytosol, increasing numbers of trapped anions are left behind without counterions. Excess negative charge therefore accumulates in the cytosol while excess positive charge accumulates on the outside of the cell, resulting in a membrane potential.

Figure 13-4 illustrates the formation of a membrane potential in a container divided into two compartments by a semipermeable membrane. The compartment on the left represents the cytosol of the cell; the one on the right represents the extracellular fluid. The semipermeable membrane is permeable to potassium ions but not to negatively charged macromolecules (represented as M^-). The cytosolic compartment contains a mixture of potassium ions and negatively charged macromolecules. For simplicity, we will assume that the extracellular compartment starts with nothing but water. Because of the concentration gradient, potassium ions diffuse across the membrane from the left side to the right side. However, the negatively charged macromolecules are not free to follow. The result is an accumulation of anions on the left side and cations on the right side. A membrane potential is created by the separation of

The cytosol has a much higher concentration of potassium ions (K^+) and impermeable anions (M^-) relative to the extracellular fluid.

As K^+ ions diffuse out of the cell (from left to right), the impermeable anions are left behind, creating a membrane potential. The magnitude of the membrane potential increases until an equilibrium is reached.

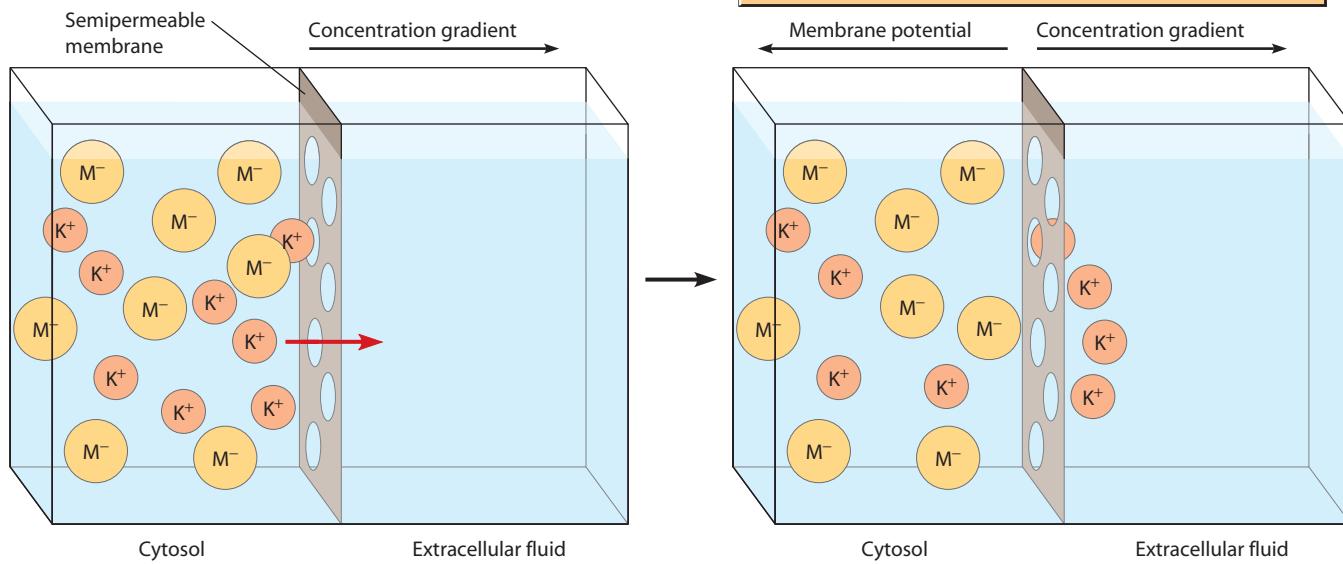

FIGURE 13-4 Development of the Equilibrium Potential. Here a two-compartment container represents the cytosol of a cell and the extracellular space, with a semipermeable membrane between them. In this example, only potassium ions (K^+) and impermeable anions (M^-) are shown.

negative charge from positive charge. Although this charge separation produces a small voltage relative to that of a typical 1.5-V battery, it is nevertheless a form of potential energy that can be used to perform work.

As potassium ions diffuse from left to right in Figure 13-4, the compartment on the left becomes increasingly negative. This potential ultimately builds to a point at which the positively charged potassium ions are pulled back into the left-hand compartment as fast as they leave. In this way, an equilibrium is reached in which the force of attraction due to the membrane potential balances the tendency of potassium to diffuse down its concentration gradient. This type of equilibrium, in which a chemical gradient is balanced with an electrical potential, is referred to as an **electrochemical equilibrium**. The membrane potential at the point of equilibrium is known as an **equilibrium, or reversal, potential**; the magnitude of the potassium ion gradient determines the magnitude of the equilibrium potential. In the next section, we will present a mathematical description of this relationship that enables us to estimate the membrane potential.

The Nernst Equation Describes the Relationship Between Membrane Potential and Ion Concentration

The **Nernst equation** is named for the German physical chemist and Nobel laureate Walther Nernst, who first formulated it in the late 1880s in the context of his work on electrochemical cells (forerunners of modern batteries). The Nernst equation describes the mathematical

relationship between an ion gradient and the equilibrium potential that will form when the membrane is permeable only to that ion:

$$E_X = \frac{RT}{zF} \ln \frac{[X]_{\text{outside}}}{[X]_{\text{inside}}} \quad (13-1)$$

Here, E_X is the equilibrium potential for ion X (in volts), R is the gas constant (1.987 cal/mol-degree), T is the absolute temperature in kelvins (recall that $0^\circ\text{C} = 273\text{K}$), z is the valence of the ion, F is the Faraday constant (23,062 cal/V-mol), $[X]_{\text{outside}}$ is the concentration of X outside the cell (in M), and $[X]_{\text{inside}}$ is the concentration of X inside the cell (in M). This equation can be simplified if we assume that the temperature is 293K (20°C)—a value appropriate for the squid giant axon—and that X is a monovalent cation and therefore has a valence of +1. If we substitute these values for R , T , F , and z into the Nernst equation and convert from natural logs to \log_{10} ($\log_{10} = \ln/2.303$), Equation 13-1 reduces to

$$E_X = 0.058 \log_{10} \frac{[X]_{\text{outside}}}{[X]_{\text{inside}}} \quad (13-2)$$

In this simplified form, we can see that for every tenfold increase in the cation gradient, the membrane potential changes by -0.058 V , or -58 mV .

The Na^+/K^+ Pump. Although the plasma membrane is relatively impermeable to sodium ions, there is always a small amount of leakage. To compensate for this leakage, the **Na^+/K^+ pump** continually pumps sodium out of the

cell while carrying potassium inward (see Figure 8-12). On average, the pump transports three sodium ions out of the cell and two potassium ions into the cell for every molecule of ATP that is hydrolyzed. The Na^+/K^+ pump maintains the large potassium ion gradient across the membrane that provides the basis for the resting membrane potential.

Steady-State Concentrations of Common Ions Affect Resting Membrane Potential

Although Equation 13-2 explains the formation of the membrane potential, it is incomplete, mainly because it does not account for the effects of anions. The main anion in the extracellular fluid is chloride. As we have seen, sodium, potassium, and chloride ions are the major ionic components present in both the cytosol and the extracellular fluid. Because of their unequal distributions across the cell membrane, each ion has a different impact on the membrane potential. The magnitude of the concentration gradient for each ion for a mammalian neuron is illustrated in **Figure 13-5**. Each ion will tend to diffuse down its electrochemical gradient (shown as red arrows in Figure 13-5) and thereby produce a change in the membrane potential.

Potassium ions tend to diffuse out of the cell, which makes the membrane potential more negative. Sodium ions tend to flow into the cell, driving the membrane potential in the positive direction and thereby causing a **depolarization** of the membrane (that is, causing the membrane potential to be less negative). Chloride ions tend to diffuse into the cell, which should in principle make the membrane potential more negative. However, chloride ions are also repelled by the negative membrane

potential, so that chloride ions usually enter the cell in association with positively charged ions such as sodium. This paired movement nullifies the depolarizing effect of sodium entry. Increasing the permeability of cells to chloride can have two effects, both of which decrease neuronal excitability. First, the net entry of chloride ions (chloride entry without a matching cation) causes *hyperpolarization* of the membrane (that is, the membrane potential becomes more highly negative than usual). Second, when the membrane becomes permeable to sodium ions, some chloride will tend to enter the cell along with sodium. This effect of chloride entry will be prominent later when we discuss inhibitory neurotransmitters.

The Goldman Equation Describes the Combined Effects of Ions on Membrane Potential

The relative contributions of the major ions are important to the resting membrane potential because, even in its resting state, the cell has some permeability to sodium and chloride ions as well as to potassium ions. To account for the leakage of sodium and chloride ions into the cell, we cannot use the Nernst equation because it deals with only one type of ion at a time, and it assumes that this ion is in electrochemical equilibrium. We must move from the more static concept of equilibrium potential to a consideration of *steady-state ion movements* across the membrane.

We can illustrate the concept of steady-state ion movements by returning once more to our model of a cell in electrochemical equilibrium (**Figure 13-6**). Remember, a cell that is permeable only to potassium will have a membrane potential equal to the equilibrium potential for

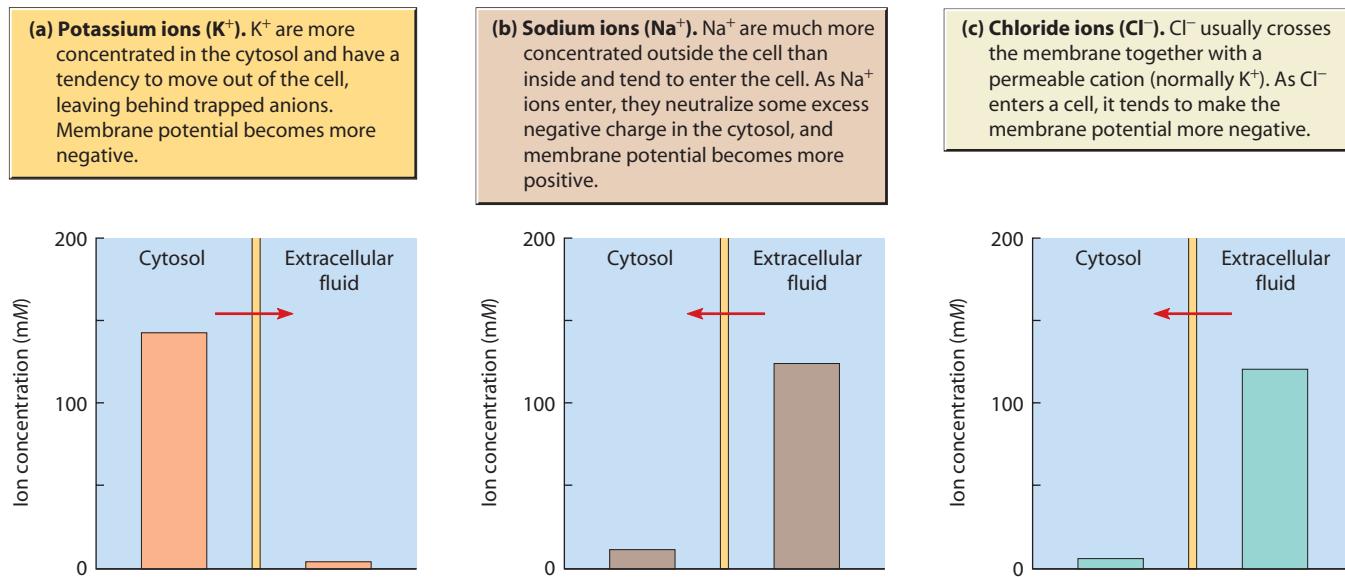

FIGURE 13-5 Relative Concentrations of Potassium, Sodium, and Chloride Ions Across the Plasma Membrane of a Mammalian Neuron. Each of the major ions in the cytosol—(a) potassium, (b) sodium, and (c) chloride—is found in a concentration gradient across the plasma membrane. The red arrow indicates the direction the ion would tend to flow in response to its electrochemical gradient.

A small number of sodium (Na^+) ions continually leak into the cell. This makes the membrane potential more positive, weakening the electrical restraint on the movement of potassium (K^+) ions. A small number of ions now leak out of the cell.

As Na^+ ions accumulate in the cytosol, they are pumped outward in exchange for potassium ions by the Na^+/K^+ pump. The result is a low concentration of Na^+ ions inside the cell. Some Na^+ ions in the cytosol cause the membrane potential to be more positive than the equilibrium membrane potential for K^+ .

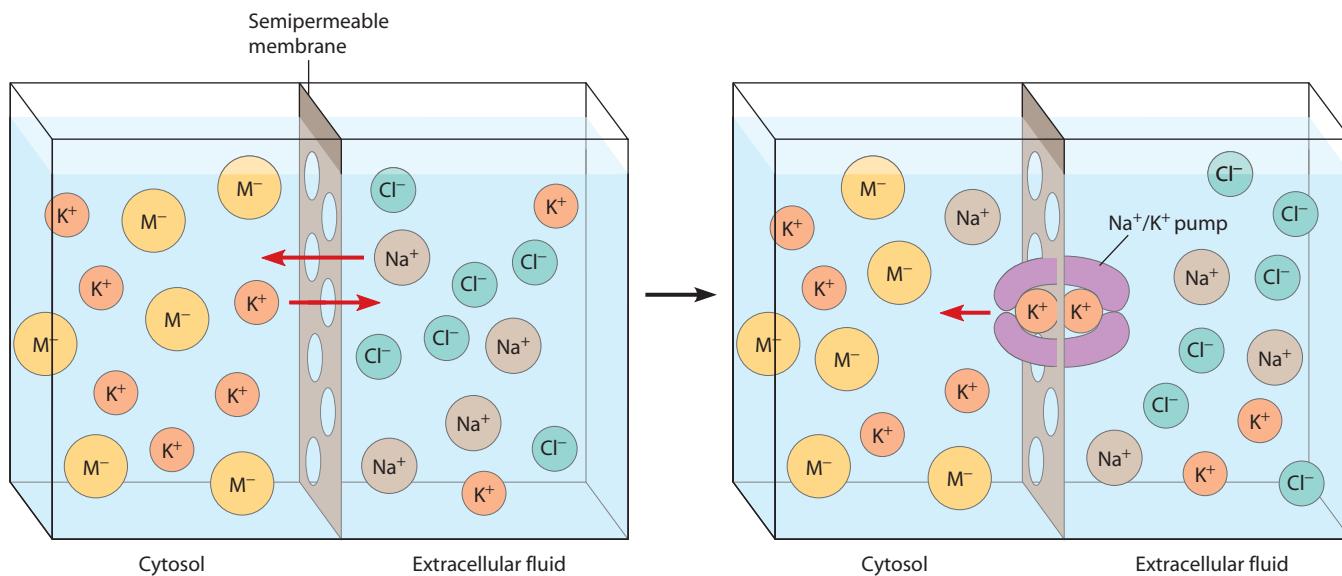

FIGURE 13-6 Steady-State Ion Movements. The actual membrane potential of a cell depends on the permeability of the plasma membrane to various ions and the steady-state movements of ions across the membrane, as illustrated here with our two-compartment model. The red arrows indicate the direction of movement of the indicated ion.

potassium ions. Under these conditions, there will be no net movement of potassium out of the cell. If we assume that the membrane is also slightly permeable to sodium ions, what will happen? We know that the cell will have both a large sodium gradient across the membrane and a negative membrane potential corresponding to the potassium equilibrium potential. These forces tend to drive sodium ions into the cell. As sodium ions leak inward, the membrane is partially depolarized. At the same time, as the membrane potential is neutralized, there is now less restraining force preventing potassium from leaving the cell, so potassium ions diffuse outward, balancing the inward movement of sodium. The inward movement of sodium ions shifts the membrane potential in the positive direction, while the outward movement of potassium ions shifts the membrane potential back in the negative direction.

Movements of sodium and potassium ions across the membrane, therefore, have essentially opposite effects on the membrane potential. For one type of squid axon, the sodium ion gradient tends toward a cell membrane potential of about +55 mV, while the potassium ion gradient tends toward a membrane potential of about -75 mV. At what value will the membrane potential come to rest? The pioneering neurobiologists David E. Goldman, Alan Lloyd Hodgkin, and Bernard Katz were the first to describe how gradients of several different ions each contribute to the membrane potential as a function of relative ionic

permeabilities. The Goldman-Hodgkin-Katz equation, more commonly known as the **Goldman equation**, is as follows:

$$V_m = \frac{RT}{F} \ln \frac{(P_K)[K^+]_{\text{out}} + (P_{\text{Na}})[\text{Na}^+]_{\text{out}} + (P_{\text{Cl}})[\text{Cl}^-]_{\text{in}}}{(P_K)[K^+]_{\text{in}} + (P_{\text{Na}})[\text{Na}^+]_{\text{in}} + (P_{\text{Cl}})[\text{Cl}^-]_{\text{out}}} \quad (13-3)$$

Because chloride ions have a negative valence, $[\text{Cl}^-]_{\text{inside}}$ appears in the numerator and $[\text{Cl}^-]_{\text{outside}}$ in the denominator.

A key difference between the Nernst equation and the Goldman equation is the incorporation of terms for permeability. Here, P_K , P_{Na} , and P_{Cl} are the *relative permeabilities* of the membrane for the respective ions. The use of relative permeabilities circumvents the complicated task of determining the absolute permeability of each ion. While the equation shown here takes into account only the contributions of potassium, sodium, and chloride ions, other ions could be added as well. Except under special circumstances, however, the permeability of the plasma membrane to other ions is usually so low that their contributions are negligible.

We can use a squid axon to illustrate how we can accurately estimate the resting membrane potential from the known steady-state concentrations and relative permeabilities of sodium, potassium, and chloride ions. To do so, we assign K^+ a permeability value of 1.0, and the permeability values of all other ions are determined relative to that of K^+ . For squid axons, the permeability of sodium ions is

only about 4% of that for potassium ions; and for chloride ions, the value is 45%. Relative values of P_K , P_{Na} , and P_{Cl} are therefore 1.0, 0.04, and 0.45, respectively. Using these values, a temperature of 20°C, and the intracellular and extracellular concentrations of Na^+ , K^+ , and Cl^- for the squid axon from Table 13-1, you should be able to estimate the resting membrane potential of a squid axon as -60.3 mV. Typical measured values for the resting membrane potential of a squid axon are about -60 mV, which is remarkably close to our calculated potential.

When the relative permeability for one ion is very high, the Goldman equation reduces to the Nernst equation for that particular ion. For example, if we ignore the contribution due to chloride ions (which we can often do), when P_{Na} is much higher than P_K ($P_{Na} \gg P_K$), Equation 13-3 reduces to:

$$V_m = \frac{RT}{F} \ln \frac{[Na^+]_{out}}{[Na^+]_{in}}, \quad (13-4)$$

which is just the Nernst equation for sodium. Since the resting potential for sodium is about +55 mV, making a cell highly permeable to sodium will cause it to depolarize. Similarly, if $P_K \gg P_{Na}$, then the Goldman equation reduces to the Nernst equation for potassium. Since the resting potential for potassium is about -75 mV, high permeability to potassium will tend to return a cell to a polarized state. As we will now see, neurons use precisely this strategy to transiently depolarize and then repolarize their plasma membranes.

Electrical Excitability

The establishment of a resting membrane potential and its dependence on ion gradients and ion permeability are properties of almost all cells. The unique feature of electrically excitable cells is their response to membrane depolarization. Whereas a nonexcitable cell that has been temporarily and slightly depolarized will simply return to its original resting membrane potential, an electrically excitable cell that is depolarized to the same degree will respond with an *action potential*.

Electrically excitable cells produce an action potential because of the presence of *voltage-gated channels* in the plasma membrane. To see how nerve cells communicate signals electrically, we need to understand the characteristics of the ion channels in the nerve cell membrane, a subject to which we now turn.

Ion Channels Act Like Gates for the Movement of Ions Through the Membrane

In Chapter 8, we introduced **ion channels**, integral membrane proteins that form ion-conducting pores through the lipid bilayer. Recall that **voltage-gated ion channels**, as the name suggests, respond to changes in the voltage across a membrane. Voltage-gated sodium and potassium

channels are responsible for the action potential. **Ligand-gated ion channels**, by contrast, open when a particular molecule binds to the channel. (*Ligand* comes from the Latin root *ligare*, meaning “to bind.”) Other channels contribute to the steady-state ionic permeabilities of membranes. These *leak channels* allow resting cells to be somewhat permeable to cations, in particular potassium ions. Detailed knowledge of the structure and function of voltage-gated sodium and potassium channels is fundamental to understanding the events of the action potential. We begin our exploration by looking at how ion channels are studied experimentally.

Patch Clamping and Molecular Biological Techniques Allow the Activity of Single Ion Channels to Be Monitored

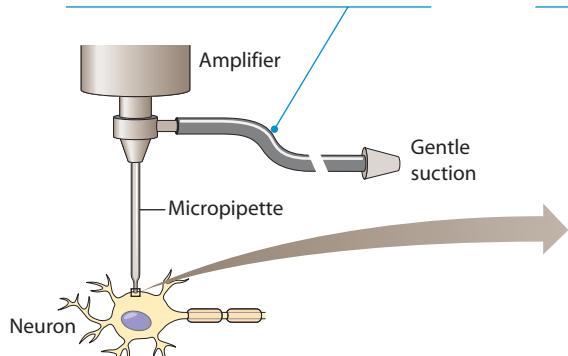

Our clearest picture of how channels operate comes from using a technique that permits the recording of ion currents passing through individual channels. This technique, known as *single-channel recording*, or more commonly as **patch clamping** (Figure 13-7), was developed by Erwin Neher and Bert Sackman, who earned a Nobel Prize in 1991 for their discovery.

To record single-channel currents, a glass micropipette with a tip diameter of approximately 1 mm is carefully pressed against the surface of a cell such as a neuron. Gentle suction is then applied, so that a tight seal forms between the pipette and the plasma membrane. There is now a patch of membrane under the mouth of the micropipette that is sealed off from the surrounding medium (Figure 13-7, ①). This patch is small enough that it usually contains only one or perhaps a few ion channels. Current can enter and leave the pipette only through these channels, thereby enabling an experimenter to study various properties of the individual channels. The channels can be studied in the intact cell, or the patch can be pulled away from the cell so that the researcher has access to the cytosolic side of the membrane (Figure 13-7, ②).

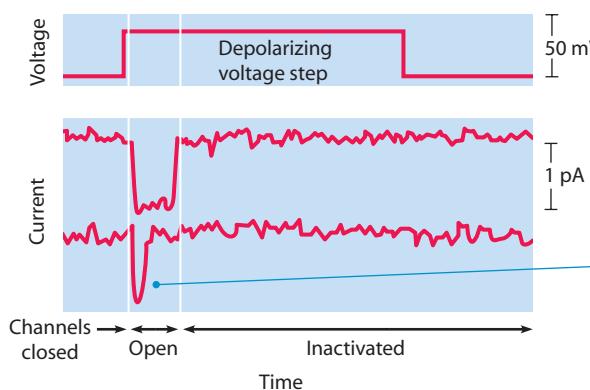

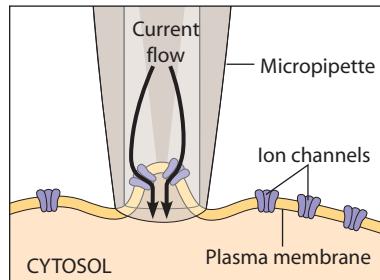

During the experimental process, an amplifier maintains voltage across the membrane with the addition of a sophisticated electronic feedback circuit called a voltage clamp (hence the term *patch clamp*). The voltage clamp keeps the cell at a fixed membrane potential, regardless of changes in the electrical properties of the plasma membrane, by injecting current as needed to hold the voltage constant. The voltage clamp then measures tiny changes in current flow—actual ionic currents through individual channels—from the patch pipette. The patch-clamp method has been used to show that when a sodium channel opens, it conducts the same amount of *current*—that is, the same number of ions per unit of time. In other words, sodium channels tend to be either open or closed.

Based on these properties of ion channels, we can characterize a particular channel in terms of its conductance. *Conductance* is an indirect measure of the permeability of a channel when a specified voltage is applied across the

1 Patch-clamping setup: A fire-polished micropipette with a diameter of about 1 μm is carefully placed against a cell, such as the neuron shown here.

2 Membrane patch isolation: Gentle suction is applied to form a tight seal between the pipette and the plasma membrane. Typically only one or a few channels will be in the membrane within the pipette.

3 The flow of ions is recorded while the membrane is subjected to a depolarizing step in voltage, yielding traces of individual Na^+ currents during channel opening. Two separate traces are shown.

FIGURE 13-7 Patch Clamping. Patch clamping makes it possible to study the behavior of individual ion channels in a small patch of membrane. When each channel opens, the amount of current that flows through it is always the same (1 pA for the sodium channels shown here). Following the burst of channel opening, a quiescent period occurs due to channel inactivation.

membrane. In electrical terms, conductance is the inverse of resistance. For voltage-gated sodium channels, when a voltage of 50 mV is applied across the membrane, a current of approximately 1 picoampere ($1 \text{ pA} = 1 \times 10^{-12} \text{ A}$) is generated. This current corresponds to about 6 million sodium ions flowing through the channel per second. This can be seen in the traces shown in Figure 13-7, ③.

In single-channel recording, membrane depolarization (triggered by changing the applied voltage to a more positive potential) increases the probability that a channel will open. Even before the membrane is depolarized, a sodium channel will occasionally flicker open and closed. Once the channel has opened, it cannot reopen unless the membrane potential is restored to a more negative value. The cessation of channel activity that occurs while the membrane is still depolarized is due to channel inactivation, which we will discuss later in this chapter.

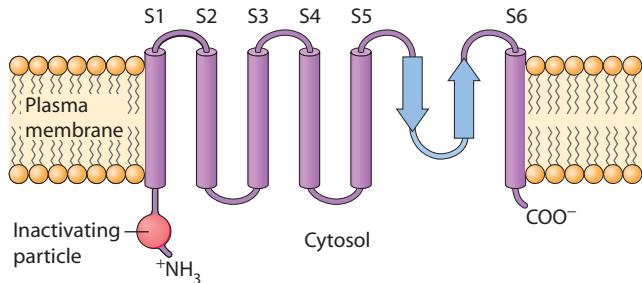

Much of the present research on ion channels combines patch clamping with molecular biology. It is now possible to synthesize large amounts of channel proteins in the laboratory and to study their functions in lipid bilayers or in frog eggs. Specific molecular modifications or mutations of the channel can be used to determine how

various regions of the channel protein are involved in channel function. This approach has been used to study the domains of the sodium and potassium channels responsible for voltage gating.

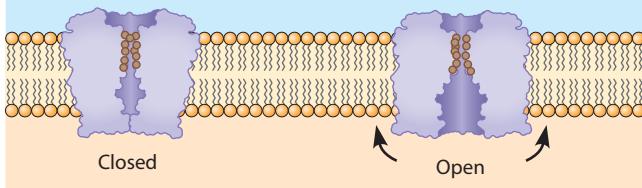

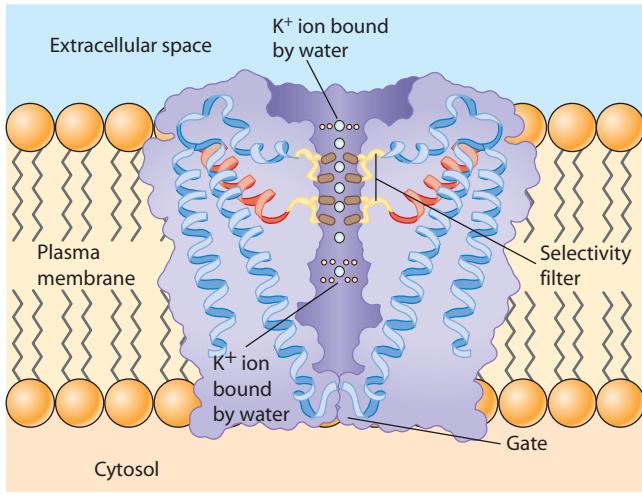

Specific Domains of Voltage-Gated Channels Act as Sensors and Inactivators

The structure of voltage-gated ion channels falls into two different, though similar, categories. *Voltage-gated potassium channels* are *multimeric* proteins—that is, they consist of several separate protein subunits that associate with one another to form the functional channel. In the case of potassium channels, four separate protein subunits come together in the membrane, forming a central pore that ions can pass through. *Voltage-gated sodium channels*, by contrast, are large, *monomeric* proteins (in other words, they consist of a single polypeptide) with four separate domains. Each domain is similar to one of the subunits of the voltage-gated potassium channel. In both kinds of channels, each subunit or domain contains six transmembrane α helices (called subunits S1–S6; **Figure 13-8a**).

(a) Domain structure of an individual subunit. Each subunit or domain contains six transmembrane helices, labeled S1–S6. The fourth transmembrane helix, S4, is a good candidate for a voltage sensor and part of the gating mechanism. For voltage-gated sodium channels and some types of potassium channels, a region near the N-terminus protrudes into the cytosol and forms an inactivating particle.

(b) Pore structure. Two of the four subunits of a voltage-gated potassium channel are shown here. Only the transmembrane part of the channel is shown. When K^+ ions bound by water enter the channel, they give up their water and bind oxygen atoms of amino acids lining the selectivity filter.

(c) Channel gating. The channel gate opens and closes depending on the conformational state of channel subunits.

The size of the central pore and, more importantly, the way it interacts with an ion, give a channel its ion selectivity. Figure 13-8b shows why this is so for the bacterial potassium channel, KcsA. Vertebrate voltage-gated potassium channels have a similar structure. Oxygen atoms in amino acids lining the center of the channel are precisely positioned to interact with ions as they move

FIGURE 13-8 The General Structure of Voltage-Gated Ion Channels. (a) Domain structure. Voltage-gated channels for sodium, potassium, and calcium ions all share the same basic structural themes. The channel is essentially a rectangular tube whose four walls are formed from either four subunits (e.g., potassium channels) or four domains of a single polypeptide (e.g., sodium channels). (b) Ion selectivity of channels. The transmembrane region of a potassium channel in the closed position. This diagram is based on the bacterial KcsA channel, but vertebrate potassium channels are similar. Hydrated potassium ions (blue) enter the channel, where they give up their water and bind oxygen atoms, precisely positioned in the amino acids lining the selectivity filter (black). (c) Channel gating. The channel is regulated by a gate, which can open or close, depending on the state of voltage sensor domains in the channel.

through the *selectivity filter*, allowing them to give up their waters of hydration. The fit between K^+ ions and oxygens lining the channel is remarkably precise. Na^+ , which is smaller than K^+ , can only interact with oxygen atoms on one side of the channel. This makes it energetically unfavorable for Na^+ to give up its waters of hydration and enter the channel. Roderick MacKinnon received the Nobel Prize in chemistry in 2003, in part for his work on the pore structure of potassium channels.

Voltage-gated sodium channels have the ability to open rapidly in response to some stimulus and then to close again, a phenomenon known as **channel gating**. This open or closed state is an all-or-none phenomenon—that is, gates do not appear to remain partially open (Figure 13-8c). One of the transmembrane α helices of vertebrate voltage-gated channels, S4, acts as a **voltage sensor** during channel gating. When positively charged amino acids in S4 are replaced with neutral amino acids, the channel does not open. This result suggests that S4 makes these channels responsive to changes in potential. The details of how this happens are currently the subject of intense debate.

Most voltage-gated channels can also adopt a second type of closed state, referred to as **channel inactivation**, which is an important feature of voltage-gated sodium and potassium channels (Figure 13-9). When a channel is inactivated, it cannot reopen immediately, even if stimulated to do so. Channel inactivation is like placing a padlock on the closed gate; only when the padlock is unlocked can the gate be opened again. Inactivation is caused by a portion of the channel called the *inactivating particle*. Common channels have four such particles. During inactivation, a particle inserts into the opening of the channel. For a channel to reactivate and open in response to a stimulus, the inactivating particle must move away from the pore. When the cytosolic side of the channel is treated with a protease or with antibodies prepared against the fragment of the channel thought to be responsible for inactivation, the inactivating particle can no longer function, and channels can no longer be inactivated.

As we will see in the next few sections of this chapter, the regulation of ion channels is crucial for the proper

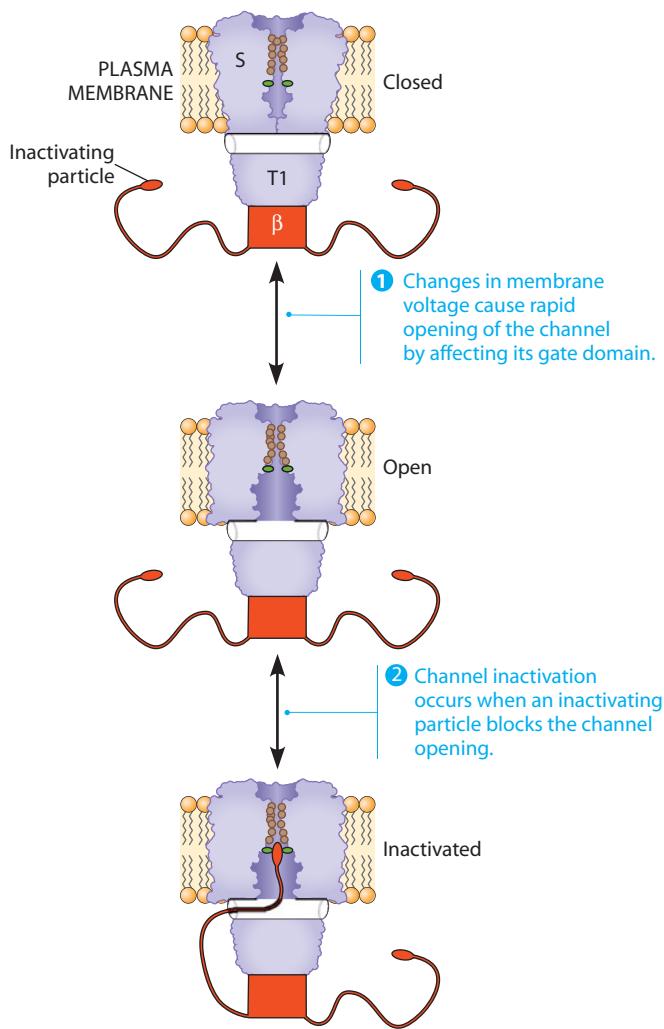

FIGURE 13-9 The Function of a Voltage-Gated Ion Channel. (a) Mammalian potassium channels have three major domains: the transmembrane (S) and cytosolic (T1) domains of the α subunit and the β subunit. The N-terminal region of the β subunit contains an inactivating particle. Channel gating occurs because a portion of the transmembrane domain changes conformation when the membrane potential changes. (b) Channel inactivation. Here, two of the four inactivating particles are shown for a voltage-gated potassium channel. Channels are inactivated when an inactivating particle moves through a "window" region of the channel, blocking the opening of the pore.

functioning of neurons. Defects in several voltage-gated ion channels have been linked to human neurological diseases (such defects have been termed “channelopathies”). For example, humans carrying mutations in certain K^+ channels suffer from ataxia (a defect in muscle coordination), and one form of epilepsy is caused by a mutation in one type of voltage-gated Na^+ channel.

The Action Potential

We have seen how an ion gradient across a selectively permeable membrane can generate a membrane potential and how, according to the Goldman equation, the

membrane potential will change in response to changes in ion permeability. We have also examined the nature of membrane ion channels, which regulate the permeability of the membrane to the different ions. Now we are ready to explore how the coordinated opening and closing of ion channels can lead to an action potential. We will begin by examining how membrane potential changes during an action potential. Because of its historical importance, we will use the squid giant axon as the model for our discussion.

Action Potentials Propagate Electrical Signals Along an Axon

A resting neuron is a system poised for electrical action. As we have seen, the membrane potential of the cell is set by a delicate balance of ion gradients and ion permeability. Depolarization of the membrane upsets this balance. If the level of depolarization is small—less than about +20 mV—the membrane potential will normally drop back to resting levels without further consequences. Further depolarization brings the membrane to the **threshold potential**. Above the threshold potential, the nerve cell membrane undergoes rapid and dramatic alterations in its electrical properties and permeability to ions, and an action potential is initiated.

An **action potential** is a brief but large electrical depolarization and repolarization of the neuronal plasma membrane caused by the inward movement of sodium ions and the subsequent outward movement of potassium ions. These ion movements are controlled by the opening and closing of voltage-gated sodium and potassium channels. In fact, we can explain the development of an action potential solely in terms of the behavior of these channels. Once an action potential is initiated in one region of the membrane, it will travel along the membrane away from the site of origin by a process called **propagation**.

Action Potentials Involve Rapid Changes in the Membrane Potential of the Axon

As we saw in Figure 13-3b, the development and propagation of an action potential can be readily studied in large axons such as those of the squid. **Figure 13-10** shows the sequence of membrane potential changes associated with an action potential. In less than a millisecond, the membrane potential rises dramatically from the resting membrane potential to about +40 mV—the interior of the membrane actually becomes positive for a brief period. The potential then falls somewhat more slowly, dropping to about -75 mV (called *undershoot* or *hyperpolarization*) before stabilizing again at the resting potential of about -60 mV. As Figure 13-10 indicates, the complete sequence of events during an action potential takes place within a few milliseconds.

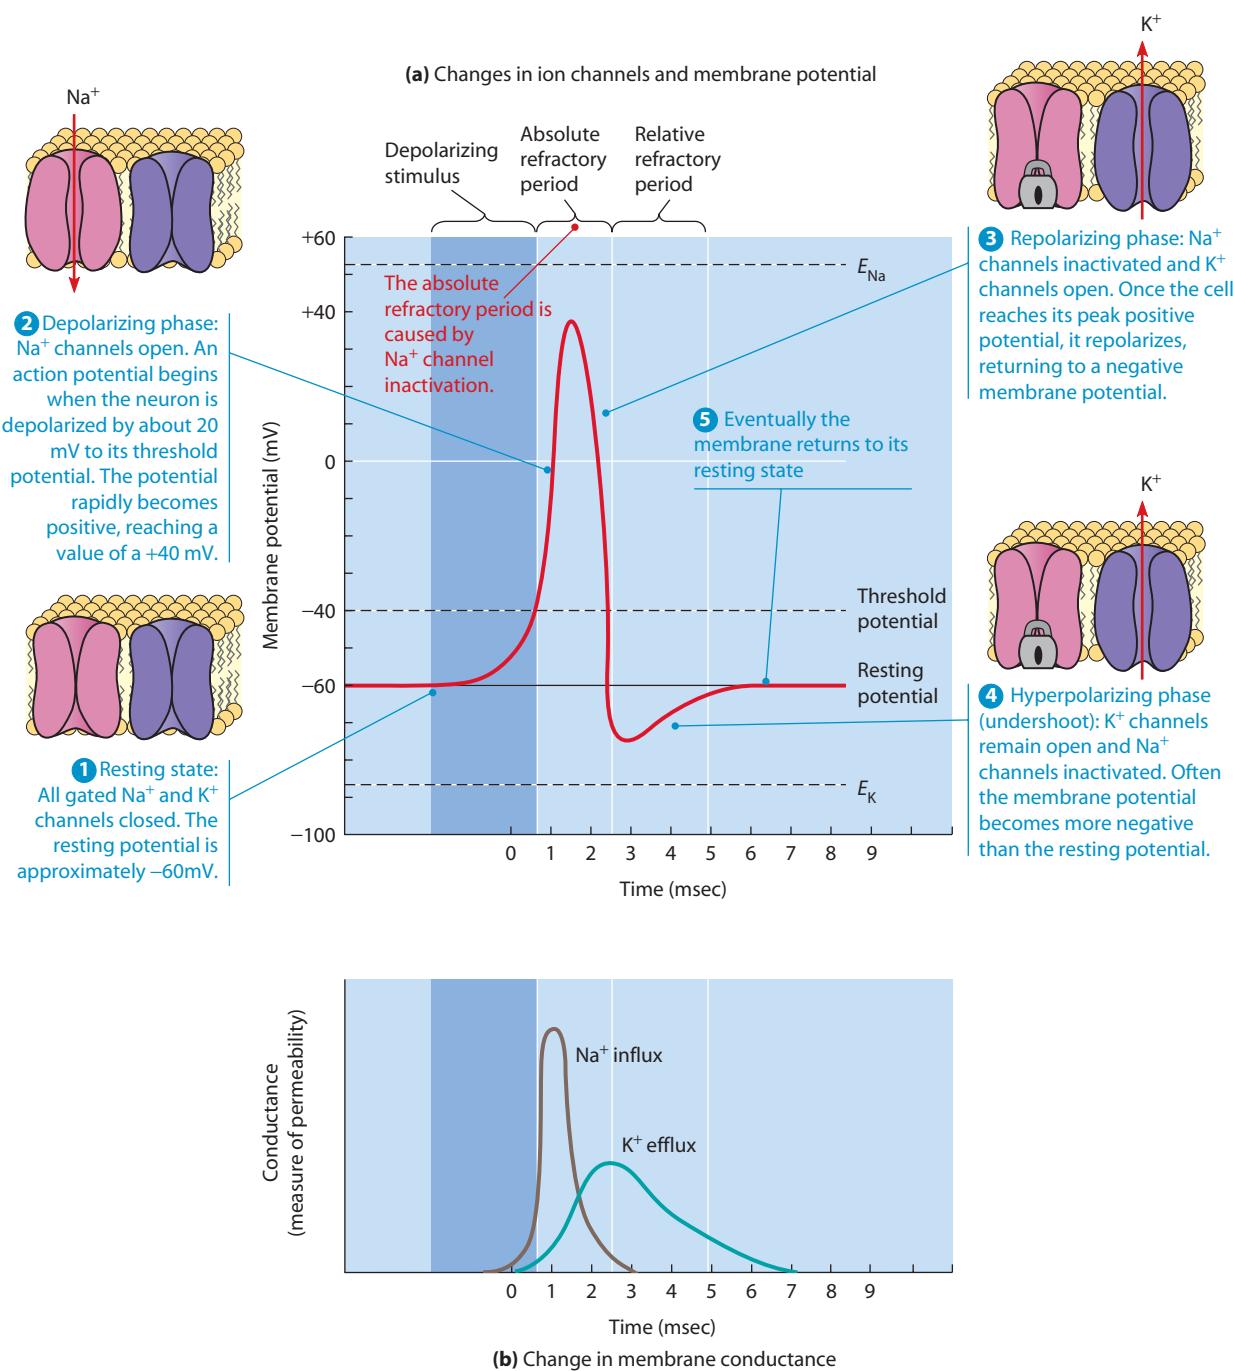

FIGURE 13-10 Changes in Ion Channels and Currents in the Membrane of a Squid Axon During an Action Potential. (a) The change in membrane potential caused by movement of Na⁺ and K⁺ through their voltage-gated channels, which are shown at each step of the action potential. The absolute refractory period is caused by sodium channel inactivation. Notice that at the peak of the action potential, the membrane potential approaches the E_{Na} (sodium equilibrium potential) value of about +55 mV; similarly, the potential undershoots nearly to the E_K (potassium equilibrium potential) value of about -75 mV. (b) The change in membrane conductance (permeability of the membrane to specific ions). The depolarized membrane initially becomes very permeable to sodium ions, facilitating a large inward rush of sodium. Thereafter, as permeability to sodium declines, the permeability of the membrane to potassium increases transiently, causing the membrane to hyperpolarize.

The apparatus shown in Figure 13-3b can also be used to measure the ion currents that flow through the membrane at different phases of an action potential. To do so, an additional electrode known as the *holding electrode* is inserted into the cell and connected to a voltage clamp, thereby enabling the investigator to set and hold

the membrane at a particular potential. Using the voltage-clamp apparatus, a researcher can measure the current flowing through the membrane at any given membrane potential. Such experiments have contributed fundamentally to our present understanding of the mechanism that causes an action potential.

Action Potentials Result from the Rapid Movement of Ions Through Axonal Membrane Channels

In a resting neuron, the voltage-dependent sodium and potassium channels are usually closed. Because of the steady-state leakiness of the membrane to potassium ions, the cell is roughly 100 times more permeable to potassium than to sodium ions at this point. When a region of the nerve cell is slightly depolarized, a fraction of the sodium channels respond and open. As they do, the increased sodium current acts to further depolarize the membrane. Increasing depolarization causes an even larger sodium current to flow, which depolarizes the membrane even more. This relationship between depolarization, the opening of voltage-gated sodium channels, and an increased sodium current constitutes a positive feedback loop known as the *Hodgkin cycle*.

Subthreshold Depolarization. Under resting conditions, the outward movement of potassium ions through leak channels restores the resting membrane potential. When the membrane is depolarized by a small amount, the membrane potential recovers and no action potential is generated. Levels of depolarization that are too small to produce an action potential are referred to as *subthreshold depolarizations*.

The Depolarizing Phase. If all the voltage-dependent sodium channels in the membrane were to open at once, the cell would suddenly become ten times more permeable to sodium than to potassium. Because sodium would then be the more permeable ion, the membrane potential would be largely a function of the sodium ion gradient. This is effectively what happens when the membrane is depolarized past the threshold potential (Figure 13-10, ① and ②). Once the threshold potential is reached, a significant number of sodium channels begin activating. At this point, the membrane potential shoots rapidly upward. When the rate of sodium entry slightly exceeds the maximum rate of potassium exit, an action potential is triggered. When the membrane potential peaks, at approximately +40 mV, the action potential approaches—although it does not actually reach—the equilibrium potential for sodium ions (about +55 mV). (It never actually reaches this value because the membrane remains permeable to other ions during this time.)

The Repolarizing Phase. Once the membrane potential has risen to its peak, the membrane quickly repolarizes (Figure 13-10, ③). This is due to a combination of the inactivation of sodium channels and the opening of voltage-gated potassium channels. When sodium channels are inactivated, they close and remain closed until the membrane potential becomes negative again. Channel inactivation thus stops the inward flow of sodium ions. The cell will now automatically repolarize as potassium ions leave the cell.

The difference in response speed between voltage-gated potassium channels and voltage-gated sodium channels plays an important role in generating the action potential. When the cell is depolarized, the potassium channels open more slowly. As a result, an action potential begins with an increase in the membrane's permeability to sodium, which depolarizes the membrane, followed by an increased permeability to potassium, which repolarizes the membrane.

The Hyperpolarizing Phase (Undershoot). At the end of an action potential, most neurons show a transient **hyperpolarization**, or **undershoot**, in which the membrane potential briefly becomes even more negative than it normally is at rest (Figure 13-10, ④). The undershoot occurs because of the increased potassium permeability that exists while voltage-gated potassium channels remain open. Note that the potential of the undershoot closely approximates the equilibrium potential for potassium ions (about -75 mV for the squid axon). As the voltage-gated potassium channels close, the membrane potential returns to its original resting state (Figure 13-10, ⑤). Notice that the rapid restoration of the resting potential following an action potential does not use the Na^+/K^+ pump but instead involves the passive movements of ions. In cells that have been treated with a metabolic inhibitor so that they cannot produce ATP (and hence their Na^+/K^+ pumps cannot use it), action potentials can still be generated. The pump helps to maintain a negative potential once an action potential has passed and the membrane has returned to its resting state.

The Refractory Periods. For a few milliseconds after an action potential, it is impossible to trigger a new action potential. During this interval, known as the **absolute refractory period**, sodium channels are inactivated and cannot be opened by depolarization. During the period of undershoot, when the sodium channels have reactivated and are capable of opening again, it is possible but difficult to trigger an action potential. This is because both potassium leak channels and voltage-gated potassium channels are open during this time. This tends to drive the membrane potential to a very negative value, far from the threshold for triggering another round of sodium channel opening. This interval is known as the **relative refractory period**.

Changes in Ion Concentrations Due to an Action Potential. Our discussion of ion movements might give the impression that an action potential involves large changes in the cytosolic concentrations of sodium and potassium ions. In fact, during a single action potential, the cellular concentrations of sodium and potassium ions hardly change at all. Remember that the membrane potential is due to a slight excess of negative charge on one side and a slight excess of positive charge on the other side of the membrane. The number of excess charges is a tiny fraction of the total ions in the cell, and the number of

ions that must cross the membrane to neutralize or alter the balance of charge is likewise small.

Nevertheless, intense neuronal activity can lead to significant changes in overall ion concentrations. For example, as a neuron continues to generate large numbers of action potentials, the concentration of potassium outside the cell will begin to rise perceptibly. This can affect the membrane potential of both the neuron itself and surrounding cells. Astrocytes, the glial cells that form the blood-brain barrier, are thought to control this problem by taking up excess potassium ions.

Action Potentials Are Propagated Along the Axon Without Losing Strength

For neurons to transmit signals to one another, the transient depolarization and repolarization that occur during an action potential must travel along the neuronal membrane. The depolarization at one point on the membrane spreads to adjacent regions through a process called the **passive spread of depolarization**. As a wave of depolarization spreads passively away from the site of origin, it also decreases in magnitude. This fading of the depolarization with distance from the source makes it difficult for signals to travel very far by passive means only. For signals to travel longer distances, an action potential must be *propagated*, or actively generated, from point to point along the membrane.

To understand the difference between the passive spread of depolarization and the propagation of an action potential, consider how a signal travels along the neuron from the site of origin at the dendrites to the end of the axon (**Figure 13-11**). Incoming signals are transmitted to a neuron at synapses that form points of contact between the synaptic boutons of the transmitting neuron and the dendrites of the receiving neuron. When these incoming signals depolarize the dendrites of the receiving neuron, the depolarization spreads passively over the membrane from the dendrites to the base of the axon—the **axon hillock**. The axon hillock is the region where action potentials are initiated most easily. This is because sodium channels are distributed sparsely over the dendrites and cell body but are concentrated at the axon hillock and nodes of Ranvier; a given amount of depolarization will produce the greatest amount of sodium entry at sites where sodium channels are abundant. The action potentials initiated at the axon hillock are then propagated along the axon.

The mechanism for propagating an action potential in nonmyelinated nerve cells is illustrated in **Figure 13-12**. Stimulation of a resting membrane results in a depolarization of the membrane and a sudden rush of sodium ions into the axon at that location (**1**). Membrane polarity is temporarily reversed at that point, and this depolarization then spreads to an adjacent point (**2**). The depolarization at this adjacent point is sufficient to bring it above the threshold potential, triggering the inward rush of sodium

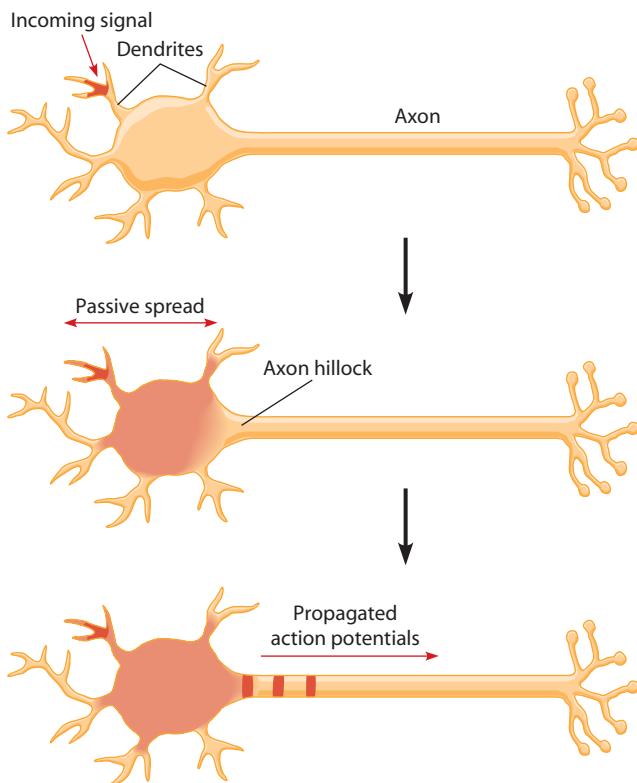

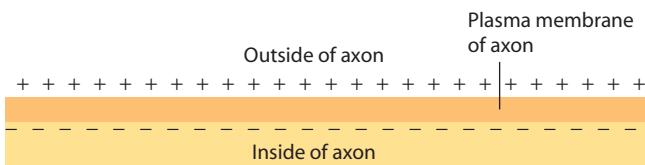

FIGURE 13-11 The Passive Spread of Depolarization and Propagated Action Potentials in a Neuron. The transmission of a nerve impulse along a neuron depends on both the passive spread of depolarization and the propagation of action potentials. A neuron is stimulated when its dendrites receive a depolarizing stimulus from other neurons. A depolarization starting at a dendrite spreads passively over the cell body to the axon hillock, where an action potential forms. The action potential is then propagated down the axon.

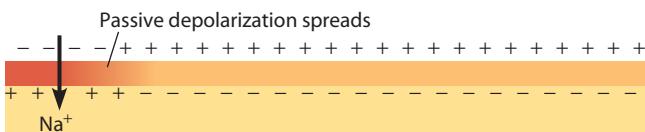

ions (**3**). By this time, the original region of membrane has become highly permeable to potassium ions. As potassium ions rush out of the cell, negative polarity is restored and that portion of the membrane returns to its resting state (**4**).

Meanwhile, the depolarization has spread to a new region, initiating the same sequence of events there (**5**). In this way, the signal moves along the membrane as a ripple of depolarization-repolarization events; the membrane polarity is reversed in the immediate vicinity of the signal but returned to normal again as the signal travels down the axon. The propagation of this cycle of events along the nerve fiber is called a *propagated action potential*, or **nerve impulse**. The nerve impulse can move only *away* from the initial site of depolarization because the sodium channels that have just been depolarized are in the inactivated state and cannot respond immediately to further stimulation.

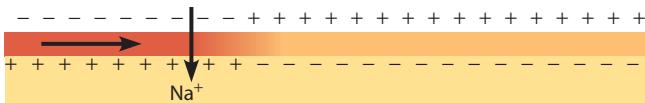

Because an action potential is actively propagated, it does not fade as it travels. The reason is that it is generated anew, as an all-or-none event, at each successive point along the membrane. Thus, a nerve impulse

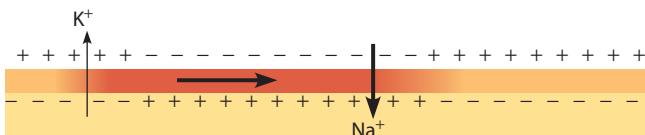

1 At the start, the membrane is completely polarized.

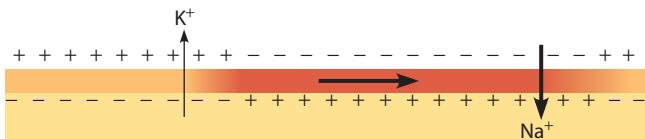

2 When an action potential is initiated, a region of the membrane depolarizes. As a result, the adjacent regions become depolarized.

3 When the adjacent region is depolarized to its threshold, an action potential starts there.

4 Repolarization occurs due to the outward flow of K⁺ ions. The depolarization spreads forward, triggering an action potential.

5 Depolarization spreads forward, repeating the process.

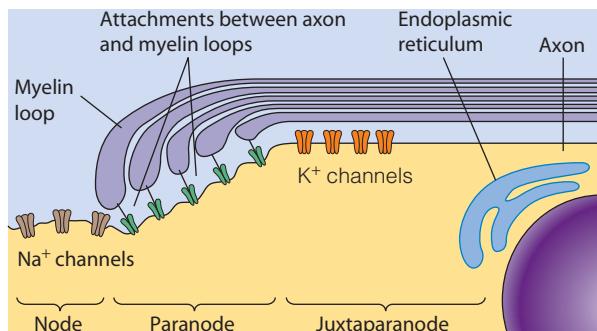

FIGURE 13-12 The Transmission of an Action Potential Along a Nonmyelinated Axon.

Along a Nonmyelinated Axon. A nonmyelinated axon can be viewed as a string of points, each capable of undergoing an action potential. Notice that no backward propagation occurs near sites where action potentials form because sodium channels are in an inactivated state and the membrane is hyperpolarized.

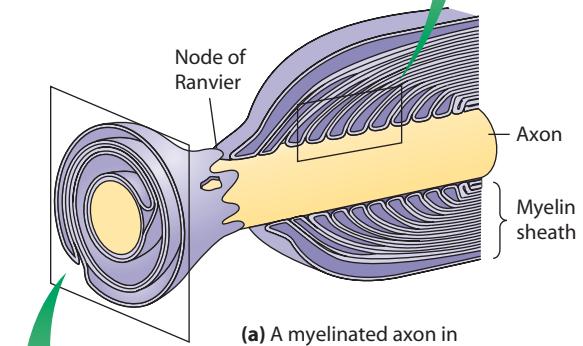

can be transmitted over essentially any distance with no decrease in strength.

The Myelin Sheath Acts Like an Electrical Insulator Surrounding the Axon

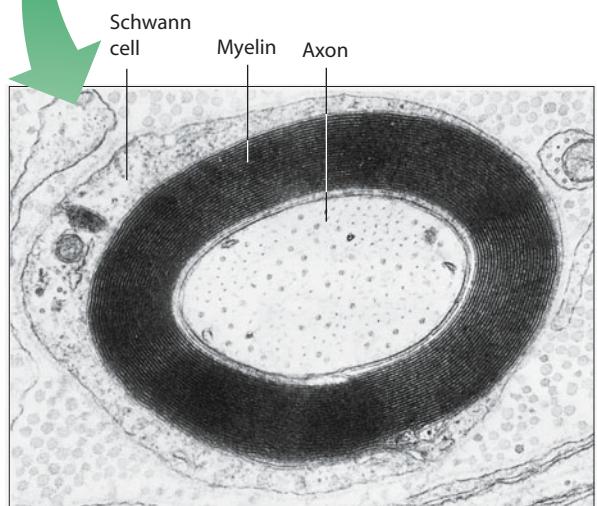

Most axons in vertebrates have an additional specialization: They are surrounded by a discontinuous **myelin sheath** consisting of many concentric layers of membrane. The myelin sheath is a reasonably effective electrical insulation for the segments of the axon that it envelops. The myelin sheath of neurons in the CNS is formed by **oligodendrocytes**; in the peripheral nervous system (PNS), the myelin sheath is formed by **Schwann cells** (see Figure 13-1), each of which wraps layer after layer of its own plasma membrane around the axon in a tight spiral (**Figure 13-13**). Because each Schwann cell surrounds a

(b) Molecular organization at a node of Ranvier

1 μm

FIGURE 13-13 Myelination of Axons. (a) An axon of the peripheral nervous system that has been myelinated by a Schwann cell. Each Schwann cell gives rise to one segment of myelin sheath by wrapping its own plasma membrane concentrically around the axon. (b) Organization of a typical node of Ranvier in the peripheral nervous system. Sodium channels (brown) are concentrated in the node. Myelin loops attach to the regions next to the node ("paranodal" regions) via proteins on the axonal membrane and on the myelin loops (green). Potassium channels (orange) cluster next to the paranodal regions. (c) This cross-sectional view of a myelinated axon from the nervous system of a cat shows the concentric layers of membrane that have been wrapped around the axon by the Schwann cell that envelops it (TEM).

short segment (about 1 mm) of a single axon, many Schwann cells are required to encase a PNS axon with a discontinuous sheath of myelin. Myelination decreases the ability of the neuronal membrane to retain electric charge (i.e., myelination decreases its *capacitance*), permitting a depolarization event to spread farther and faster than it would along a nonmyelinated axon.

Myelination does not eliminate the need for propagation, however. For depolarization to spread from one site to the rest of the neuron, the action potential must still be renewed periodically down the axon. This happens at the *nodes of Ranvier*, interruptions in the myelin layer that are spaced just close enough together (1–2 mm) to ensure that the depolarization spreading out from an

action potential at one node is still strong enough to bring an adjacent node above its threshold potential (**Figure 13-14**). The nodes of Ranvier are the only places on a myelinated axon where an action potential can be generated because current flow through the membrane is restricted elsewhere and because voltage-gated sodium channels are concentrated there. Thus, action potentials jump from node to node along myelinated axons rather than moving as a steady ripple along the membrane. This so-called *saltatory propagation* is much more rapid than the continuous propagation that occurs in nonmyelinated axons (*saltatory* is derived from the Latin word for “dancing”; see Figure 13-14). Myelination is a crucial feature of mammalian axons. Loss of myelination results in a dramatic decrease in the electrical resistance of the axonal membrane. Much like the flow of water through a leaky garden hose, this loss of resistance dramatically reduces conduction velocity along an axon. The debilitating human disease multiple sclerosis results when a patient’s immune system attacks his or her own myelinated nerve fibers, causing demyelination. If the affected nerves innervate muscles, the patient’s capacity for movement can be severely compromised.

Nodes of Ranvier are highly organized structures that involve close contact between the loops of glial or Schwann cell membrane and the plasma membrane of the axon(s) they myelinate. Three distinct regions are associated with these specialized sites of contact. In the node of Ranvier itself, voltage-sensitive sodium channels are highly concentrated. In the adjacent regions, called paranodal regions (*para-* means “alongside”), the axonal and glial cell membranes contain specialized adhesive proteins that are similar to those in septate junctions (see Chapter 17). Finally, in the region next to the paranodal areas, called juxtaparanodal regions (*juxta-* means “next to”), potassium channels are highly concentrated (see Figure 13-13b). The organization of nodes of Ranvier prevents free movement of the sodium and potassium channels within the axon’s plasma membrane in regions around the nodes.

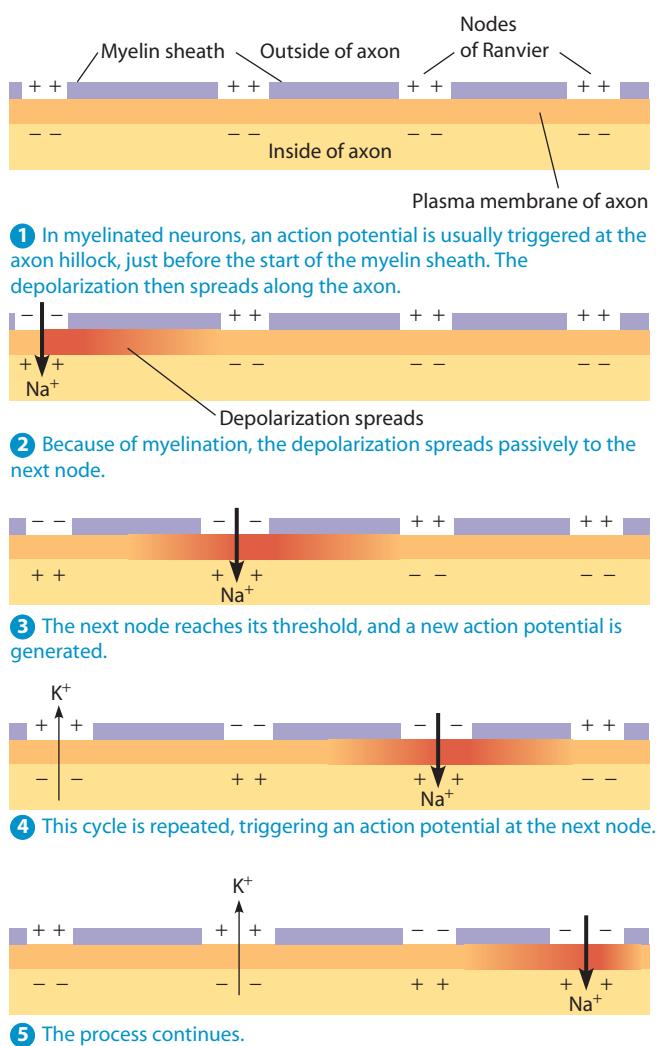

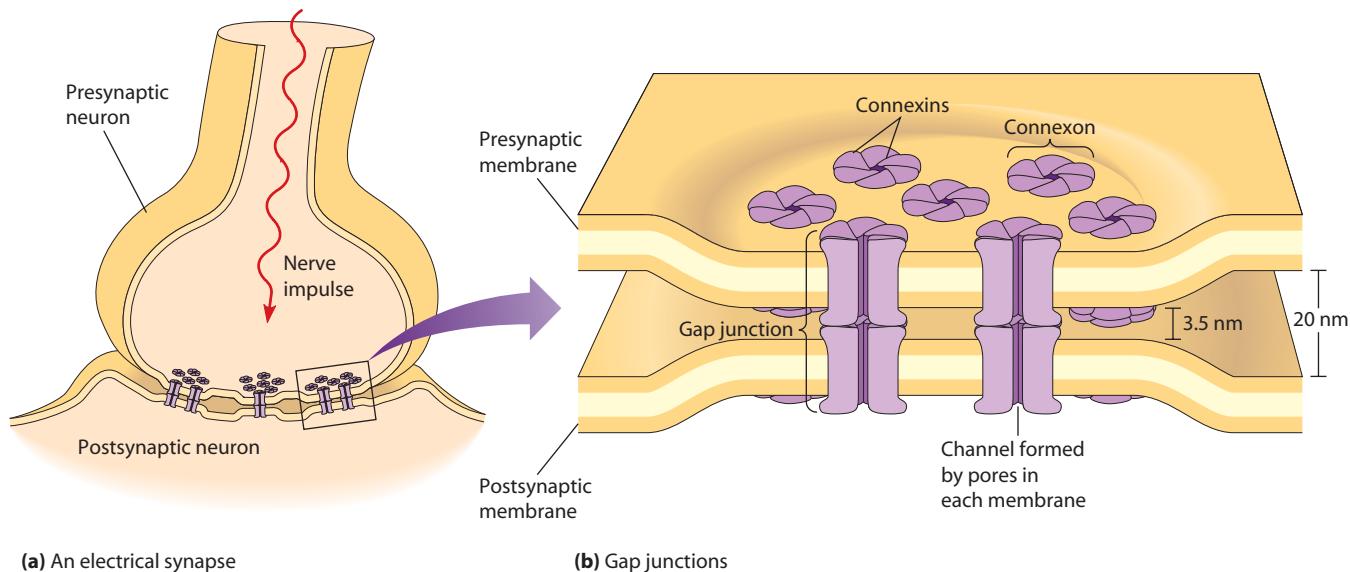

FIGURE 13-14 The Transmission of an Action Potential Along a Myelinated Axon. In a myelinated axon, action potentials can be generated only at nodes of Ranvier. Myelination reduces membrane capacitance, thereby allowing a given amount of sodium current, entering at one point of the membrane, to spread much farther along the membrane than it would in the absence of myelin. The result is a wave of depolarization-repolarization events that are propagated along the axon from node to node.

Synaptic Transmission

Nerve cells communicate with one another and with glands and muscles at synapses. There are two structurally distinct types of synapses, electrical and chemical. In an **electrical synapse**, one neuron, called the **presynaptic neuron**, is connected to a second neuron, the **postsynaptic neuron**, by gap junctions (**Figure 13-15**; we will explore gap junctions in more detail in Chapter 17). As ions move back and forth between the two cells, the depolarization in one cell spreads passively to the connected cell. Electrical synapses provide for transmission with virtually no delay and occur in places in the nervous system where speed of transmission is critical. Similar electrical connections can be found between nonneuronal cells, such as the cardiac muscle cells in the heart (see Chapter 16).

(a) An electrical synapse

(b) Gap junctions

FIGURE 13-15 An Electrical Synapse. (a) In electrical synapses, the presynaptic and postsynaptic neurons are coupled by gap junctions, which allow small molecules and ions to pass freely from the cytosol of one cell to the next. When an action potential arrives at the presynaptic side of an electrical synapse, the depolarization spreads passively, due to the flow of positively charged ions, across the gap junction. (b) The gap junction is composed of sets of channels. A channel is made up of six protein subunits, each called a connexin. The entire set of six subunits together is called a connexon. Two connexons, one in the presynaptic membrane and one in the postsynaptic membrane, make up a gap junction.

In a **chemical synapse**, the presynaptic and postsynaptic neurons are not connected by gap junctions, (Figure 13-16), although they are connected by cell adhesion proteins (which we will consider in Chapter 17). Instead, the presynaptic plasma membrane is separated from the postsynaptic membrane by a small space of about 20–50 nm, known as the **synaptic cleft**. A nerve signal arriving at the terminals of the presynaptic neuron cannot bridge the synaptic cleft as an electrical impulse. For synaptic transmission to take place, the electrical signal must be converted at the presynaptic neuron to a chemical signal carried by a neurotransmitter. Neurotransmitter molecules are stored in the synaptic boutons of the presynaptic neuron. An action potential arriving at the terminal causes the neurotransmitter to be secreted into and diffuse across the synaptic cleft. The neurotransmitter molecules then bind to specific proteins embedded within the plasma membrane of the postsynaptic neuron (*receptors*) and are converted back into electrical signals, setting in motion a sequence of events that either stimulates or inhibits the production of an action potential in the postsynaptic neuron, depending on the kind of synapse.

Neurotransmitter receptors fall into two broad groups: *ligand-gated ion channels* (sometimes called *ionotropic* receptors), in which activation directly affects the cell, and receptors that exert their effects indirectly through a system of intracellular messengers (sometimes called *metabotropic* receptors; Figure 13-17). We will discuss the latter category of receptors in Chapter 14; here, we

focus on *ligand-gated channels*. These membrane ion channels open in response to the binding of a neurotransmitter, and they can mediate either excitatory or inhibitory responses in the postsynaptic cell.

Neurotransmitters Relay Signals Across Nerve Synapses

A **neurotransmitter** is essentially any signaling molecule released by a neuron. Many kinds of molecules act as neurotransmitters. Most are detected by the postsynaptic cell via a specific type of receptor; most neurotransmitters have more than one type of receptor. When a neurotransmitter molecule binds to its receptor, the properties of the receptor are altered, and the postsynaptic neuron responds accordingly. An *excitatory receptor* causes depolarization of the postsynaptic neuron, whereas an *inhibitory receptor* typically causes the postsynaptic cell to hyperpolarize.

Although definitions vary, to qualify as a neurotransmitter, a compound must satisfy three criteria: (1) It must elicit the appropriate response when introduced into the synaptic cleft, (2) it must occur naturally in the presynaptic neuron, and (3) it must be released at the right time when the presynaptic neuron is stimulated. Many molecules meet these criteria, including acetylcholine, a group of biogenic amines called the catecholamines, certain amino acids and their derivatives, peptides, endocannabinoids, nucleotides such as ATP, some ions, and gases (such as nitric oxide). Table 13-2 lists several common neurotransmitters; we will discuss some of them here.

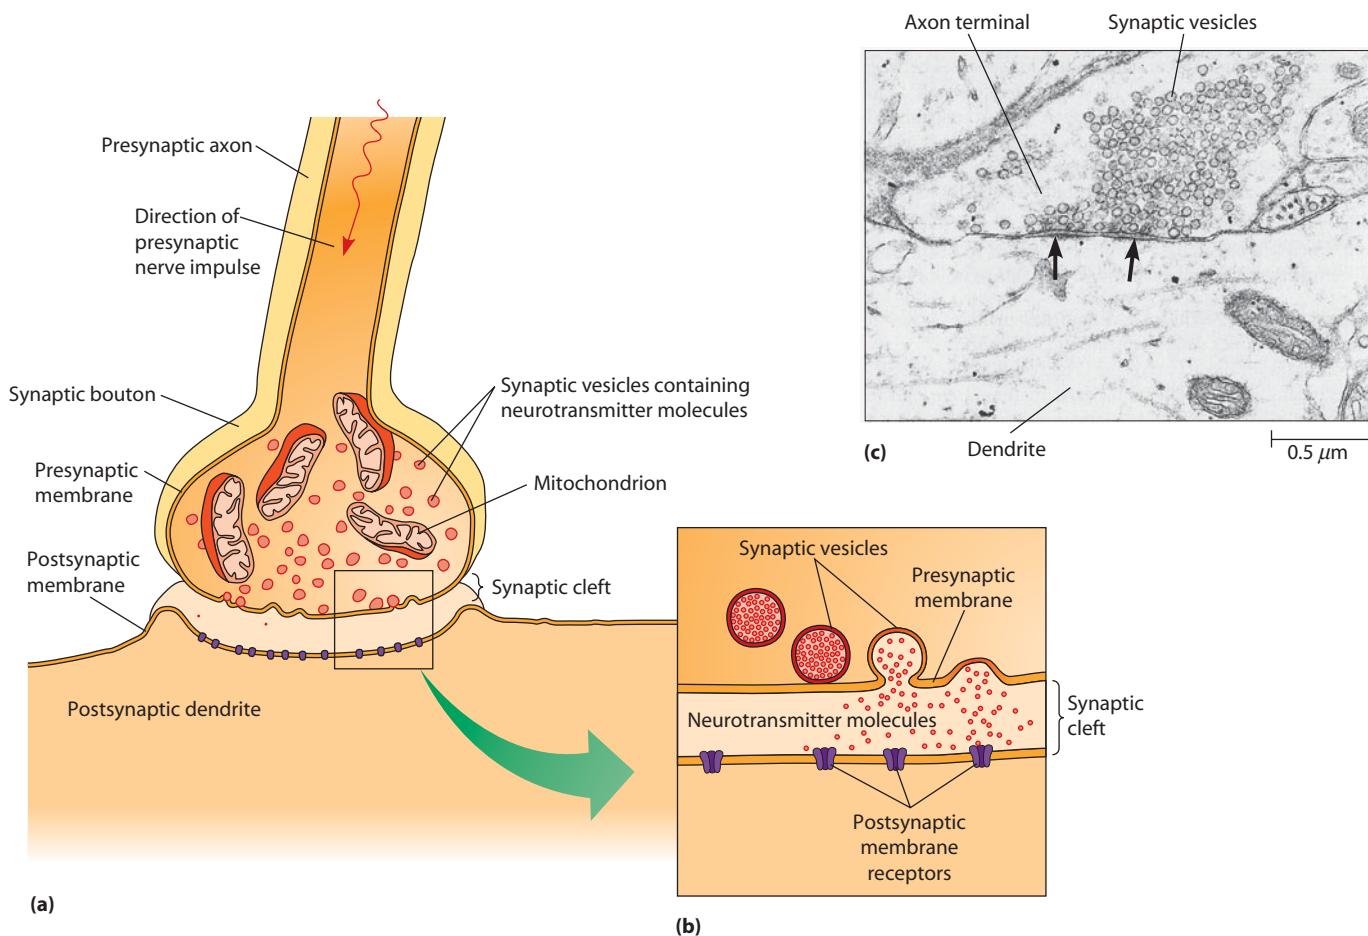

FIGURE 13-16 A Chemical Synapse. (a) When a nerve impulse from the presynaptic axon arrives at the synapse (red arrow), it causes synaptic vesicles containing neurotransmitter in the synaptic bouton to fuse with the presynaptic membrane, releasing their contents into the synaptic cleft. (b) Neurotransmitter molecules diffuse across the cleft from the presynaptic (axonal) membrane to the postsynaptic (dendritic) membrane, where they bind to specific membrane receptors and change the polarization of the membrane, either exciting or inhibiting the postsynaptic cell. (c) Electron micrograph of a chemical synapse (TEM). Arrows indicate a postsynaptic density, where membrane receptors and other proteins cluster.

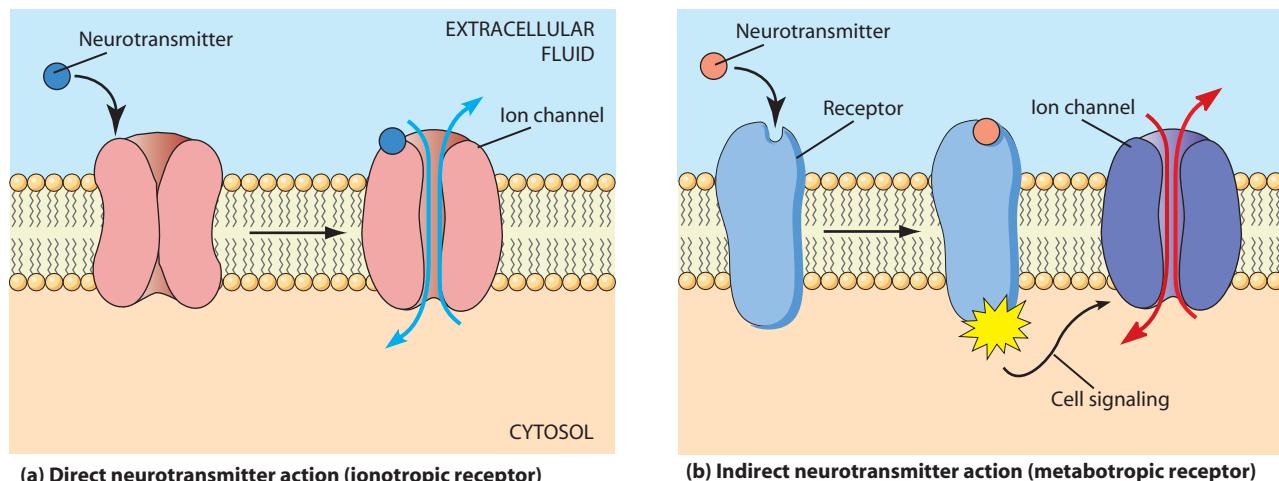

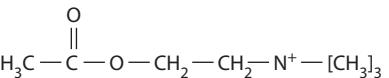

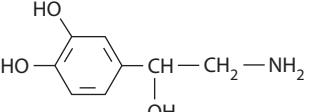

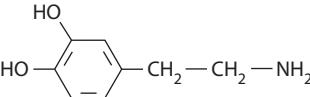

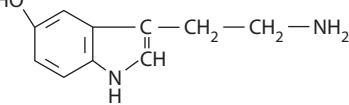

FIGURE 13-17 Different Kinds of Receptors That Act at Chemical Synapses. (a) Direct neurotransmitter action. Ionotropic receptors act directly as ion channels. When they bind a neurotransmitter, they undergo a conformational change, and ions can pass through them. (b) Indirect neurotransmitter action. When metabotropic receptors bind neurotransmitters, they set in motion a series of cell signaling events that indirectly lead to the opening of an ion channel. Because they act indirectly, metabotropic receptors act more slowly than ionotropic receptors.

Table 13-2 Different Kinds of Neurotransmitters

Neurotransmitter	Structure	Functional Class	Secretion Sites
Catecholamines			
Acetylcholine		Excitatory to vertebrate skeletal muscles; excitatory or inhibitory at other sites	CNS; PNS; vertebrate neuromuscular junction
Biogenic Amines			
Norepinephrine		Excitatory or inhibitory	CNS; PNS
Dopamine		Generally excitatory; may be inhibitory at some sites	CNS; PNS
Serotonin		Generally inhibitory	CNS
Amino Acids			
GABA (γ -aminobutyric acid)	$\text{H}_2\text{N}-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{COOH}$	Inhibitory	CNS; invertebrate neuromuscular junction
Glutamate	$\text{H}_2\text{N}-\underset{\text{COOH}}{\text{CH}}-\text{CH}_2-\text{CH}_2-\text{COOH}$	Excitatory	CNS; invertebrate neuromuscular junction
Glycine	$\text{H}_2\text{N}-\text{CH}_2-\text{COOH}$	Inhibitory	CNS
Neuropeptides			
Substance P	Arg — Pro — Lys — Pro — Gln — Gln — Phe — Phe — Gly — Leu — Met	Excitatory	CNS; PNS
Met-enkephalin (an endorphin)	Tyr — Gly — Gly — Phe — Met	Generally inhibitory	CNS
Endocannabinoids			
Anandamide		Inhibitory	CNS
Gases			
Nitric oxide	$\text{N}=\text{O}$	Excitatory or inhibitory	PNS

Acetylcholine. In vertebrates, **acetylcholine** is the most common neurotransmitter for synapses between neurons outside the central nervous system (CNS), as well as for neuromuscular junctions (see Chapter 16). Acetylcholine is an excitatory neurotransmitter. Bernard Katz and his collaborators were the first to make the important observation that acetylcholine increases the permeability of the postsynaptic membrane to sodium within 0.1 msec of binding to its receptor. Synapses that use acetylcholine as their neurotransmitter are called **cholinergic synapses**.

Catecholamines. The **catecholamines** include **dopamine** and the hormones **norepinephrine** and **epinephrine**, all derivatives of the amino acid tyrosine. Because the cate-

cholamines are also synthesized in the adrenal gland, synapses that use them as neurotransmitters are termed **adrenergic synapses**. Adrenergic synapses are found at the junctions between nerves and smooth muscles in internal organs such as the intestines, as well as at nerve-nerve junctions in the brain. The mode of action of adrenergic hormones will be considered in Chapter 14.

Amino Acids and Derivatives. Other neurotransmitters that consist of amino acids and derivatives include **histamine**, **serotonin**, and **γ -aminobutyric acid (GABA)**, as well as **glycine** and **glutamate**. Serotonin functions in the CNS. It is considered an excitatory neurotransmitter because it indirectly causes potassium channels to close,

which has an effect similar to opening sodium channels in that the postsynaptic cell is depolarized. However, its effect is exerted much more slowly than that of sodium channels. GABA and glycine are inhibitory neurotransmitters, whereas glutamate has an excitatory effect.

Neuropeptides. Short chains of amino acids called **neuropeptides** are formed by proteolytic cleavage of precursor proteins. Hundreds of different neuropeptides have been identified. Some neuropeptides exhibit characteristics similar to neurotransmitters in that they excite, inhibit, or modify the activity of other neurons in the brain. However, they differ from typical neurotransmitters in that they act on groups of neurons and have long-lasting effects.

Examples of neuropeptides include the *enkephalins*, which are naturally produced in the mammalian brain and inhibit the activity of neurons in regions of the brain involved in the perception of pain. The modification of neural activity by these neuropeptides appears to be responsible for the insensitivity to pain experienced by individuals under conditions of great stress or shock. The analgesic (i.e., pain-killing) effectiveness of drugs such as morphine, codeine, Demerol, and heroin derives from their ability to bind to the same sites within the brain that are normally targeted by enkephalins.

Other substances released at synapses include the lipid derivatives known as the *endocannabinoids*, which inhibit the activity of presynaptic neurons. The main endocannabinoid receptor found in the brain is also stimulated by tetrahydrocannabinol, or THC, a substance found in plants of the genus *Cannabis*. Marijuana is derived from the leaves of the species *Cannabis sativa* and owes its effects to THC.

Elevated Calcium Levels Stimulate Secretion of Neurotransmitters from Presynaptic Neurons

Secretion of neurotransmitters by the presynaptic cell is directly controlled by the concentration of calcium ions in the synaptic bouton (Figure 13-18). Each time an action potential arrives, the depolarization causes the calcium concentration in the synaptic bouton to increase temporarily due to the opening of **voltage-gated calcium channels** in the synaptic boutons. Normally, the cell is relatively impermeable to calcium ions, so that the cytosolic calcium concentration remains low (about 0.1 mM). However, there is a very large concentration gradient of calcium across the membrane because the calcium concentration outside the cell is about 10,000 times higher than that of the cytosol. As a result, calcium ions will rush into the cell when the calcium channels open.

Before they are released, neurotransmitter molecules are stored in small, membrane-bounded **neurosecretory vesicles** in the synaptic boutons (see Figure 13-18). The release of calcium within the synaptic bouton has two main effects on neurosecretory vesicles. First, vesicles held in storage are mobilized for rapid release. Second, vesicles that are ready for release rapidly dock and fuse with the

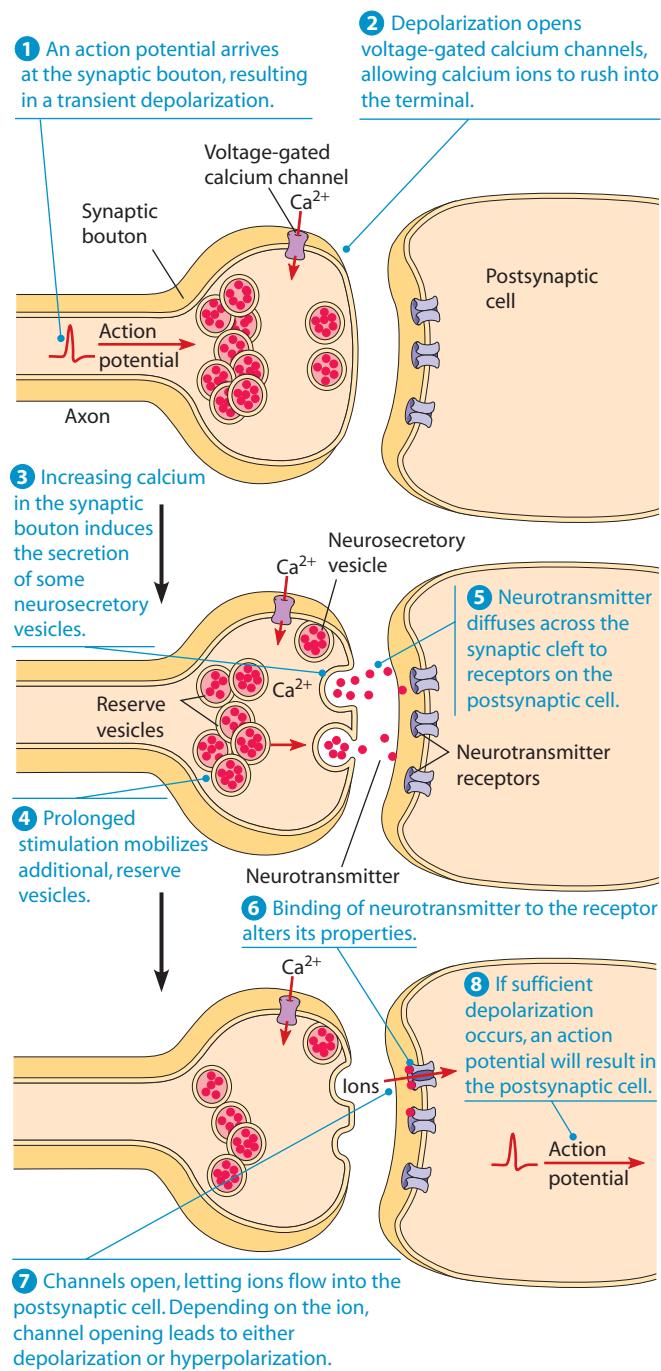

FIGURE 13-18 The Transmission of a Signal Across a Synapse. When an action potential arrives at the presynaptic bouton, a transient depolarization occurs, which leads to opening of voltage-gated calcium channels. Calcium elevation results in secretion of a neurotransmitter, which moves across the synapse and binds to receptors on the postsynaptic cell. The resulting depolarization can trigger an action potential.

www.thecellplace.com How synapses work

plasma membrane in the synaptic bouton region. During this process, the membrane of a vesicle moves into close contact with the plasma membrane of the axon terminal and then fuses with it to release the contents of the vesicle. We will now examine this process in more detail.

Secretion of Neurotransmitters Involves the Docking and Fusion of Vesicles with the Plasma Membrane

For the neurotransmitter to act on a postsynaptic cell, it must be secreted by the process of *exocytosis* (see Chapter 12 for details of exocytosis), in which the neurosecretory vesicle fuses with the plasma membrane, discharging the vesicle's contents into the synaptic cleft.

When an action potential arrives at an axon terminal and triggers the opening of voltage-gated calcium channels, calcium enters the synaptic bouton. Neurosecretory vesicles near the plasma membrane are now capable of fusing with the plasma membrane of the presynaptic neuron. Because it can occur very rapidly, vesicle fusion is thought to involve vesicles that are already “docked” at the plasma membrane. Docking and fusion of neurosecretory vesicles with the plasma membrane of the active zone are mediated by t- and v-SNARE proteins, just as we saw with other exocytosis events in Chapter 12 (see **Figure 13-19**; specific mechanisms involved in the docking steps of exocytosis are discussed in more detail in Chapter 12). The calcium “sensor” involved in coordinated docking of vesicles appears to be the protein *synaptotagmin*. Synaptotagmin can bind calcium; when it does, it undergoes a conformational change that allows the t- and v-SNARE complexes to interact efficiently.

Docking takes place at a specialized site, called the **active zone**, within the membrane of the presynaptic neuron (see Figure 13-19). The active zone is a highly organized structure. Synaptic vesicles and the calcium channels that elicit their release are found in close proximity to one another, which helps to explain the extremely rapid fusion of docked vesicles with the presynaptic neuron's plasma membrane when that neuron is stimulated. Two familiar and potentially deadly illnesses result from interference with vesicle docking and fusion events. Both tetanus and botulism result from interference by **neurotoxins** with vesicle docking and release. *Tetanus toxin* prevents the release of neurotransmitter from inhibitory neurons in the spinal cord, resulting in uncontrolled muscle contraction (which is why tetanus has been colloquially referred to as “lockjaw”). *Botulinum toxin* prevents release of neurotransmitter from motor neurons, resulting in muscle weakness and paralysis.

Recall from Chapter 12 that exocytosis of vesicles involves addition of the vesicle's membrane to the plasma membrane. When neurons release many neurosecretory vesicles in rapid succession, this has the potential to lead to accumulation of excess membrane in the presynaptic nerve terminal. Neurons solve this problem by *compensatory endocytosis*. Compensatory endocytosis relies on the formation of clathrin-dependent vesicles (see Chapter 12), which allow the recycling of membranes and thereby maintains the size of the nerve terminal.

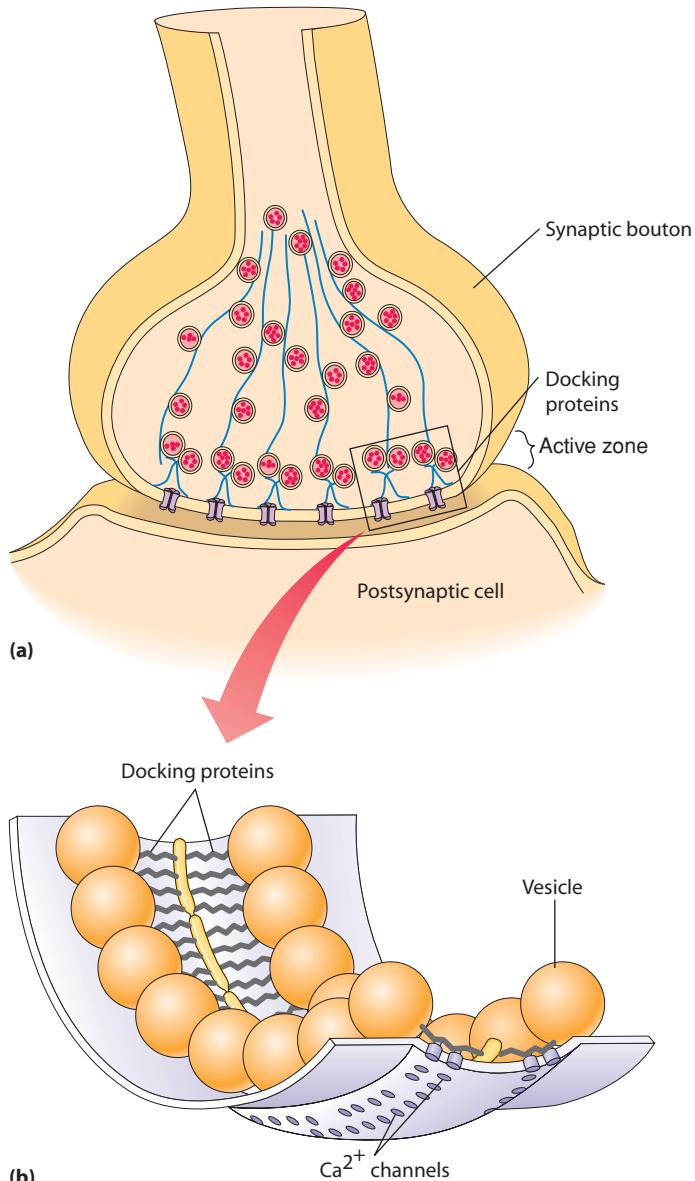

FIGURE 13-19 Docking of Synaptic Vesicles with the Plasma Membrane of the Presynaptic Neuron. (a) In response to local elevation of calcium in the presynaptic neuron, some synaptic vesicles become tightly associated (or docked) with the plasma membrane. When nearby calcium channels open, such docked vesicles fuse with the plasma membrane, releasing their contents. (b) A drawing based on an actual TEM reconstruction of the active zone of a motor neuron from a frog. Docked vesicles are arranged in rows and connected by a complex of proteins associated with docking. Calcium channels lie immediately beneath the vesicles.

In cases in which neurons need to fire very rapidly, they may use a more transient method for release of neurotransmitter, called *kiss-and-run exocytosis*. In this case, a vesicle may temporarily fuse with the plasma membrane via a tiny opening, causing release of some neurotransmitter from the vesicle. The vesicle then rapidly reseals without the added step of complete fusion with the plasma membrane.

Neurotransmitters Are Detected by Specific Receptors on Postsynaptic Neurons

When neurotransmitters are secreted across a synapse, their presence must be detected by the postsynaptic cell. Typically this response requires a protein *receptor*, which binds the neurotransmitter and mediates the response of the postsynaptic neuron. Different neurotransmitters are bound by specific receptors. We will discuss receptors more generally in Chapter 14; here we discuss several well-studied receptors that function specifically during synaptic transmission.

The Nicotinic Acetylcholine Receptor. One type of receptor to which acetylcholine binds is a ligand-gated sodium channel known as the *nicotinic acetylcholine receptor* (*nAChR*). (It is called “nicotinic” because the actions of acetylcholine on this receptor can be mimicked by nicotine; muscarinic AchRs, which are also activated by acetylcholine, are activated by the mushroom toxin muscarine and not by nicotine.) When two molecules of acetylcholine bind, the channel opens and lets sodium ions rush into the postsynaptic neuron, causing depolarization.

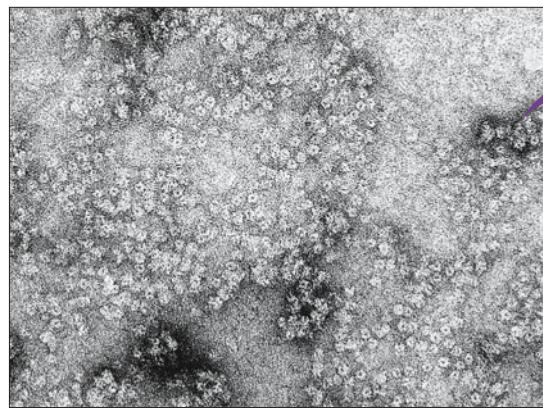

Our understanding of the nAChR has been greatly aided by study of the electric organs of the electric ray (*Torpedo californica*). The electric organ consists of *electroplaxes*—stacks of cells that are innervated on one side but not on the other. The innervated side of the stack can

undergo a potential change from about -90 mV to about $+60$ mV upon excitation, whereas the noninnervated side stays at -90 mV. Therefore, at the peak of an action potential, a potential difference of about 150 mV can be built up across a single electroplax. Because the electric organ contains thousands of electroplaxes arranged in series, their voltages are additive, allowing the ray to deliver a jolt of several hundred volts.

When examined under the electron microscope, electroplax membranes are found to be rich in rosette-like particles about 8 nm in diameter (**Figure 13-20a**); these particles are the nicotinic acetylcholine receptors.

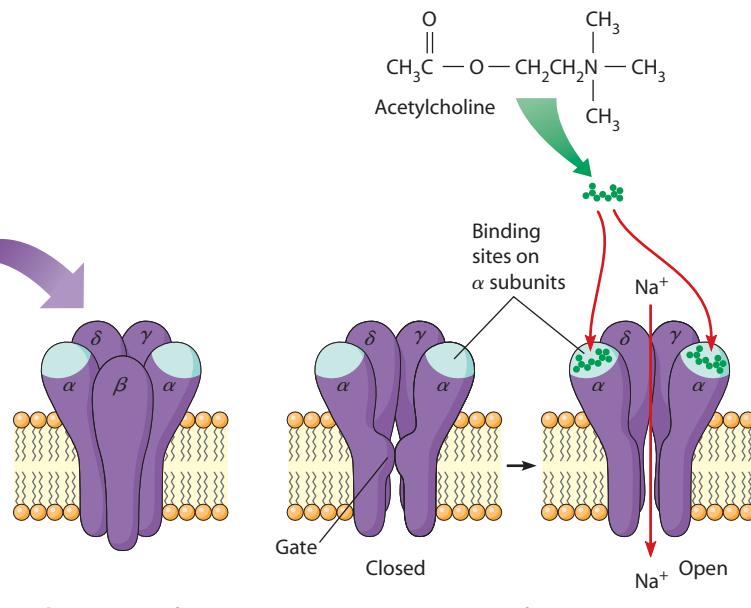

Biochemical purification of the acetylcholine receptor was greatly aided by the availability of several neurotoxins from snake venom, including *α -bungarotoxin* and *cobra-toxin*. These neurotoxins serve as a highly specific means of locating and quantifying nAChRs because they can be easily radiolabeled and bind tightly and specifically to the receptor protein. Other neurotoxins act on other synaptic components (**Box 13A**).

The purified nAChR has a molecular weight of about $300,000$ and consists of four kinds of subunits— α , β , γ , and δ —each containing about 500 amino acids (Figure 13-20 b, c). These receptors play a key role in transmitting nerve impulses to muscle (for more information, see Box 13A). In some cases, human patients develop an autoimmune response to their own acetylcholine receptors (in other words, their immune system attacks their

FIGURE 13-20 The Nicotinic Acetylcholine Receptor. The nicotinic acetylcholine receptor (nAChR) is an important excitatory receptor of the central nervous system. (a) This micrograph of an electroplax postsynaptic membrane shows rosette-like nAChR particles (TEM). (b) The nAChR contains five subunits, including two α subunits with binding sites for acetylcholine and one each of β , γ , and δ . The subunits aggregate in the lipid bilayer in such a way that the transmembrane portions form a channel. (c) The channel (shown here with the β subunit removed) is normally closed; however, when acetylcholine binds to the two sites on the α subunits, the subunits are altered so that the channel opens to allow sodium ions to cross.

Poisoned Arrows, Snake Bites,
and Nerve Gases

Because the functioning of the human body depends so critically on the nervous system, anything that disrupts the transmission of nerve impulses is likely to be harmful. And because acetylcholine is such an important neurotransmitter, any substance that interferes with its function is almost certain to be lethal. Various toxins have specific effects on cholinergic synapses, and their effects can be explained once the physiology of synaptic transmission is understood.

After acetylcholine has been released into the synaptic cleft and the postsynaptic membrane has been depolarized, excess acetylcholine must be rapidly hydrolyzed by the enzyme acetylcholinesterase. If it is not, the membrane cannot be restored to its polarized state, and further transmission is not possible. Substances that inhibit the activity of acetylcholinesterase are therefore usually very toxic.

One family of acetylcholinesterase inhibitors are the carbamoyl esters. These compounds inhibit acetylcholinesterase by covalently blocking the active site of the enzyme, effectively preventing the breakdown of acetylcholine. An example of such an inhibitor is *physostigmine* (sometimes also called *eserine*), a naturally occurring alkaloid produced by the Calabar bean.

Many synthetic organic phosphates form even more stable covalent complexes with the active site of acetylcholinesterase and are thus even more potent inhibitors. These include the widely used insecticides *parathion* and *malathion*, as well as nerve gases such as *tabun* and *sarin*. The primary effect of these compounds is muscle paralysis, caused by an inability of the postsynaptic membrane to regain its polarized state.

own receptors). When this happens, the patients can develop a condition known as *myasthenia gravis*, in which degenerative muscle weakness occurs.

The GABA Receptor. The γ -aminobutyric acid (GABA) receptor is also a ligand-gated channel, but when open, it conducts chloride ions rather than sodium ions. Since chloride ions are normally found at a higher concentration in the medium surrounding a neuron (see Table 13-1), opening GABA receptor channels produces an influx of chloride into the postsynaptic neuron, causing it to hyperpolarize. Hyperpolarization of the postsynaptic nerve terminal decreases the chance that an action potential will be initiated in the postsynaptic neuron. *Benzodiazepine* drugs, such as Valium and Librium, can enhance the effects of GABA on its receptor. Presumably, this produces the tranquilizing effects of these drugs.

Neurotransmitters Must Be Inactivated Shortly After Their Release

For neurons to transmit signals effectively, it is just as important to turn the stimulus off as it is to turn it on. Whether excitatory or inhibitory, once the neurotransmitter has been secreted, it must be rapidly removed from

Nerve transmission at cholinergic synapses can also be blocked by substances that compete with acetylcholine for binding to its receptor on the postsynaptic membrane. A notorious example of such a poison is *curare*, a plant extract once used by native South Americans to poison arrows. Among the active factors in curare is *d-tubocurarine*. Snake venoms act in the same way. Both α -bungarotoxin (from kraits, snakes of the genus *Bungarus*) and *cobra toxin* (from cobra snakes) are small, basic proteins that bind covalently to the acetylcholine receptor, thereby blocking depolarization of the postsynaptic membrane.

Substances that function in this way are called *antagonists* of cholinergic systems. Other compounds, called *agonists*, have just the opposite effect. Agonists also bind to the acetylcholine receptor, but in doing so they mimic acetylcholine and cause depolarization of the postsynaptic membrane. Unlike acetylcholine, however, agonists cannot be rapidly inactivated, so the membrane does not regain its polarized state.

Though of disparate origins and uses, poisoned arrows, snake venom, nerve gases, and surgical muscle relaxants all have some features in common. Each interferes in some way with the normal functioning of acetylcholine, and each is therefore a neurotoxin because it disrupts the transmission of nerve impulses, potentially with lethal consequences. Each has also turned out to be useful as an investigative tool, illustrating again the strange but powerful arsenal of exotic tools that biologists and biochemists are able to draw upon in their continued probing into the intricacies of cellular function.

the synaptic cleft. If it were not, stimulation or inhibition of a postsynaptic neuron would be abnormally prolonged, even without further signals from presynaptic neurons. In the case of acetylcholine, for example, excess acetylcholine must be hydrolyzed to restore the postsynaptic membrane to its polarized state; otherwise major problems arise (see Box 13A).

Neurotransmitters are removed from the synaptic cleft by two specific mechanisms: degradation into inactive molecules or reuptake. The first mechanism is exemplified by acetylcholine. The enzyme *acetylcholinesterase* hydrolyzes acetylcholine into acetic acid (or acetate ion) and choline, neither of which stimulates the acetylcholine receptor. Purine nucleotide neurotransmitters are also degraded by specific enzymes. The second, very common method of terminating synaptic transmission is **neurotransmitter reuptake**. Reuptake involves pumping neurotransmitters back into the presynaptic axon terminals or nearby support cells (you learned about such pumps in Chapter 8). The rate of neurotransmitter reuptake can be rapid; for some neurons, the synapse may be cleared of stray neurotransmitter within as little as a millisecond. Some antidepressant drugs act by blocking the reuptake of specific neurotransmitters. For example, Prozac blocks the reuptake of serotonin, leading to a

local increase in the level of serotonin available to postsynaptic neurons.

Integration and Processing of Nerve Signals

Sending a signal across a synapse does not automatically generate an action potential in the postsynaptic cell. There is not necessarily a one-to-one relationship between an action potential arriving at the presynaptic neuron and one initiated in the postsynaptic neuron. A single action potential can cause the secretion of enough neurotransmitter to produce a detectable depolarization in the postsynaptic neuron but usually is not enough to cause the firing of an action potential in the postsynaptic cell. These incremental changes in potential due to the binding of neurotransmitter are referred to as *postsynaptic potentials (PSPs)*. If a neurotransmitter is excitatory, it will cause a small amount of depolarization known as an **excitatory postsynaptic potential (EPSP)**. Likewise, if the neurotransmitter is inhibitory, it will hyperpolarize the postsynaptic neuron by a small amount; this is called an **inhibitory postsynaptic potential (IPSP)**.

For a presynaptic neuron to stimulate the formation of an action potential in the postsynaptic neuron, the EPSP must rise to a point at which the postsynaptic membrane reaches its threshold potential. EPSPs can do this in two different ways, which we will examine next.

Neurons Can Integrate Signals from Other Neurons Through Both Temporal and Spatial Summation

An individual action potential will produce only a temporary EPSP. However, if two action potentials fire in rapid succession at the presynaptic neuron, the postsynaptic neuron will not have time to recover from the first EPSP before experiencing a second EPSP. The result is that the postsynaptic neuron will be more depolarized. A rapid sequence of action potentials effectively sums EPSPs over time and brings the postsynaptic neuron to its threshold. This process is called *temporal summation*.

The amount of neurotransmitter released at a single synapse following an action potential is usually not sufficient to produce an action potential in the postsynaptic cell. When many action potentials cause the release of neurotransmitter simultaneously, their effects combine; sometimes this results in a large depolarization of the postsynaptic cell. This process is known as *spatial summation* because the postsynaptic neuron integrates the numerous small depolarizations that occur over its surface into one large depolarization.

Neurons Can Integrate Both Excitatory and Inhibitory Signals from Other Neurons

Besides receiving stimuli of varying strength, postsynaptic neurons can receive inputs from both excitatory and inhibitory neurons (Figure 13-21). Neurons can receive

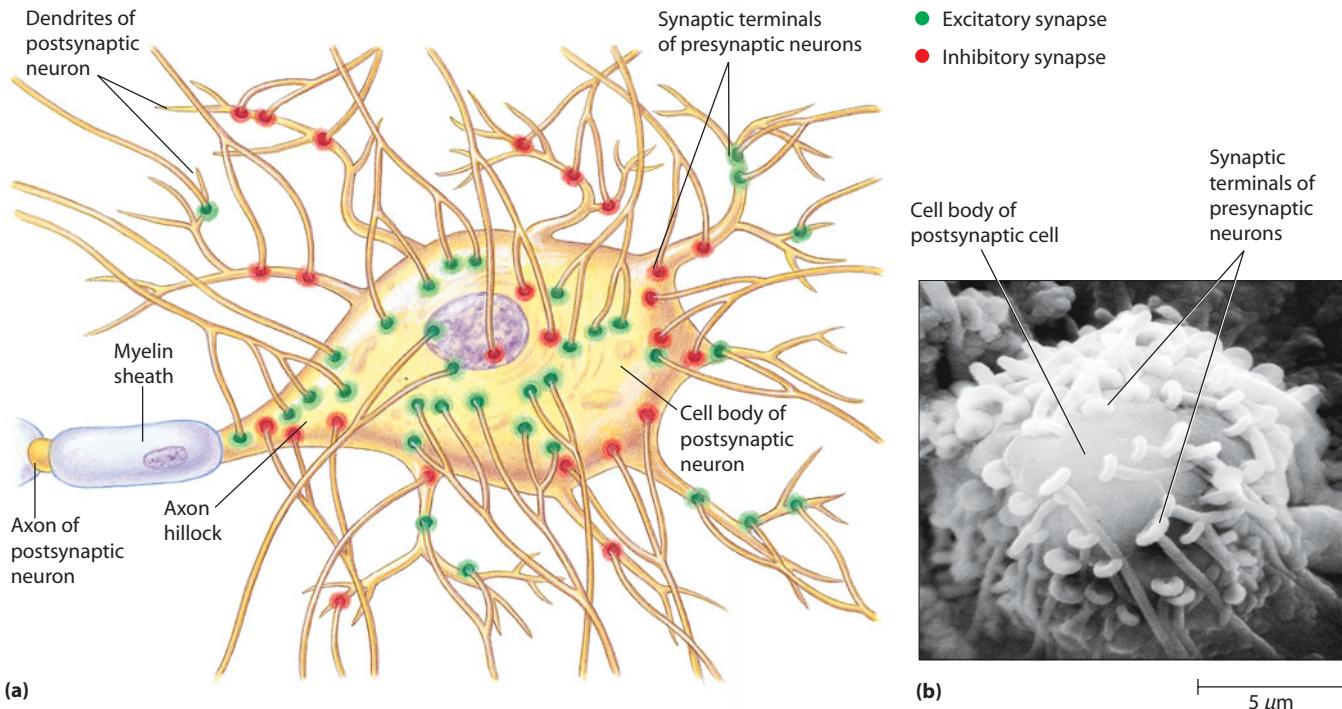

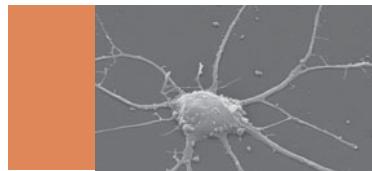

FIGURE 13-21 Integration of Synaptic Inputs. (a) Neurons, particularly those in the CNS, receive inputs from thousands of synapses, some of them excitatory (green) and others inhibitory (red). An action potential may be generated in such a neuron at the axon hillock if the combined effects of membrane potentials induced by these synapses results in depolarization above the threshold potential. Both temporal and spatial summation contribute to the likelihood that an action potential will be initiated. (b) This SEM shows that the synaptic terminals of many presynaptic neurons can make contact with a single postsynaptic neuron.

literally thousands of synaptic inputs from other neurons. When these different neurons fire at the same time, they exert combined effects on the membrane potential of the

postsynaptic neuron. Thus, by physically summing EPSPs and IPSPs, an individual neuron effectively integrates incoming signals (excitatory or inhibitory).

SUMMARY OF KEY POINTS

Neurons

- Cells in the nervous system are highly specialized to transmit electric impulses, using slender processes (dendrites and axons) that either receive transmitted impulses (dendrites) or conduct them to the next cell (axons).
- The membrane of an axon may or may not be encased in a myelin sheath, which provides electrical insulation that allows faster propagation of nerve impulses.

Membrane Potential

- Cells develop a membrane potential due to the separation of positive and negative charges across the plasma membrane. This potential develops as each ion to which the membrane is permeable moves down its electrochemical gradient.
- The Goldman equation is used to calculate the resting membrane potential of a cell, which depends on the permeability of the membrane to a particular ion. The resting potential for the plasma membrane of most animal cells is usually in the range of -60 to -75 mV, quite near the equilibrium potential for potassium ion.

Electrical Excitability and Action Potentials

- An action potential is a transient depolarization and repolarization of the neuronal membrane, due to the sequential opening and closing of voltage-gated sodium and potassium channels. In voltage-gated ion channels, the probability of opening, and consequently their conductance, depends on membrane potential.
- The properties of ion channels have been studied using molecular techniques combined with patch clamping to measure the conductance of single channels.

- An action potential is initiated when the membrane is depolarized to its threshold, at which point the opening of voltage-gated sodium channels allows sodium ions to enter the cells, driving the membrane potential to approximately $+40$ mV. Eventually, voltage-gated sodium channels inactivate.
- Repolarization of the membrane involves the opening of slower, voltage-gated potassium channels, which leads to repolarization of the membrane and includes a short period of hyperpolarization. This sequence of channel opening and closing generally takes a few milliseconds.
- Depolarization of the membrane due to an action potential spreads by passive conductance to adjacent regions of the membrane, which in turn generates a new action potential. In this way, an action potential is propagated along the membrane.

Synaptic Transmission

- Action potentials eventually reach the synapse between a nerve cell and another cell that it communicates with. Such synapses may be either electrical or chemical.
- In an electrical synapse, depolarization is transmitted from the presynaptic cell to the postsynaptic cell by gap junctions. In a chemical synapse, the electrical impulse increases the permeability of the membrane to calcium, stimulating release of neurotransmitter into the synaptic cleft.
- There are many different types of neurotransmitters. They bind specific types of receptors, causing either hyperpolarization or depolarization of the postsynaptic membrane.
- Transmission of nerve impulses requires that the cell body of the postsynaptic neuron integrate the excitatory and inhibitory activity of thousands of synaptic inputs.

MAKING CONNECTIONS

In this chapter we have introduced you to a specialized type of cell, the neuron, which uses membrane potentials as a means of transmitting signals from one part of an organism to another. Although they are highly specialized to receive and transmit electrical impulses, neurons and other cells with excitable membranes use the same ion transport processes you learned about in Chapter 8 to regulate their equilibrium potentials. The action potential

of a neuron involves a tightly controlled, transient depolarization and repolarization of its membrane due to the sequential opening and closing of voltage-gated sodium and potassium ion channels. The importance of steady-state ion movements to the generation of an action potential adds a new wrinkle to the equilibrium potentials discussed in Chapter 8. Electrical synapses allow direct transmission of electrical potentials from neuron to neuron. Such

synapses rely on gap junctions, which you will learn more about in Chapter 17. In chemical synapses, action potentials move from neuron to neuron through the secretion of neurotransmitters, which are released from presynaptic neurons through the process of exocytosis described in Chapter 12. The binding of neurotransmitters to postsynaptic cell membranes sets in motion a chain of events

leading to the depolarization of the postsynaptic membrane. Although in some cases neurotransmitters act directly on proteins that serve as ion channels, in other cases, neurotransmitters act indirectly through cell signaling events in the postsynaptic neuron. You will learn much more about these signaling events in the next chapter.

PROBLEM SET

More challenging problems are marked with a •.

13-1 The Truth About Nerve Cells. For each of the following statements, indicate whether it is true of all nerve cells (A), of some nerve cells (S), or of no nerve cells (N).

- (a) Axonal endings are in direct contact with the cells they innervate.
- (b) The resting membrane potential of the axonal membrane is positive.
- (c) Nodes of Ranvier are found at regular intervals along the axon.
- (d) The resting potential of the membrane is much closer to the equilibrium potential for potassium ions than to that for sodium ions because the permeability of the axonal membrane is much greater for potassium than for sodium.
- (e) Excitation of the membrane results in a transient increase in its permeability to sodium ions.
- (f) The electrical potential across the membrane of the axon can be easily measured using electrodes.
- (g) Calcium elevation stimulates release of neurosecretory vesicles containing serotonin.

• **13-2 The Resting Membrane Potential.** The Goldman equation is used to calculate V_m , the resting potential of a biological membrane. As presented in the chapter, this equation contains terms for sodium, potassium, and chloride ions only.

- (a) Why do only these three ions appear in the Goldman equation as it applies to nerve impulse transmission?
- (b) Suggest a more general formulation for the Goldman equation that would be applicable to membranes that might be selectively permeable to other monovalent ions as well.
- (c) How much would the resting potential of the membrane change if the relative permeability for sodium ions were 1.0 instead of 0.01?
- (d) Would you expect a plot of V_m versus the relative permeability of the membrane to sodium to be linear? Why or why not?

13-3 Patch Clamping. Patch-clamp instruments enable researchers to measure the opening and closing of a single channel in a membrane. A typical acetylcholine receptor channel passes about 5 pA (picoampères) of ionic current (1 picoampere = 10^{-12} ampere) over a period of about 5 msec at -60 mV .

- (a) Given that an electrical current of 1 A is about 6.2×10^{18} electrical charges per second, how many ions (potassium or sodium) pass through the channel during the time it is open?
- (b) Do you think the opening of a single receptor channel would be sufficient to depolarize a postsynaptic membrane? Why or why not?

13-4 The Equilibrium Potential. Answer each of the following questions with respect to E_{Cl} , the equilibrium potential for chloride ions. The chloride ion concentration inside the squid giant axon can vary from 50 to 150 mM.

- (a) Before doing any calculations, predict whether E_{Cl} will be positive or negative. Explain.
- (b) Now calculate E_{Cl} , assuming an internal chloride concentration of 50 mM.
- (c) How much difference would it make in the value of E_{Cl} if the internal chloride concentration were 150 mM instead?

13-5 Heart Throbs. An understanding of muscle cell stimulation involves some of the same principles as nerve cell stimulation, except that calcium ions play an important role in the former. The following ion concentrations are typical of those in human heart muscle and in the serum that bathes the muscles:

$$\begin{aligned} [\text{K}^+] &: 150\text{ mM in cell, } 4.6\text{ mM in serum} \\ [\text{Na}^+] &: 10\text{ mM in cell, } 145\text{ mM in serum} \\ [\text{Ca}^{2+}] &: 0.001\text{ mM in cell, } 6\text{ mM in serum} \end{aligned}$$

Figure 13-22 depicts the change in membrane potential with time upon stimulation of a cardiac muscle cell.

- (a) Calculate the equilibrium potential for each of the three ions, given the concentrations listed.
- (b) Why is the resting membrane potential significantly more negative than that of the squid axon (-75 mV versus -60 mV)?
- (c) The more positive membrane potential in region A of the graph could in theory be due to the movement across the membrane of one or both of two cations. Which cations are they, and in what direction would you expect each of them to move across the membrane?

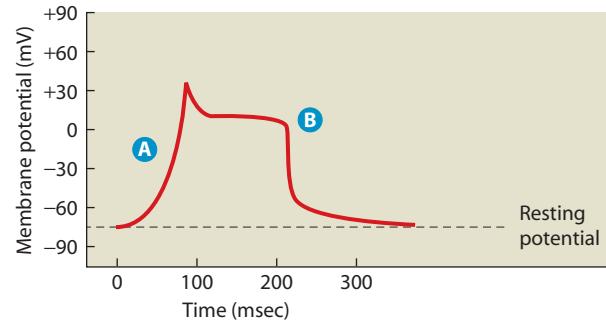

FIGURE 13-22 The Action Potential of a Muscle Cell of the Human Heart. See Problem 13-5.

- (d) How might you distinguish between the possibilities suggested in part c?
- (e) The rapid decrease in membrane potential that is occurring in region **B** is caused by the outward movement of potassium ions. What are the driving forces that cause potassium to leave the cell at this point? Why aren't the same forces operative in region **A** of the curve?

13-6 The All-or-None Response of Membrane Excitation. A nerve cell membrane exhibits an all-or-none response to excitation; that is, the magnitude of the response is independent of the magnitude of the stimulus, once a threshold value is exceeded.

- (a) Explain in your own words why this is so.
- (b) If every neuron exhibits an all-or-none response, how do you suppose the nervous system of an animal can distinguish different intensities of stimulation? How do you think your own nervous system can tell the difference between a warm iron and a hot iron or between a chamber orchestra and a rock band?

13-7 One-Way Propagation. Why does an action potential move in only one direction down the axon?

13-8 Multiple Sclerosis and Action Potential Propagation.

Multiple sclerosis (MS) is an autoimmune disease that attacks myelinated nerves and degrades the myelin sheath around them. How do you think the propagation of action potentials would be affected in a nerve cell that has been damaged in a patient with MS?

13-9 Going Bananas. Athletes who experience muscle cramping are often told to eat bananas, which are rich in potassium. Explain why increasing the extracellular potassium concentration would make it more difficult to stimulate an action potential in neurons that innervate muscle cells, thereby decreasing their contraction.

13-10 Down and Out. Endocannabinoids are produced by postsynaptic neurons but act on receptors (CB1 receptors) in presynaptic neurons. One type of neuron that is a target of endocannabinoids is *glutamatergic* neurons (that is, neurons that release glutamate as a neurotransmitter).

- (a) CB1 agonists such as THC reduce calcium influx by blocking the activity of voltage-dependent calcium channels. What effect would this have on the release of glutamate?
- (b) Glutamate causes the membrane of postsynaptic neurons to become hyperpolarized. How would THC be expected to affect the rate of nerve impulse transmission in postsynaptic neurons that make synapses with the glutamatergic neuron?

13-11 Trouble at the Synapse. Drugs that affect the reuptake of neurotransmitters are in widespread use for the treatment of attention-deficit/hyperactivity disorder and clinical depression. In molecular terms, explain what effect(s) such reuptake inhibitors have on postsynaptic neurons, assuming that the neurotransmitter in question is excitatory for that postsynaptic neuron.

Signal Transduction Mechanisms: II. Messengers and Receptors

In the previous chapter, we learned how nerve cells communicate with one another and with other types of cells. We saw how, in most cases, the arrival of an action potential at a synapse causes the release of neurotransmitters, which in turn bind to receptors on the adjacent postsynaptic cell membrane, thereby passing on the signal. Now we are ready to explore a second major means of intercellular communication. In this case, however, the signal is transmitted by regulatory chemical messengers, and the receptors are located on the surfaces of cells that may be quite distant from the secreting cells. Thus, animals have two different but complementary systems of communication and control, and receptors play a crucial role in both systems.

Chemical Signals and Cellular Receptors

All cells have some ability to sense and respond to specific chemical signals. Prokaryotes, for instance, have membrane-bound receptor molecules on the cell surface that enable them to respond to substances in their environment. The human body has receptors on the tongue and in the nose that detect chemicals in food and the air. Even the cells of the early animal embryo possess sophisticated machinery for detecting changes in their surroundings.

Cells also produce signals. One way they do this is by displaying molecules on their surfaces that are recognized by receptors on the surfaces of other cells. This kind of cell-to-cell communication requires that cells come into direct contact with each other. Alternatively, one cell can release chemical signals that are recognized by another cell, either nearby or at a distant location. In complex multicellular organisms, the problem of regulating and coordinating the various activities of cells or tissues is particularly important because the whole organism is organized into different tissues made up of specialized cells. Furthermore, the specific functions of these cells may be critical

only on certain occasions, or one tissue may need to perform different functions in different circumstances. Multicellular organisms often control the activities of specialized cells through the release of *chemical messengers*, the topic of this chapter.

Different Types of Chemical Signals Can Be Received by Cells

A variety of compounds can function as chemical messengers (Figure 14-1). Signaling molecules are often classified based on the distance between their site of production and the target tissue(s) upon which they act. Some messengers, such as hormones, act as *endocrine signals* (from Greek words meaning “to secrete into”). They are produced at great distances from their target tissues and are carried by the circulatory system to various sites in the body. Other signals, such as growth factors, are released locally, where they diffuse to act at short range on nearby tissues. Such signals are referred to as *paracrine signals* (from the Greek *para*, which means “beside”). When signals are passed at such short range that they require physical contact between the sending and receiving cells, they are said to be *juxtacrine signals*. Still other local mediators act on the same cell that produces them; such signals are called *autocrine signals*.

Once a messenger reaches its target tissue, it binds to **receptors** on the surface of the target cells, initiating the signaling process. The logic and general flow of information involved in such signaling is shown in Figure 14-2a. A molecule coming from either a long or a short distance functions as a **ligand** by binding to a receptor. A ligand often binds to a receptor embedded within the plasma membrane of the cell receiving the signal. In other cases, such as steroid hormones, the ligand binds to a receptor inside the cell. In either case, the ligand is a “primary messenger.” The binding of ligand to receptor often results in the production of additional molecules within the cell receiving the signal. Such

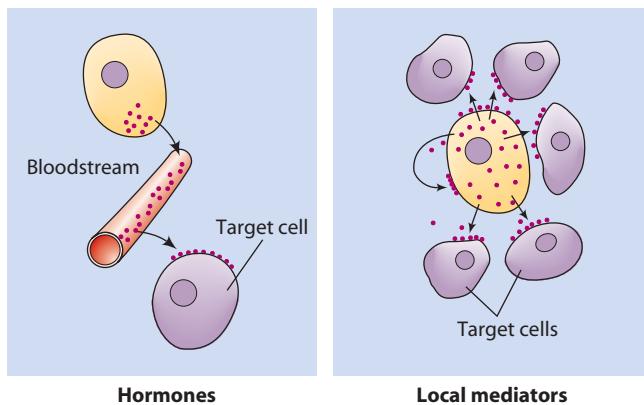

FIGURE 14-1 Cell-to-Cell Signaling by Hormones and Local Mediators. The main distinction between classes of signaling molecules is the distance the molecule travels before encountering its target cell or tissue. Endocrine hormones are carried by the bloodstream. Local mediators, such as growth factors, can act on nearby cells (paracrine signals) or on the cell that produces them (autocrine signals). Although many signaling molecules act on the cell surface, certain hydrophobic molecules enter their target cells.

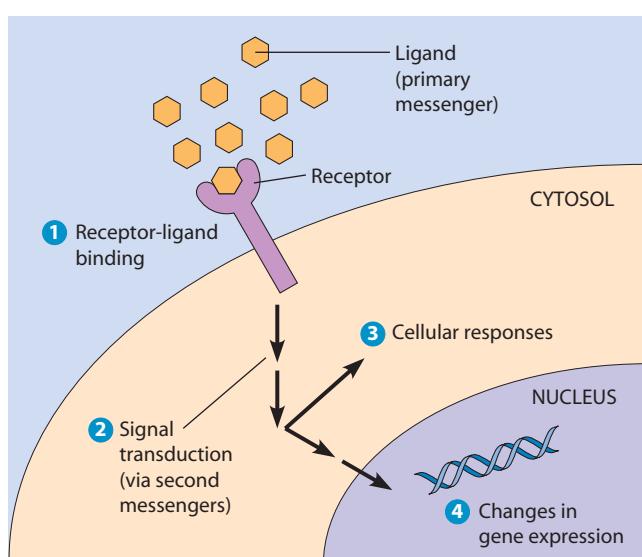

second messengers are small molecules or ions that relay the signals from one location in the cell, such as the plasma membrane, to the interior of the cell, initiating a cascade of changes within the receiving cell. Often these events affect the expression of specific genes within the receiving cell. The ultimate result is a change in the identity or function of the cell. The ability of a cell to translate a receptor-ligand interaction to changes in its behavior or gene expression is known as **signal transduction**.

Messenger molecules can be chemically characterized as amino acids or their derivatives, peptides, proteins, fatty acids, lipids, nucleosides, or nucleotides. Many messengers are hydrophilic compounds whose function lies entirely in their ability to bind to one or more specific receptors on a target cell. Hydrophobic messengers, on the other hand, act on receptors in the nucleus or cytosol whose function is to regulate the transcription of particular genes. Among the hydrophobic messengers that bind to intracellular receptors are *steroid hormones*, which are derived from the compound cholesterol, and *retinoids*, derived from vitamin A.

Receptor Binding Involves Specific Interactions Between Ligands and Their Receptors

How do cells distinguish messengers from the multitude of other chemicals in the environment or from messengers intended for other cells? The answer lies in the highly specific way the messenger molecule binds to the receptor. A messenger forms noncovalent chemical bonds with the receptor protein. Individual noncovalent bonds are generally weak; therefore, several bonds must form to achieve strong binding. For a receptor to make numerous bonds with its ligand, the receptor must have a *binding site* (or *binding pocket*) that fits the messenger molecule closely, like

(a) The general flow of information during cell signaling

(b) Different ways in which signals can be integrated

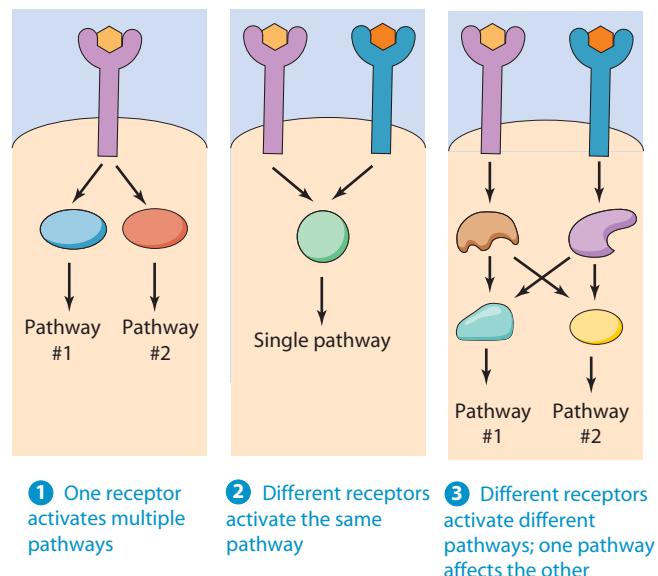

FIGURE 14-2 The Overall Flow of Information During Cell Signaling. (a) The general flow of information in cell signaling. Binding of a ligand by a receptor activates a series of events known as signal transduction, which relays the signal to the interior of the cell and results in specific cellular responses and/or changes in gene expression. (b) Different ways signals can be integrated. ① One signal can activate multiple signal transduction pathways. ② Multiple signals can result in activation of the same pathway. ③ Different signals can activate different pathways, but one component of a pathway can regulate a component of another pathway.

ACTIVITIES www.thecellplace.com Signal transduction pathways

a hand in a glove. Furthermore, within the ligand-binding site on the receptor, appropriate amino acid side chains must be positioned so that they can form chemical bonds with the messenger molecule. This combination of binding site shape and the strategic positioning of amino acid side chains

within the binding site is what enables the receptor to distinguish its specific ligand from thousands of other chemicals.

In most cases, the binding reaction between a ligand and the receptor specific for it, known as its *cognate receptor*, is similar to the binding of an enzyme to its substrate. When a receptor binds its ligand, the receptor is said to be *occupied*. Similarly, the ligand can be either bound (to a receptor) or free in solution. The amount of receptor that is occupied by ligand is proportional to the concentration of free ligand in solution. As the ligand concentration increases, more and more of its cognate receptors become occupied, until most receptors are occupied—a condition known as *saturation*. Further increases in ligand concentration will, in principle, have no further effect on the target cell.

Receptor Affinity. The relationship between the concentration of ligand in solution and the number of receptors occupied can be described qualitatively in terms of **receptor affinity**. When almost all of the receptors are occupied at low concentrations of free ligand, we say that the receptor has a high affinity for its ligand. Conversely, when it takes a relatively high concentration of ligand for most receptors to be occupied, we say that the receptor has a low affinity for its ligand. Receptor affinity can be described quantitatively in terms of the **dissociation constant, K_d** , the concentration of free ligand needed to produce a state in which half the receptors are occupied. Values for K_d range from roughly 10^{-7} to $10^{-10} M$. As with the Michaelis constant in enzyme kinetics (K_m ; see Chapter 6), the importance of the value is that it tells us at what concentration a particular ligand will be effective in producing a cellular response. Thus receptors with a high affinity for their ligands have a very small dissociation constant, and, conversely, low-affinity receptors have a high K_d . Typically, the ligand concentration must be in the range of the K_d value of the receptor for the ligand to affect the target tissue.

In addition to the intrinsic properties of the receptor, receptor-ligand interactions can also be affected by *coreceptors* on the cell surface. Coreceptors help to facilitate the interaction of the receptor with its ligand through their physical interaction with the receptor. One well-studied class of such molecules are *heparan sulfate proteoglycans*, including *glycans* and *syndecans*. Coreceptors provide another layer of regulation of receptor-ligand interactions.

Receptor Down-Regulation. Although receptors have a characteristic affinity for their ligands, cells are geared to sense *changes* in ligand concentration rather than fixed ligand concentrations. When a ligand is present and receptors are occupied for prolonged periods of time, the cell adapts so that it no longer responds to the ligand. To further stimulate the cell, the ligand concentration must be increased. Such changes are known as *receptor down-regulation*. There are two main ways in which such adaptation occurs. First, cells can change the density of receptors on their surfaces in response to a signal. The removal of receptors from the cell surface takes place

through the process of *receptor-mediated endocytosis*, in which small portions of the plasma membrane containing receptors invaginate and are internalized. (Receptor-mediated endocytosis was discussed in detail in Chapter 12.) The reduced number of receptors on the cell surface results in a diminished cellular response to ligand.

A second way that cells can adapt to signals is known as *desensitization*. Desensitization involves alterations of the receptor that lower its affinity for ligand or render it unable to initiate changes in cellular function. Desensitization provides a way for cells to adapt to permanent differences in levels of messenger concentration. One common way that desensitization occurs involves addition of phosphate groups to specific amino acids within the cytosolic portion of the receptor. As we will see, one well-known example of such phosphorylation involves the β -adrenergic receptor. Once a ligand is no longer present, a cell must “reset” itself to a resting level of responsiveness. In the case of the β -adrenergic receptor, the continuous activity of phosphatases in the cytosol removes the inhibitory phosphates, returning the receptor to a more responsive state.

Understanding the nature of receptor-ligand binding has provided great opportunities for researchers and pharmaceutical companies. Although receptors have binding sites that fit the messenger molecule quite closely, it is possible to make similar synthetic ligands that bind even more tightly or selectively. This is especially important when more than one type of receptor exists for the same ligand. Drugs that activate the receptor to which they bind are known as **agonists**. In contrast, whereas normal messengers cause a change in the receptor when they bind, both synthetic and natural compounds have been discovered that can bind to receptors without triggering such a change. These **antagonists** inhibit the receptor by preventing the naturally occurring messenger from binding and activating the receptor.

Drugs that selectively activate or inhibit particular kinds of receptors have become central to the treatment of many medical problems. For example, *isoproterenol* and *propranolol* activate or inhibit β -adrenergic receptors, which will be discussed later in the chapter. Isoproterenol is used to treat asthma or to stimulate the heart, whereas propranolol is used to reduce blood pressure and the strength of cardiac contractions and to control anxiety attacks. Another example is *famotidine*, a compound that selectively binds and inhibits a particular type of histamine receptor found on cells in the stomach. Famotidine is sold as a stomach “acid controller” under the trade name *Pepcid AC*. Another drug—*cimetidine*, sold under the trade name *Tagamet*—acts in a similar manner.

Receptor Binding Activates a Sequence of Signal Transduction Events Within the Cell

When a ligand binds to its cognate receptor, the receptor is altered in a way that causes changes in cellular activities. In general, the binding of a ligand either induces a change in receptor conformation or causes receptors to cluster

together. Once one of these changes takes place, the receptor initiates a preprogrammed sequence of events inside the cell. By *preprogrammed*, we mean that cells have a greater repertoire of functions than are in use at any particular time. Some of these cellular processes remain unused until particular signals are received that trigger them.

Signal Integration. Cells in the human body can be exposed to a multitude of signals at any given moment. How do cells respond to such complexity? For much of the rest of this chapter, we will treat each signal transduction pathway as if it occurs in isolation within a cell. But in reality, cells must *integrate* these signals to produce coordinated responses to their environment. Indeed, many different signaling pathways may operate at any given moment within a cell. These pathways interact with one another in complex ways because components of one pathway affect the ability of another pathway to transmit its signals (see Figure 14-2b). Sometimes a single receptor can activate multiple pathways, as we will see with both G protein-linked receptors and receptor tyrosine kinases. In other cases, different pathways converge onto the same molecules; second messengers are good examples of such “signal integrators.” In still other cases, different ligands bind their corresponding receptors at the cell surface, activating specific signaling pathways within

the cells. Activated components from one pathway then affect components in another pathway. Such an interaction is known as *signaling crosstalk*. For example, the activity of the receptor for the growth factor TGF β can be inhibited by proteins activated when the same cell is exposed to other growth factors that act through a very different type of receptor (a receptor tyrosine kinase). It is better not to think of cell signaling in a linear sense but as a complex network of biochemical pathways leading to changes in a cell’s properties at any given moment.

Signal Amplification. Signal transduction pathways allow another important aspect of a cell’s response to an external signal: signal amplification. Exceedingly small quantities of a ligand are often sufficient to elicit a response from a target cell, yet the responding cell reacts in dramatic ways. Often the strong response of the target cell results from a signaling cascade with the responding cell. At each step in the cascade, a signaling intermediate persists long enough to stimulate the production of many molecules required for the next step in the cascade, thereby multiplying the effects of a single receptor-ligand interaction on the cell surface. A well-known example of such signal amplification involves the breakdown of glycogen in liver cells in response to the hormone epinephrine (Figure 14-3). As a

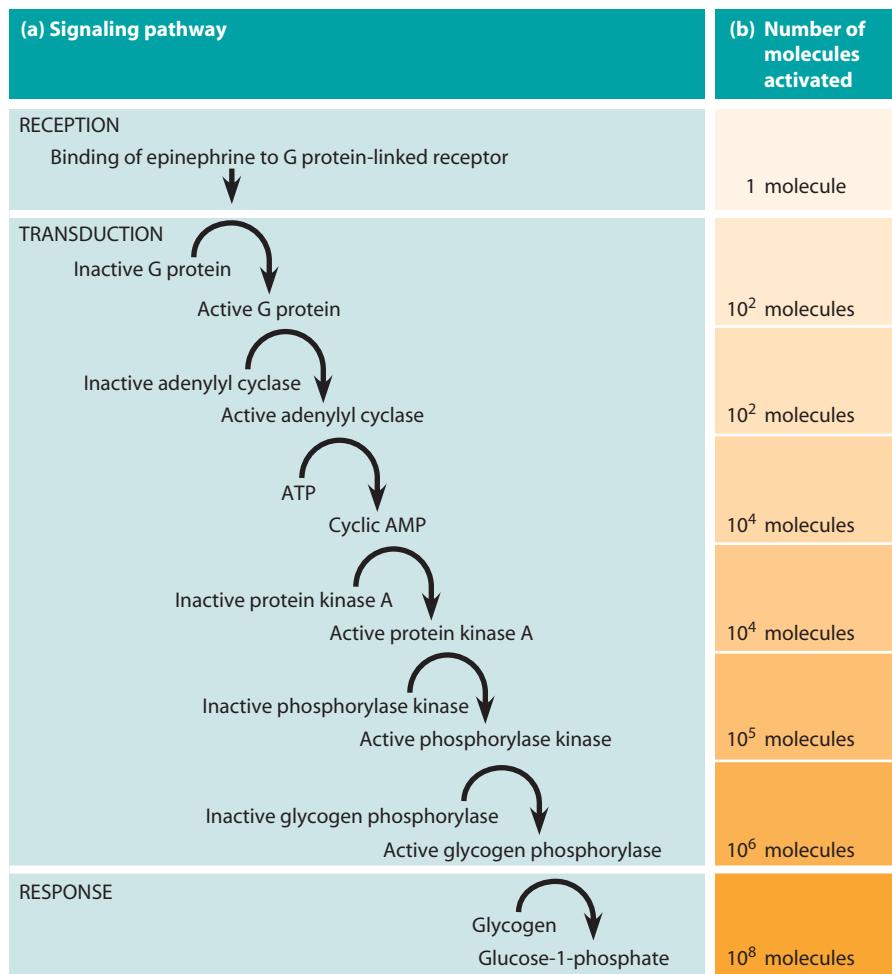

FIGURE 14-3 Signal Transduction

Pathways Can Amplify the Cellular Response to an External Signal. Liver cells respond to the hormone epinephrine by breaking down glycogen to liberate glucose-1-phosphate. (a) The epinephrine receptor is a G protein-linked receptor, which activates an enzyme known as adenylyl cyclase. Adenylyl cyclase catalyzes formation of a second messenger, cAMP, which activates a protein kinase (protein kinase A), which in turn activates another kinase (phosphorylase kinase). Ultimately, the enzyme glycogen phosphorylase is activated, which catalyzes the breakdown of glycogen. (b) The approximate number of molecules produced at each step is shown on the right. One epinephrine molecule is capable of triggering the production of hundreds of millions of glucose-1-phosphate molecules.

result of the cascade, a single epinephrine ligand can stimulate the release of hundreds of millions of glucose molecules from glycogen, a glucose polymer that stockpiles glucose for storage within cells.

Signal transduction events are initiated or altered within a cell when a ligand binds to its cognate receptor on the cell surface or within the cell. Depending on their mode of action, receptors can be classified into several basic categories. We discussed *ligand-gated channels* in Chapter 13. Here, *plasma membrane receptors* are the main focus of our discussion. Many of these receptors can be classified into two families: those linked to G proteins and those linked to protein kinases. We begin by looking at the former.

G Protein-Linked Receptors

Many Seven-Membrane Spanning Receptors Act via G Proteins

The **G protein-linked receptor family** is so named because ligand binding causes a change in receptor conformation that activates a particular **G protein** (an abbreviation for *guanine-nucleotide binding protein*). A portion of the activated G protein in turn binds to a target protein, such as an enzyme or a channel protein, thereby altering the target's activity. Examples of G protein-linked receptors include olfactory receptors (responsible for our sense of smell), norepinephrine receptors, and hormone receptors such as those for thyroid-stimulating hormone and follicle-stimulating hormone. A class of G protein-linked receptors of great clinical importance is the *opioid receptors*. Narcotic drugs such as morphine bind to these receptors, which accounts for their pain-killing benefits. Unfortunately, morphine and related drugs, such as heroin, also induce long-term changes in synaptic function in the brain that are responsible for their addictive effects.

The Structure and Regulation of G Protein-Linked Receptors. G protein-linked receptors are remarkable in that they all have a similar structure yet differ significantly in their amino acid sequences. In each case, the receptor protein forms seven transmembrane α helices connected by alternating cytosolic or extracellular loops. The N-terminus of the protein is exposed to the extracellular fluid, while the C-terminus resides in the cytosol (Figure 14-4). The extracellular portion of each G protein-linked receptor has a unique messenger-binding site, and the cytosolic loops allow the receptor to interact with only certain types of G proteins.

G protein-linked receptors can be regulated in several ways. One of the most important is via phosphorylation of specific amino acids in their cytosolic domain. When these amino acids are phosphorylated, the receptor becomes desensitized. One class of proteins that carry out this function are **G protein-linked receptor kinases (GRKs)**, which specifically act on activated receptors.

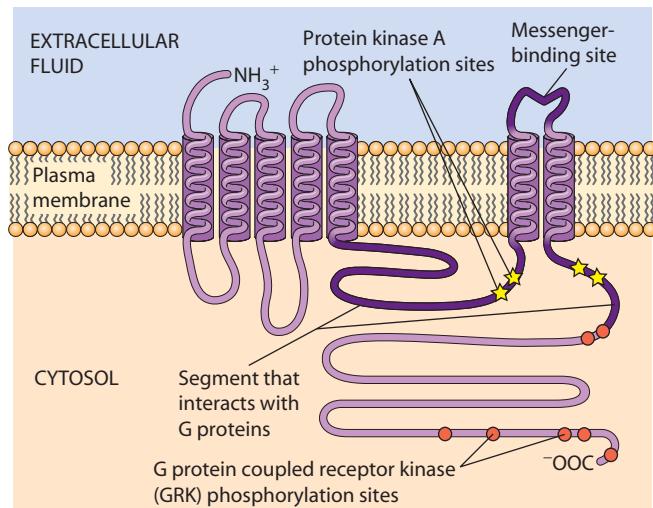

FIGURE 14-4 The Structure of G Protein-Linked Receptors.

Each G protein-linked receptor has seven transmembrane α helices. A ligand binds to the extracellular portion of the receptor, causing an intracellular portion of the receptor to bind and activate a G protein. Besides the regions shown, the second cytosolic loop is also involved in G protein interactions in some cases. Specific amino acids in the cytosolic region are also targets for phosphorylation by G protein-linked receptor kinases (GRKs) and protein kinase A.

When specific amino acids within the cytosolic portion of G protein-linked receptors, such as the β -adrenergic receptor, are heavily phosphorylated by GRKs, a protein known as β -arrestin can bind to them and completely inhibit their ability to associate with G proteins. Another kinase, **protein kinase A (PKA)**, which is itself activated by G protein-mediated signaling, can phosphorylate other amino acids on the receptor. Such inhibitory action is a good example of negative feedback during cell signaling.

The Structure, Activation, and Inactivation of G Proteins. G proteins act very much like molecular switches, whose “on” or “off” state depends on whether the G protein is bound to GTP (guanosine triphosphate) or GDP (guanosine diphosphate). There are two distinct classes of G proteins: the *large heterotrimeric G proteins* and the *small monomeric G proteins*. The large heterotrimeric G proteins contain three different subunits, called G alpha (G_α), G beta (G_β), and G gamma (G_γ). Heterotrimeric G proteins mediate signal transduction through G protein-linked receptors. The small monomeric G proteins include *Ras*, which we will discuss later in this chapter. Here we will restrict our discussion to the heterotrimeric type.

G proteins have the same basic structure and mode of activation. Of the three subunits in the $G_{\alpha\beta\gamma}$ heterotrimer, G_α , the largest, binds to a guanine nucleotide (GDP or GTP). When G_α binds to GTP, it also detaches from the $G_\beta\gamma$ complex. The G_β and G_γ subunits, on the other hand, are permanently bound together. Some G proteins, such as G_s , act as stimulators of signal transduction (hence *s*, for “stimulatory”); others, such as G_i , act to inhibit signal transduction (hence *i*, for “inhibitory”).

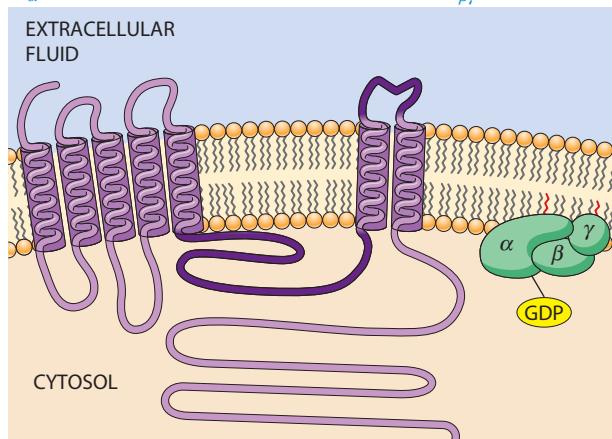

When a messenger binds to a G protein-linked receptor on the surface of the cell, the change in conformation of the receptor causes a G protein to associate with the receptor, which in turn causes the G_{α} subunit to release its bound GDP. The G_{α} then acquires a new, different molecule of GTP and detaches from the complex (Figure 14-5). Depending on the G protein and the cell type, either the free GTP- G_{α} subunit or the $G_{\beta\gamma}$ complex can then initiate signal transduction events in the cell. Each portion of the G protein exerts its effect by binding to a particular enzyme or other protein in the cell. In some cases, both the GTP- G_{α} and $G_{\beta\gamma}$ subunits simultaneously regulate different processes in the cytosol.

The activity of a G protein persists only as long as the G_{α} subunit is bound to GTP, and the G_{α} and $G_{\beta\gamma}$ subunits remain separated. Because the G_{α} subunit catalyzes GTP hydrolysis, it remains active only until it hydrolyzes its associated GTP to GDP, at which time it reassociates with $G_{\beta\gamma}$. This feature allows the signal transduction pathway to shut down when the messenger is utilized. Some G_{α}

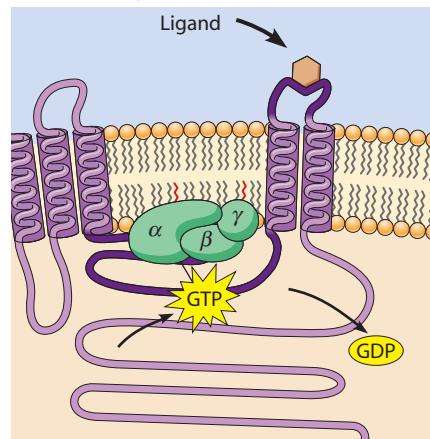

proteins are very inefficient at catalyzing GTP hydrolysis; however, their efficiency is dramatically improved by **regulators of G protein signaling (RGS) proteins**. When RGS proteins bind G_{α} , they stimulate GTP hydrolysis. Such *GTPase activating proteins (GAPs)* are important regulators of G protein function, as we will see later in the case of the Ras protein.

The large number of different G proteins provides for a diversity of G protein-mediated signal transduction events, only a few of which we will consider here. Perhaps the most important and widespread G protein-mediated signal transduction events are the release or formation of second messengers. As we will see in the next section, two widely used second messengers are cyclic AMP and calcium ions, which stimulate the activity of target enzymes when their cytosolic concentrations are elevated. Other well-studied examples of G protein-mediated signaling, in the retina of the eye and in endothelial cells, use a different second messenger, cyclic GMP (Box 14A).

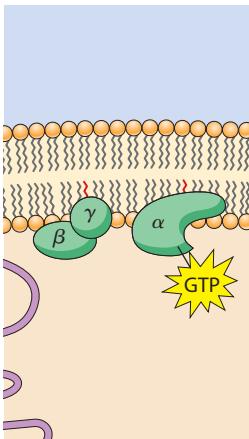

1 Resting state: Receptor is not bound to ligand; G_{α} subunit is bound to GDP and associated with $G_{\beta\gamma}$.

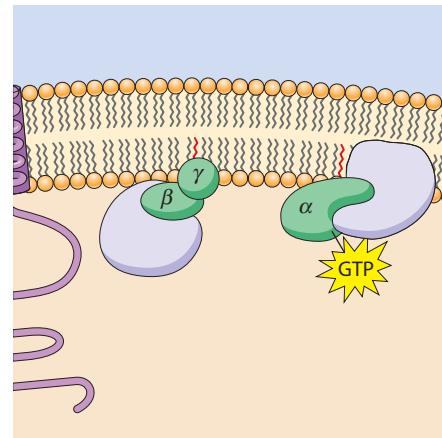

2 Ligand binds receptor; the receptor binds a G protein; G_{α} releases GDP and acquires GTP.

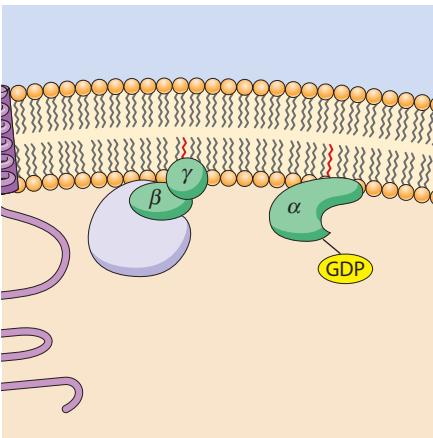

3 G_{α} and $G_{\beta\gamma}$ subunits separate.

4 G protein subunits activate or inhibit target proteins, initiating signal transduction events.

5 The G_{α} subunit hydrolyzes its bound GTP to GDP, becoming inactive.

6 Subunits recombine to form an inactive G protein.

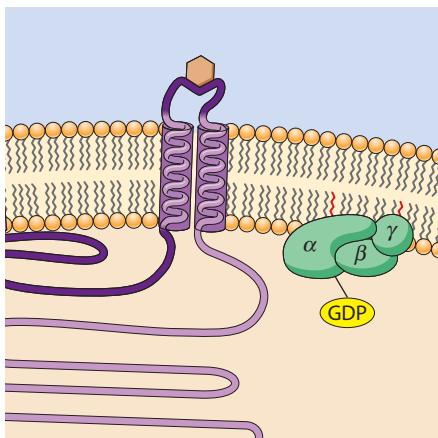

FIGURE 14-5 The G Protein Activation/Inactivation Cycle. When a G protein-linked receptor binds a ligand, it binds and activates a G protein. Its dissociated subunits can regulate target proteins. Hydrolysis of GTP bound to G_{α} ultimately terminates the signal.

G Proteins and Cyclic GMP

Cyclic AMP (cAMP) is an important second messenger in many cell signaling events. However, cAMP is not the only cyclic nucleotide that is important in cell signaling. Just as the enzyme adenylyl cyclase can catalyze the formation of cAMP, the enzyme guanylyl cyclase catalyzes the formation of cyclic GMP (cGMP). Cyclic GMP is derived from GTP in a manner analogous to the production of cAMP from ATP, and, like cAMP, cGMP can act as a second messenger. Here we consider one example of G protein-mediated signaling that involves cGMP: nitric oxide signaling in endothelial cells.

Nitric Oxide Couples G Protein-Linked Receptor Stimulation in Endothelial Cells to Relaxation of Smooth Muscle Cells in Blood Vessels

An important signaling molecule in the cardiovascular system is **nitric oxide (NO)**, a toxic, short-lived gas molecule produced by the enzyme *NO synthase*, which converts the amino acid arginine to NO and citrulline. It has been known for many years that acetylcholine dilates blood vessels by causing their smooth muscles to relax. In 1980, Robert Furchtgott demonstrated that acetylcholine dilated blood vessels only if the *endothelium* (the inner lining of the blood vessel) was intact. He concluded that blood vessels are dilated because the endothelial cells produce a signal molecule (or *vasodilator*) that makes vascular smooth muscle cells relax. In 1986, work by Furchtgott and parallel work by Louis Ignarro identified NO as the signal released by endothelial cells that causes relaxation of the vascular smooth muscle.

Figure 14-A1 illustrates how the binding of acetylcholine to the surface of vascular endothelial cells results in release of NO. There are six steps to this process. ① Acetylcholine binds to G protein-linked receptors that activate the phosphoinositide signaling pathway, causing IP₃ to be produced by the endothelial cells. ② IP₃ causes the release of calcium from the endoplasmic reticulum. ③ The calcium ions bind to calmodulin, forming a complex that stimulates NO synthase to produce nitric oxide. ④ Nitric oxide is a gas that readily diffuses through plasma membranes, allowing it to pass from the endothelial cell into the adjacent smooth muscle cells. ⑤ Once inside the smooth muscle cell, NO activates guanylyl cyclase. ⑥ The increase in cGMP concentration activates a protein known as *protein kinase G*, which induces muscle relaxation by catalyzing the phosphorylation of the appropriate muscle proteins.

The mechanism by which acetylcholine stimulation of the endothelial cells leads to smooth muscle relaxation also explains

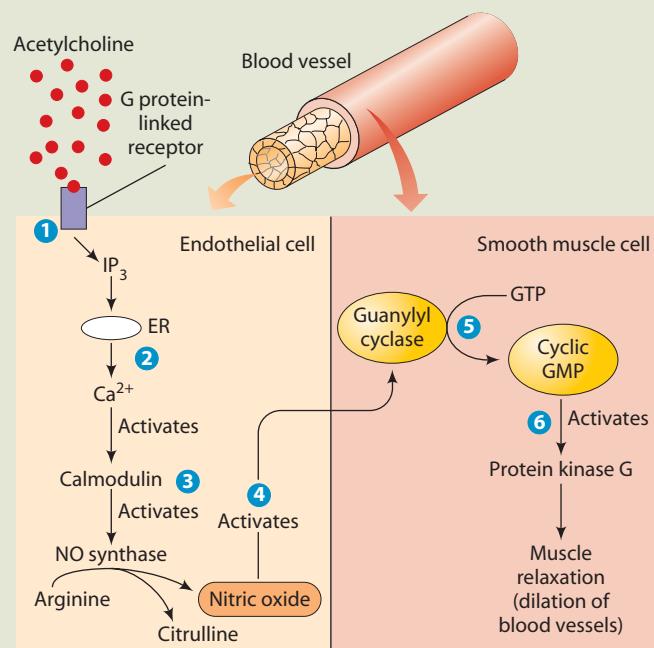

FIGURE 14-A1 The Action of Nitric Oxide on Blood Vessels. The binding of acetylcholine to endothelial cells triggers the production of nitric oxide, which diffuses into the adjacent smooth muscle cells and stimulates guanylyl cyclase, thereby leading to muscle relaxation.

the mechanism of action of the chemical *nitroglycerin*. Nitroglycerin is often taken by patients with angina (chest pain due to inadequate blood flow to the heart) to relieve constriction of coronary arteries. In 1977, Ferid Murad found that nitroglycerin and similar vasodilators elicit release of nitric oxide, which relaxes arterial smooth muscle cells. In 1998, Furchtgott, Ignarro, and Murad received a Nobel Prize for their elucidation of NO's effects on the cardiovascular system.

Nitric oxide is also used by neurons to signal nearby cells. For example, nitric oxide released by the neurons in the penis results in the blood vessel dilation responsible for penile erection. The drug *sildenafil*, sold under the trade name *Viagra*, is an inhibitor of a phosphodiesterase that normally catalyzes the breakdown of cyclic GMP. By maintaining elevated levels of cyclic GMP in erectile tissue, this pathway is stimulated for a longer time period following NO release.

Cyclic AMP Is a Second Messenger Whose Production Is Regulated by Some G Proteins

Cyclic AMP (cAMP) is formed from cytosolic ATP by the enzyme **adenylyl cyclase** (Figure 14-6). Adenylyl cyclase is anchored in the plasma membrane, with its catalytic portion protruding into the cytosol. Normally, the enzyme is inactive until it binds to an activated G_α subunit of a

specific G protein, such as G_s. When a G protein-linked receptor is coupled to G_s, the binding of ligand stimulates the G_{sα} subunit to release GDP and acquire a GTP (Figure 14-7). This in turn causes GTP-G_{sα} to detach from the G_{sβγ} subunits and bind to adenylyl cyclase. When GTP-G_{sα} binds to adenylyl cyclase, the enzyme becomes active and converts ATP to cAMP. In contrast, another G_α protein, G_i, inhibits adenylyl cyclase. The

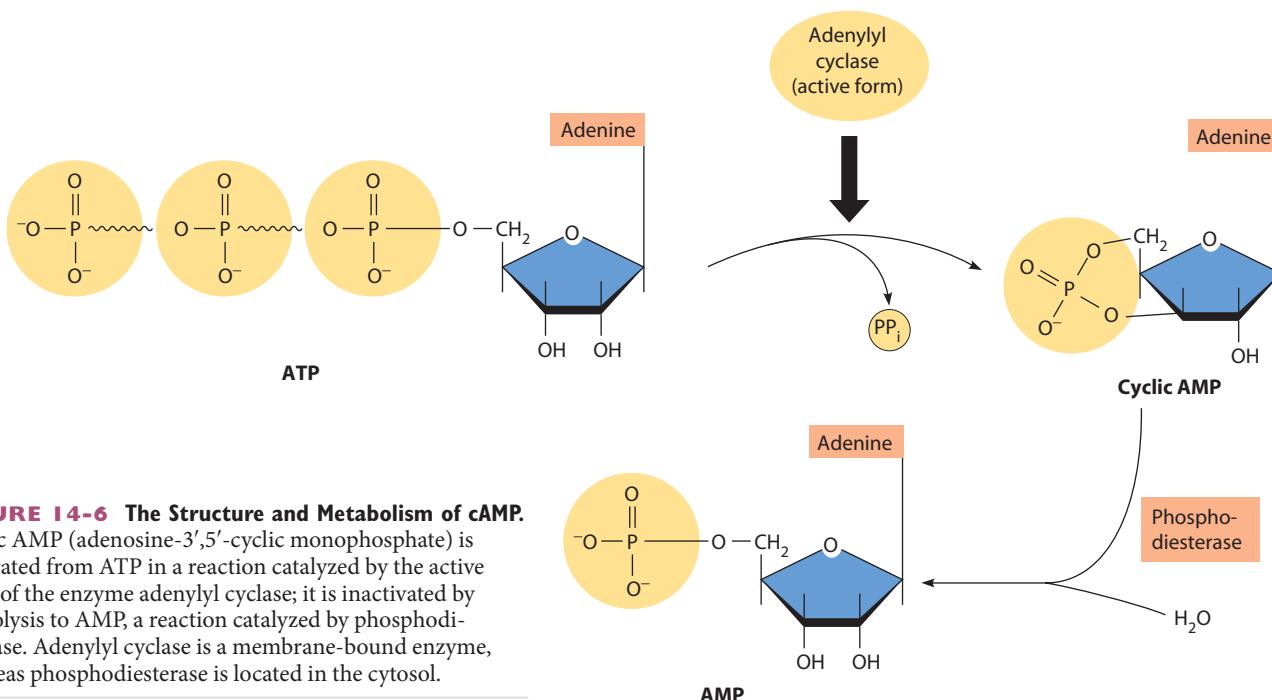

FIGURE 14-6 The Structure and Metabolism of cAMP.
Cyclic AMP (adenosine-3',5'-cyclic monophosphate) is generated from ATP in a reaction catalyzed by the active form of the enzyme adenylyl cyclase; it is inactivated by hydrolysis to AMP, a reaction catalyzed by phosphodiesterase. Adenylyl cyclase is a membrane-bound enzyme, whereas phosphodiesterase is located in the cytosol.

role of G_i in regulating potassium channels via its G_{βγ} subunits will be discussed later in this chapter.

G proteins respond quickly to changes in ligand concentration because they remain active for only a short time before the G_α subunit hydrolyzes its bound GTP and converts to the inactive state. Once the G protein becomes inactive, the adenylyl cyclase ceases to make cAMP. However, cAMP levels would still remain elevated in the cell if not for the enzyme **phosphodiesterase**, which degrades cAMP. This further ensures that the signal transduction pathway will shut down promptly when the concentration of the ligand outside the cell declines.

cAMP is important for many cellular events, a few of which are listed in **Table 14-1**. cAMP appears to have one main intracellular target—the enzyme protein kinase A. PKA phosphorylates a wide variety of cellular proteins by transferring a phosphate from ATP to a serine or threonine found within the target protein. cAMP regulates the activity of PKA by causing the detachment of its two regulatory subunits from its two catalytic subunits (**Figure 14-8**). Once the catalytic subunits are free, PKA can catalyze the phosphorylation of various proteins in the cell.

An increase in cAMP concentration can produce different effects in different cells. When cAMP is elevated in skeletal muscle and liver cells, the breakdown of glycogen is stimulated. In cardiac muscle, the elevation of cAMP strengthens heart contraction, whereas in smooth muscle contraction is inhibited. In blood platelets, the elevation of cAMP inhibits their mobilization during blood clotting, and in intestinal epithelial cells, it causes the secretion of salts and water into the lumen of the gut. Each of these reactions is an example of the preprogrammed response discussed earlier. In fact, if the concentration of cAMP is artificially raised in these different types of cells, these same

cellular responses can be triggered even in the absence of a ligand. This can be done in two different ways: either by stimulating cAMP production directly or by inhibiting the enzyme phosphodiesterase that degrades cAMP. Examples of phosphodiesterase inhibitors are the *methylxanthines*, compounds such as caffeine and theophylline, found in coffee, tea, and soft drinks. (Theophylline is often used to treat asthma because it relaxes bronchial smooth muscle.)

Disruption of G Protein Signaling Causes Several Human Diseases

What would happen if the G protein–adenylyl cyclase system could not be shut off? This question can be answered by examining what happens in two human diseases caused by bacteria. The bacteria *Vibrio cholerae* (which causes cholera) and *Bordetella pertussis* (which causes whooping cough) both cause disease through their effects on heterotrimeric G proteins. Cholera results from the secretion of *cholera toxin* when *V. cholerae* colonizes the gut. The toxin alters

Table 14-1 Examples of Cell Functions Regulated by cAMP

Regulated Function	Target Tissues	Hormone
Glycogen degradation	Muscle, liver	Epinephrine

Bone resorption	Bone	Parathyroid hormone

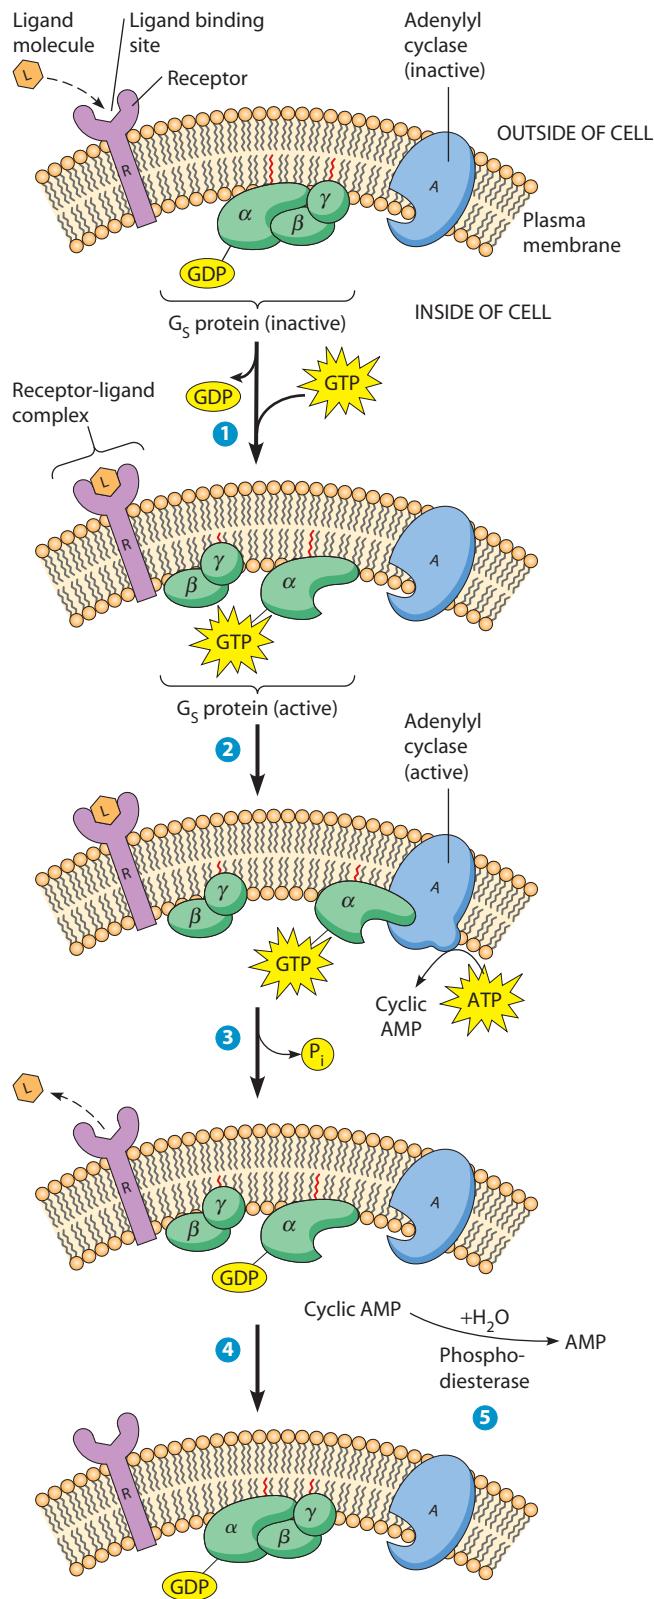

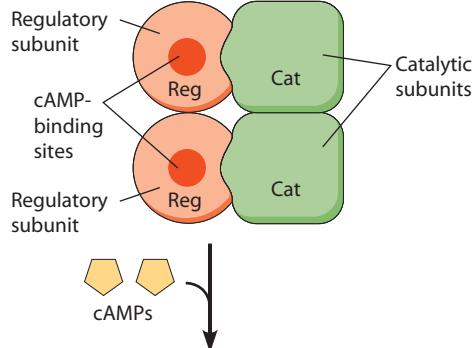

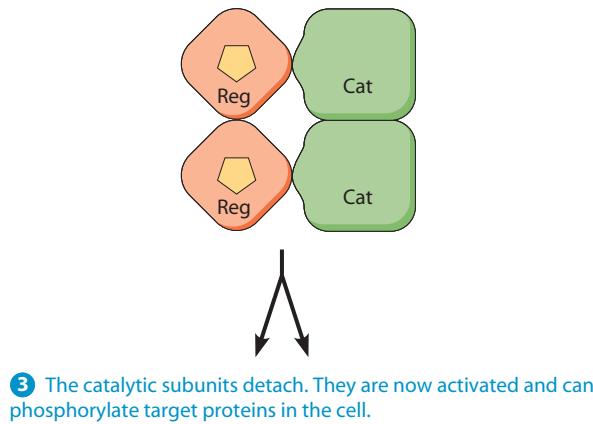

FIGURE 14-7 The Roles of G Proteins and Cyclic AMP in Signal Transduction.

Transduction. In the inactive state, the α, β, and γ subunits are present as a complex, with GDP bound to the α subunit. When a ligand (L) binds its receptor, it binds and activates a G_s protein. **1** When a receptor is activated by ligand binding, the receptor-ligand complex associates with the G_s protein, causing the displacement of GDP by GTP and the dissociation of the G_s_α-GTP complex. **2** The GTP-G_s_α complex then binds to and activates membrane-bound adenyl cyclase, which synthesizes cAMP. **3** Activation ends when the ligand leaves the receptor, the GTP is hydrolyzed to GDP by the GTPase activity of the G_s_α subunit, and the G_s_α dissociates from adenyl cyclase. **4** Adenyl cyclase then reverts to the inactive form, the G_s_α re-associates with the G_s_{βγ} complex, and **5** cAMP molecules in the cytosol are hydrolyzed to AMP by the phosphodiesterase.

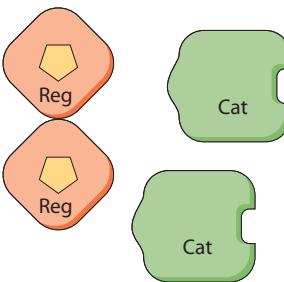

1 Protein kinase A is composed of two catalytic and two regulatory subunits. The regulatory subunits inhibit the catalytic subunits in the absence of cAMP.

2 Cyclic AMP activates protein kinase A by binding to the regulatory subunits, causing the regulatory subunits to change conformation.

3 The catalytic subunits detach. They are now activated and can phosphorylate target proteins in the cell.

secretion of salts (sodium chloride and sodium bicarbonate) and fluid in the intestinal lumen, which is normally regulated by hormones that act through the G protein G_s to alter intracellular levels of cAMP. A portion of the cholera toxin is an enzyme that chemically modifies G_s so that it can no longer hydrolyze GTP to GDP (by adding

FIGURE 14-8 The Activation of Protein Kinase A by Cyclic AMP.

PKA is composed of four subunits, two catalytic and two regulatory. The regulatory subunits inhibit the catalytic subunits in the absence of cAMP, but cAMP binding activates the catalytic subunits, which then regulate target proteins.

an ADP-ribose to it). As a result, G_s cannot be shut off, cAMP levels remain high, and the intestinal cells secrete large amounts of salt and water. If left untreated, this condition can result in death by dehydration. The *pertussis toxin* secreted by *B. pertussis* acts in a similar manner but on the inhibitory G protein, G_i . This protein normally shuts off adenylyl cyclase. When inactivated by pertussis toxin, G_i no longer inhibits adenylyl cyclase. The resulting fluid accumulation in the lungs leads to the characteristic cough associated with this disease.

The discovery of these toxins and their mode of action has provided not only advances in medical treatment but also powerful tools for studying G protein-mediated signal transduction. Because these two toxins act on different G proteins, researchers have been able to use the purified toxins to associate a signaling pathway with a particular G protein.

Many G Proteins Use Inositol Trisphosphate and Diacylglycerol as Second Messengers

The importance of inositol phospholipids in cell signaling was first brought to light in the pioneering studies of Robert Michell and Michael Berridge. In the early 1980s, Berridge noticed that when the salivary glands of certain insect larvae were stimulated to secrete, changes occurred in membrane inositol phospholipids. We now know that **inositol-1,4,**

5-trisphosphate (IP₃), one of the breakdown products of inositol phospholipids, functions as a second messenger. IP₃ is generated from *phosphatidylinositol-4,5-bisphosphate* (PIP₂), a relatively uncommon membrane phospholipid, when the enzyme **phospholipase C** is activated. Phospholipase C cleaves PIP₂ into two molecules—inositol trisphosphate and **diacylglycerol (DAG)** (Figure 14-9). After their discovery, IP₃ and DAG were quickly shown to be second messengers in a variety of regulated cell functions, some of which are indicated in Table 14-2.

The roles of IP₃ and DAG as second messengers in the inositol-phospholipid-calcium pathway are shown in Figure 14-10. The sequence begins with the binding of a ligand to its membrane receptor, leading to the activation of a specific G protein called G_q . G_q then activates a type of phospholipase C known as C_β , thereby generating both IP₃ and DAG. Inositol trisphosphate is water soluble and quickly diffuses through the cytosol, binding to a ligand-gated calcium channel known as the **IP₃ receptor** channel in the endoplasmic reticulum (ER). When IP₃ binds, the channel opens, releasing calcium ions into the cytosol. Calcium then elicits the desired physiological response.

Intracellular calcium release, as well as the formation of DAG in the membrane by phospholipase C activity, activates members of the **protein kinase C (PKC)** family of enzymes. PKC can then phosphorylate specific serine and threonine groups on a variety of target proteins,

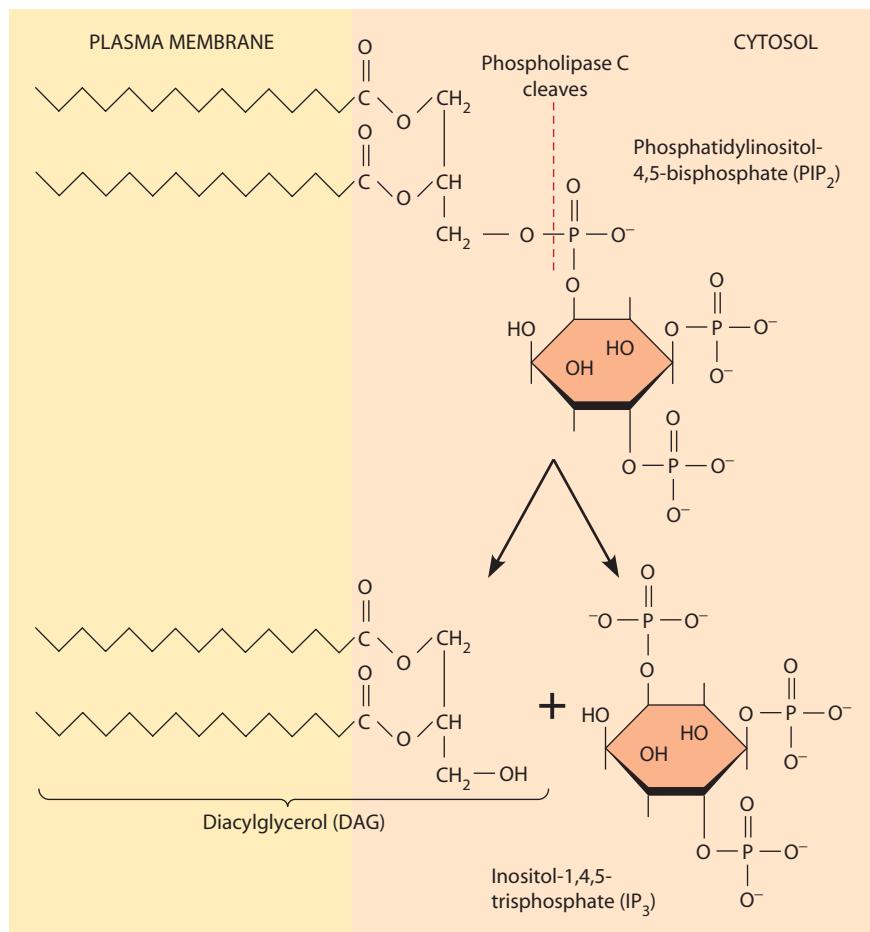

FIGURE 14-9 The Formation of Inositol Trisphosphate and Diacylglycerol. Inositol trisphosphate (IP₃) and diacylglycerol (DAG) are formed when phospholipase C cleaves phosphatidylinositol-4,5-bisphosphate (PIP₂), one of the phospholipids present in the membrane. IP₃ is released into the cytosol, whereas DAG remains within the membrane. Both IP₃ and DAG are second messengers in a variety of signal transduction pathways.

Table 14-2

Examples of Cell Functions Regulated by Inositol Trisphosphate and Diacylglycerol

Regulated Function	Target Tissues	Messenger
Platelet activation	Blood platelets	Thrombin
Muscle contraction	Smooth muscle	Acetylcholine
Insulin secretion	Pancreas, endocrine	Acetylcholine
Amylase secretion	Pancreas, exocrine	Acetylcholine
Glycogen degradation	Liver	Antidiuretic hormone
Antibody production	B lymphocytes	Foreign antigens

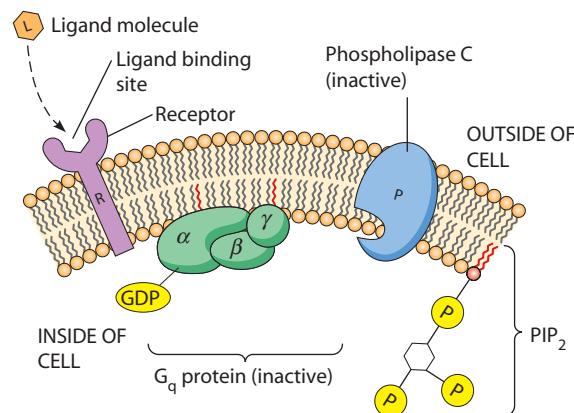

depending on the cell type. The role of DAG was established experimentally by showing that its effects could be mimicked by *phorbol esters*, plant metabolites that bind to PKC, activating it directly. Using a variety of pharmacological agents, researchers showed that IP₃-stimulated calcium release and DAG-mediated kinase activity are both required to produce a full response in target cells.

A wide variety of cellular effects have been linked to the activation of protein kinase C, including the stimulation of cell growth, the regulation of ion channels, changes in the cytoskeleton, increases in cellular pH, and effects on secretion of proteins and other substances.

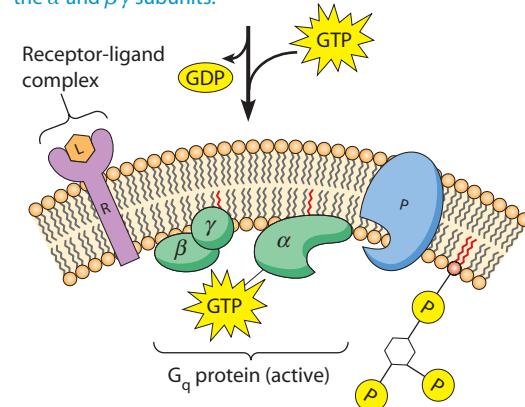

The Release of Calcium Ions Is a Key Event in Many Signaling Processes

How do we know that the sequence of events shown in Figure 14-10, especially the link between IP₃ signaling and the release of calcium within cells, actually occurs in cells? The answer begins with the observation that a specific physiological phenomenon—salivary secretion, in this case—could be activated by the products of phospholipase action: IP₃ and DAG. Evidence for the role of calcium was provided by an experimental approach involving the injection of a calcium-dependent fluorescent dye, such as fura-2, into a target cell. Because the fluorescence of the dye varies with the calcium concentration, the dye is a sensitive indicator of intracellular calcium concentration. Such dyes are typically referred to as **calcium indicators** (Figure 14-11). By measuring the increase in fluorescence in response to activation by a ligand or by IP₃ directly, investigators were able to establish that ligand binding leads to an increase in IP₃ concentration, which in turn triggers an increase in cytosolic calcium concentration. More recently, genetically engineered proteins called “cameleons,” which increase their fluorescence in response to elevated calcium, have been used to monitor cytosolic calcium levels.

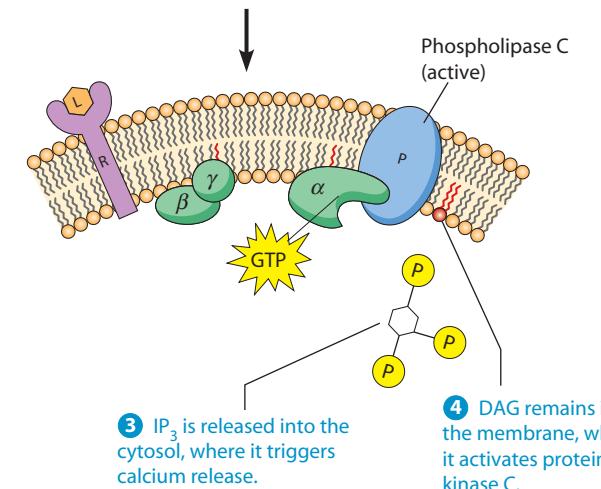

To complete the sequence of events, the increase in calcium concentration had to be linked to the actual physiological response of the target cell. This link was established by treating target cells with a **calcium ionophore** (such as the drugs ionomycin or A23187) in the absence of extracellular calcium. The ionophore renders membranes permeable to calcium, thereby releasing intracellular

1 A receptor is activated by the binding of its ligand. The receptor-ligand complex associates with the G protein G_q' causing displacement of GDP by GTP and dissociation of the α and βγ subunits.

2 The GTP-G_α complex then binds to phospholipase C (P), activating it and causing cleavage of PIP₂ into IP₃ and DAG.

3 IP₃ is released into the cytosol, where it triggers calcium release.

4 DAG remains in the membrane, where it activates protein kinase C.

FIGURE 14-10 The Role of IP₃ and DAG in Signal Transduction.

When a receptor (R) is activated by the binding of its ligand (L) on the outer surface of the plasma membrane, G protein activation results in production of IP₃ and diacylglycerol (DAG), which trigger calcium release and protein kinase C activation, respectively.

stores of calcium in the absence of a physiological stimulus. Treatment with calcium ionophore mimicked the effect of IP₃, thus implicating calcium as an intermediary in the IP₃ signal transduction pathway.

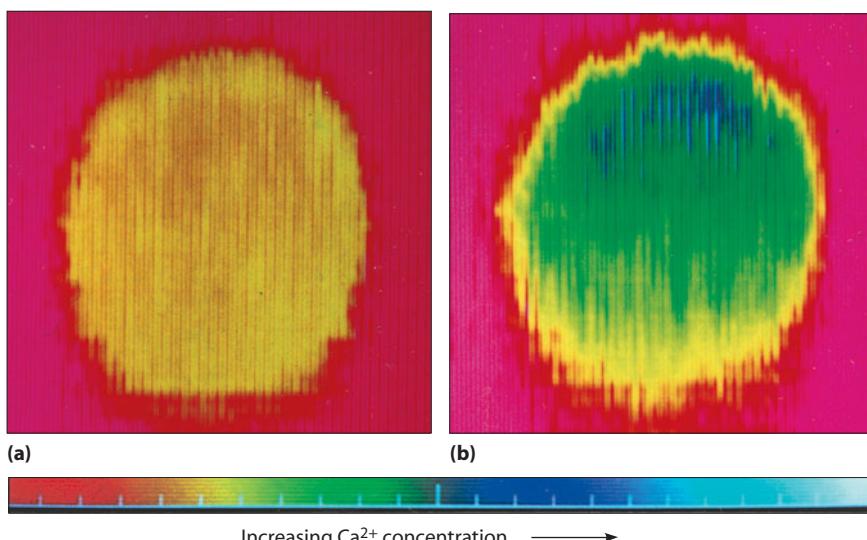

FIGURE 14-11 Increase in Free Cytosolic Ca^{2+} Concentration Triggered by a Hormone That Stimulates the Formation of Inositol Trisphosphate. Cells from a bovine adrenal gland were loaded with fura-2, a dye that fluoresces when bound to Ca^{2+} . The color of the fluorescence changes with alterations in Ca^{2+} concentration. (a) Fluorescence micrograph of an unstimulated adrenal cell color-coded to reflect different levels of fluorescence in response to free Ca^{2+} . The yellow color indicates a relatively low concentration of free Ca^{2+} . (b) Fluorescence in the adrenal cell stimulated by angiotensin, a hormone that triggers the formation of IP_3 . The green and blue colors indicate an increased concentration of free Ca^{2+} .

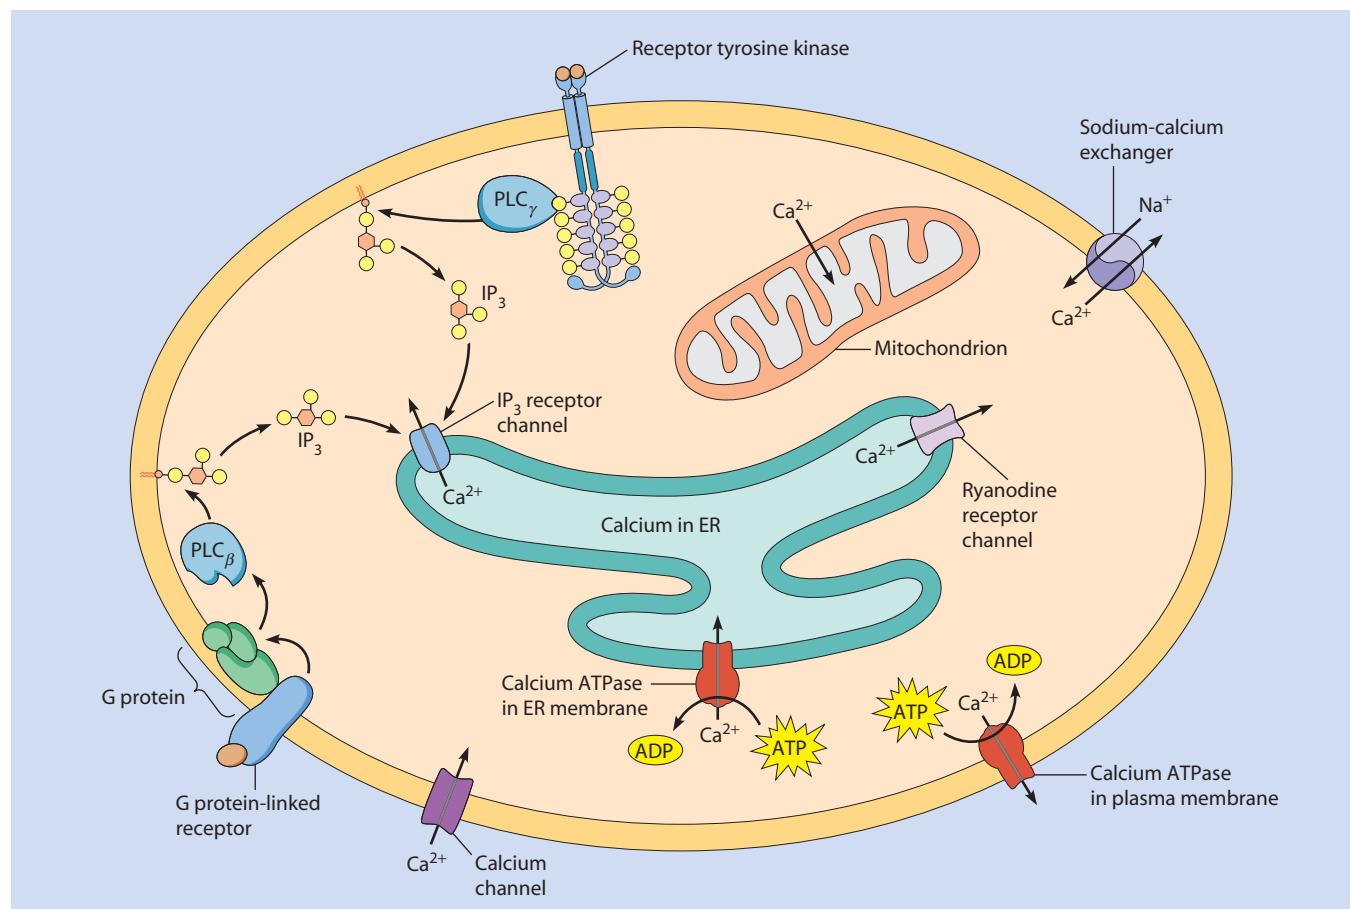

FIGURE 14-12 An Overview of Calcium Regulation in Cells. Cytosolic Ca^{2+} concentration is lowered by the actions of the ER calcium ATPase, the plasma membrane calcium ATPase, $\text{Na}^+/\text{Ca}^{2+}$ exchangers, and mitochondria. Ca^{2+} concentration increases in the cytosol because of the opening of Ca^{2+} channels in the plasma membrane and the release of Ca^{2+} through the IP_3 or ryanodine receptor channels in the ER membrane.

Calcium ions (Ca^{2+}) play an essential role in regulating a variety of cellular functions. **Figure 14-12** provides an overview of the various mechanisms of calcium regulation. The concentration of calcium is normally maintained at very low levels in the cytosol due to the presence of calcium

ATPases in the plasma membrane and the ER. Calcium ATPases in the plasma membrane transport calcium out of the cell, whereas the calcium ATPases in the ER sequester calcium ions in the lumen of the ER. In addition, some cells have sodium-calcium exchangers that further reduce

the cytosolic calcium concentration. Finally, mitochondria can transport calcium into the mitochondrial matrix. For most cells in their resting state, the action of calcium ATPases maintains the calcium concentration in the cytosol at $0.1 \mu M$.

There are several different ways that various stimuli can cause cytosolic calcium concentrations to increase. One way, discussed in Chapter 13 in relation to neurons, is by the opening of calcium channels in the plasma membrane. The calcium concentration in the extracellular fluid and the blood is about 1.2 mM , more than 10,000 times as high as that of the cytosol. As a result, when calcium channels open, calcium ions rush into the cell.

Calcium levels can also be elevated by the release of calcium from intracellular stores. Calcium ions sequestered in the ER can be released through the IP_3 receptor channel, discussed earlier, and through the ryanodine receptor channel, so named because it is sensitive to the plant alkaloid *ryanodine*. *Ryanodine receptor channels* are particularly important for calcium release from the sarcoplasmic reticulum of cardiac and skeletal muscle (see Chapter 16), but nonmuscle cells such as neurons also have ryanodine receptors. Surprisingly, both the ryanodine and IP_3 receptors are sensitive to calcium itself. When a neuron is depolarized, for example, calcium channels in the plasma membrane open and allow some calcium to enter the cytosol. Upon exposure to a rapid increase in calcium ions, the ryanodine receptor channel opens, allowing calcium to escape from the ER into the cytosol. This phenomenon has been aptly named *calcium-induced calcium release*.

Calcium Release Following Fertilization of Animal Eggs. Local calcium levels can affect a wide variety of cellular processes. One important process regulated by calcium is exocytosis, which you learned about in Chapter 12. In Chapter 13 we saw that neurotransmitter release is a particularly good example of calcium-regulated exocytosis. Fertilization of animal eggs is another striking example of the importance of calcium-mediated signal transduction. In many animals, release of calcium from inside sperm cells results in their activation. Activated sperm can then bind to the surface of mature eggs and unite with them at fertilization, triggering a striking sequence of events. One of the early responses of the egg—within 30 seconds to several minutes after fertilization—is the release of calcium from internal stores. Calcium release occurs initially at the site where the sperm penetrates the egg surface and then spreads across the egg via calcium-induced calcium release, much as a ripple on the surface of a pond spreads away from the site where a pebble strikes the water. The wavelike propagation of calcium release can be visualized using calcium indicators (**Figure 14-13a**).

The calcium release is necessary for two crucial events. First, it stimulates the exocytosis of vesicles, known as *cortical granules* (Figure 14-13b). The release of cortical granules results in alterations of the protein coat

surrounding many eggs (typically known as the *vitelline envelope*). These alterations render the egg unable to bind additional sperm, thereby preventing more than one sperm from fertilizing the egg. This process is known as the *slow block to polyspermy*. (An earlier *fast block to polyspermy* involves a transient depolarization of the egg plasma membrane.)

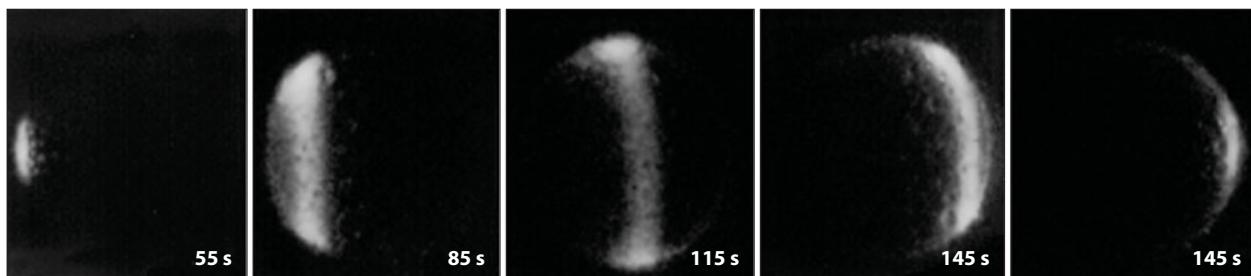

The second major function of the calcium wave following fertilization is *egg activation*. Egg activation involves the resumption of many metabolic processes, the reorganization of the internal contents of the egg, and other events that initiate the process of embryonic development. Many features of the slow block to polyspermy and egg activation can be initiated by treating unfertilized eggs with calcium ionophore in the absence of sperm, demonstrating the key role elevated calcium levels within the egg play in its activation.

Egg activation is a good example of how a dynamic change in calcium concentration can result in dramatic cellular responses. In other cases, it is the *oscillation* of calcium concentration over time that elicits a cellular response. Calcium oscillations occur in neurons and in fertilized mammalian eggs and may contribute to stable changes in the state of these cells. Calcium oscillations are also important in regulating the opening and closing of stomata in plants.

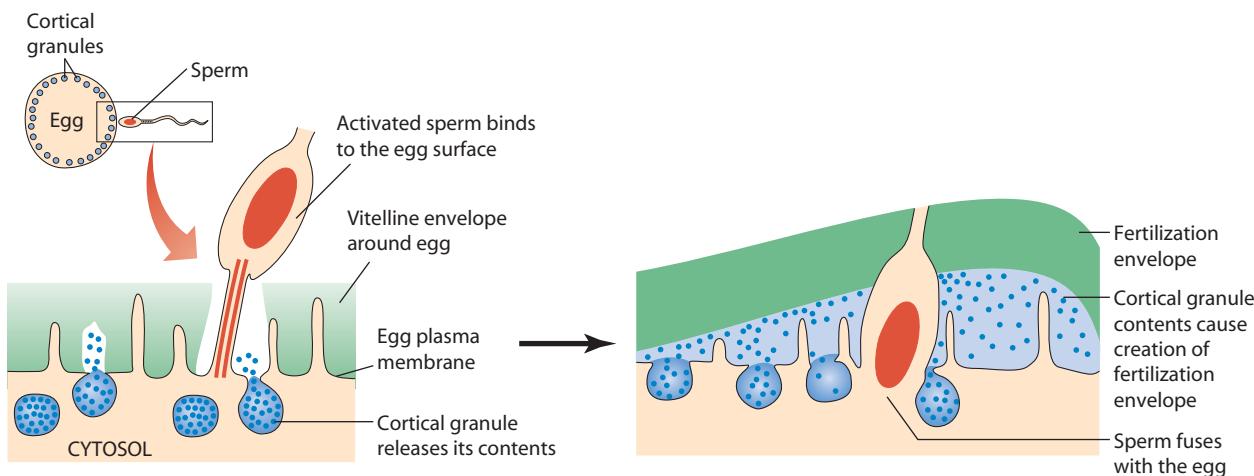

Calcium Binding Activates Many Effector Proteins. Calcium can bind directly to many different *effector proteins*, altering their activity. The response of a target cell to an increase in calcium concentration depends on the particular calcium-binding proteins that are present in the cell. This means that the same change in calcium concentration can produce markedly different effects in two target cells if each possesses different calcium-sensitive enzyme systems. One of these proteins is the protein **calmodulin**.

How does calmodulin mediate calcium-activated events in the cell? The calmodulin molecule has been compared to a flexible “arm” with a “hand” at each end (**Figure 14-14a**). Two calcium ions bind at each of two “hand” regions, causing the calmodulin to undergo a change in shape that forms the active *calcium-calmodulin complex* (Figure 14-14b, steps ① and ②). When a protein is present that contains a calmodulin-binding site, such as a protein kinase or phosphatase, the hands and arm bind to it by wrapping around the binding site (Figure 14-14b, step ③). Calmodulin binding, in turn, can influence the function of such a protein dramatically.

An important feature of calmodulin is its affinity for calcium: Calmodulin binds to calcium when the cytosolic calcium concentration increases to about $1.0 \mu M$, but it releases calcium when cytosolic calcium levels decline back to the resting level of $0.1 \mu M$. Thus, calmodulin is uniquely suited to operate within the typical range of cytosolic calcium concentrations.

(b)

FIGURE 14-13 Transient Increase in Free Ca^{2+} Concentration That Occurs in an Egg Cell Immediately After Fertilization.

Immediately After Fertilization. (a) In this classic experiment, a fish egg has been injected with aequorin, a dye that emits light when bound to free Ca^{2+} in the cytosol. The amount of time that has elapsed after fertilization is indicated in seconds in each photograph. In the first few minutes after fertilization, a transient wave of increased Ca^{2+} concentration passes across the egg, starting from the point of sperm entry on the left. (b) An activated sperm cell, such as the sea urchin sperm shown here, binds to the egg surface, resulting in local Ca^{2+} release and cortical granule exocytosis. The result is the creation of the fertilization envelope, which prevents additional sperm from penetrating the egg.

The $\beta\gamma$ Subunits of G Proteins Can Also Transduce Signals

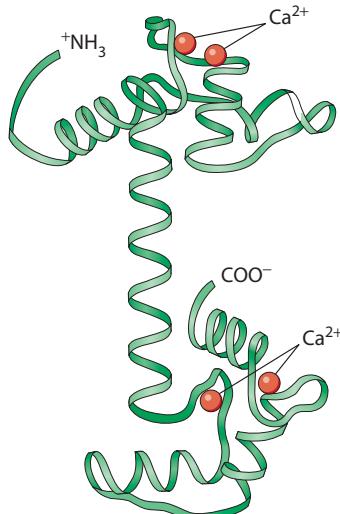

We have seen that the α subunits of activated G proteins can interact with proteins such as adenylyl cyclase and phospholipase C to elicit changes in a cell that receives a signal. However, $G_{\beta\gamma}$ can also engage in signaling. For example, G protein receptor kinases, which we have already encountered, can be activated by the $\beta\gamma$ subunit of a dissociated G protein, providing a feedback mechanism on G protein signals. One well-studied example of $G_{\beta\gamma}$ signaling involves the *muscarinic acetylcholine receptor*. Recall from Chapter 13 that some neurotransmitter receptors act indirectly, via intracellular signaling, to cause changes in ion channels. When acetylcholine binds the muscarinic acetylcholine receptor, the $\beta\gamma$ subunit of its associated G protein (G_i) acts on potassium channels in the plasma membrane, causing them to open (Figure 14-15). When acetylcholine is no longer present, the α and $\beta\gamma$ subunits re-associate, causing the potassium channels to close again.

Another example of $G_{\beta\gamma}$ signaling involves signaling in the budding yeast, *Saccharomyces cerevisiae* (see Figure

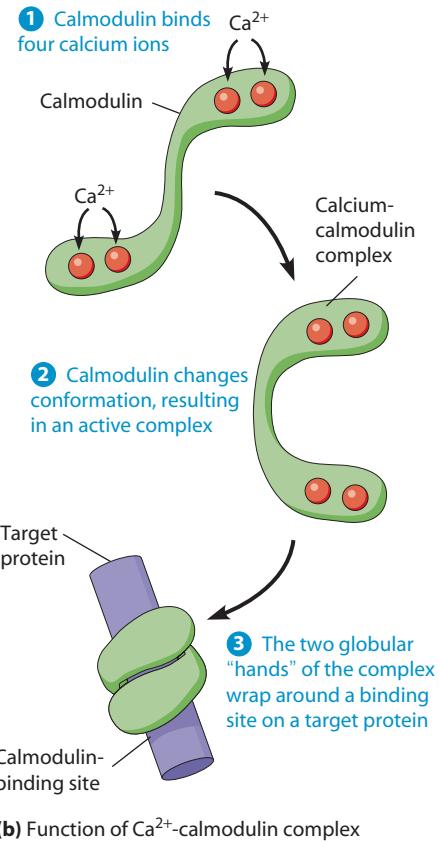

14-18). Yeast use G protein-mediated signaling during mating and to sense changes in osmolarity, availability of nutrients, and other environmental factors. Interestingly, the activated $\beta\gamma$ subunits in this case initiate a series of phosphorylation events that lead to activation of a type of kinase known as *MAP kinase*. MAP kinases are key proteins in another type of signaling pathway in higher eukaryotes, the receptor tyrosine kinase pathway, which we consider in the next section.

Other Signaling Pathways Can Activate G Proteins

In addition to the examples we have described, there are many other pathways that can lead to activation of heterotrimeric G proteins. These include Wnts, which act through seven-pass receptors known as Frizzleds (see Chapter 24), and the Hedgehog pathway, which acts in part through another seven-pass protein known as *Smoothed*. These further illustrate the complexity of cell signaling pathways within the cell.

Protein Kinase-Associated Receptors

We have seen that G protein-linked receptors transmit their signals to the interior of the cell by causing changes in a G protein, which in turn initiates a cascade of signal transduction events. Another large family of proteins uses a different strategy to transmit signals. They not only function as receptors but are themselves protein kinases. When they bind to the appropriate ligand, their kinase

activity is stimulated, and they transmit signals through a cascade of phosphorylation events within the cell.

Recall that kinases add phosphate groups to particular amino acids within substrate proteins (see Chapter 6). Receptor kinases generally fall into two major categories: those that phosphorylate a tyrosine residue (*tyrosine kinases*) and those that phosphorylate a serine or threonine residue (*serine/threonine kinases*). We will now examine these *receptor protein kinases* in some detail.

- 1 In the absence of acetylcholine (Ach), a G protein associated with the muscarinic Ach receptor is bound to GDP.

- 2 Binding of Ach results in activation of the G protein. The $\beta\gamma$ subunit interacts with a K⁺ ion channel, causing it to open.

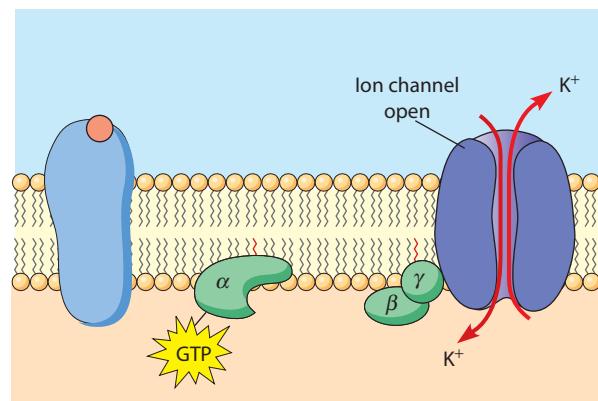

FIGURE 14-15 The $G_{\beta\gamma}$ Subunits of a G Protein Indirectly Regulate Ion Channels in Some Neurons.

One type of acetylcholine receptor (the muscarinic receptor) is a G protein-linked receptor. When acetylcholine binds, it activates the $G_{\beta\gamma}$ subunit of G_i , which regulates the opening of potassium channels.

Growth Factors Often Bind Protein Kinase-Associated Receptors

Protein kinase-associated receptors function in many important cellular processes. One well-studied case where they come into play is cell proliferation. For a cell to divide, it must have all the nutrients needed for synthesis of its component parts, but the availability of nutrients is usually not itself sufficient for growth. Cells often also need additional signals to stimulate cell growth. Biologists encountered the requirements for cell growth when they first tried to culture cells *in vitro*. Although provided with a growth medium rich in nutrients, including the presence of blood plasma, cells would not grow. A turning point came when blood serum was used instead of plasma: Serum was able to support the growth of cells, whereas plasma would not. Many of the messengers present within the serum have now been purified, and they are members of various classes of proteins known as **growth factors**.

The difference between blood serum and blood plasma held an important clue about growth factors. *Plasma* is whole blood, including unreacted *platelets* (which contain clotting components) but without the red and white blood cells. *Serum* is the clear fluid remaining after blood has clotted. During clotting, platelets secrete growth factors into the blood that stimulate the growth of cells called *fibroblasts*, which form the new connective tissue that makes up a scar. After clotting, the resulting serum is full of *platelet-derived growth factor (PDGF)*. Plasma does not contain this factor because the clotting reaction has not taken place.

We now know that the receptor for PDGF is a receptor tyrosine kinase. In fact, several growth factors act by stimulating receptor tyrosine kinases, including *insulin*, *insulin-like growth factor-1*, *fibroblast growth factor*, *epidermal growth factor*, and *nerve growth factor*. Many other types of growth factors have also been isolated. A small sampling is shown in **Table 14-3**, which also lists some cell types affected by each factor and the general class of molecule that serves as a receptor for each growth factor.

Although collectively known as growth factors, the proteins that activate tyrosine kinase and other types of

receptors function in many diverse events. These include growth and cell division as well as crucial events during the development of embryos, responses to tissue injury, and many other activities. We will examine the effects of growth factors on cell division in Chapter 19 and their role in cancer in Chapter 24. For now, all we need to recognize is that growth factors are secreted molecules that act at short range and have specific effects on cells possessing the appropriate receptor to sense the presence of the growth factor.

Receptor Tyrosine Kinases Aggregate and Undergo Autophosphorylation

Many **receptor tyrosine kinases (RTKs)** trigger a chain of signal transduction events inside the cell that ultimately lead to cell growth, proliferation, or the specialization of cells. Examples of RTKs include the insulin receptor, the nerve growth factor receptor, and the epidermal growth factor (EGF) receptor (**Figure 14-16**).

The Structure of Receptor Tyrosine Kinases. Receptor tyrosine kinases differ structurally from G protein-linked receptors in many ways. These receptors often consist of a single polypeptide chain with only one transmembrane segment. Within this polypeptide chain are several distinct domains (Figure 14-16a). The extracellular portion of the receptor contains the *ligand-binding domain*. The other end of the peptide protrudes through the plasma membrane into the cytosol. On the cytosolic side, a portion of the receptor forms the tyrosine kinase. The cytosolic portion of the receptor contains tyrosine residues that are in fact themselves targets for the tyrosine kinase portion of the receptor.

The tyrosine kinase is frequently an integral part of the receptor protein. In some cases, however, the receptor and the tyrosine kinase are two separate proteins, and the tyrosine kinase is then referred to as a *nonreceptor tyrosine kinase*. However, it can bind to the receptor and be activated when the receptor binds its ligand, so the net effect is quite similar to the activation of a typical receptor tyrosine kinase.

Nonreceptor tyrosine kinases were, in fact, the first tyrosine kinases to be discovered. The first nonreceptor

Table 14-3 Examples of Growth Factor Families

Growth Factor	Target Cells	Type of Receptor Complex
Epidermal growth factor (EGF)	Wide variety of epithelial and mesenchymal cells	Tyrosine kinase
Transforming growth factor α (TGF α)	Same as EGF	Tyrosine kinase
Platelet-derived growth factor (PDGF)	Mesenchyme, smooth muscle, trophoblast	Tyrosine kinase
Transforming growth factor β (TGF β)	Fibroblastic cells	Serine-threonine kinase
Fibroblast growth factor (FGF)	Mesenchyme, fibroblasts, many other cell types	Tyrosine kinase
Interleukin-2 (IL-2)	Cytotoxic T lymphocytes	Complex of three subunits
Colony-stimulating factor-1 (CSF-1)	Macrophage precursors	Tyrosine kinase
Wnts	Many types of embryonic cells	Frizzled (seven-pass protein)
Hedgehogs	Many types of embryonic cells, melanocytes	Patched (seven-pass protein)

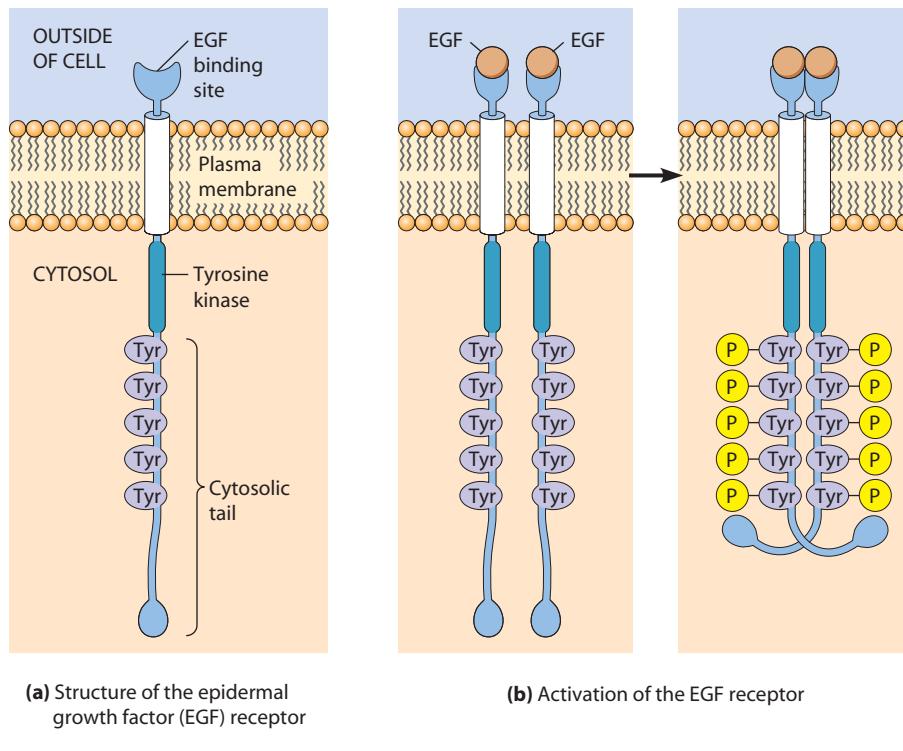

FIGURE 14-16 The Structure and Activation of a Receptor Tyrosine Kinase.

Kinase. (a) The receptor for epidermal growth factor (EGF), shown here, is typical of many receptor tyrosine kinases (RTKs). These receptors often have only one transmembrane segment. The extracellular portion of the receptor binds to the ligand (EGF in this case). Inside the cell, a portion of the receptor has tyrosine kinase activity. The remainder of the receptor contains a series of tyrosine residues that are substrates for the tyrosine kinase. (b) The activation of RTKs starts with ligand binding, causing receptor clustering. Once the receptors aggregate, they cross-phosphorylate each other at a number of tyrosine amino acid residues. The formation of tyrosine phosphate (Tyr-P) residues on the receptor creates binding sites for cytosolic proteins that contain SH2 domains.

(a) Structure of the epidermal growth factor (EGF) receptor

(b) Activation of the EGF receptor

tyrosine kinase identified was the Src protein, which is encoded by the *src* gene of the avian sarcoma virus. One form of Src can transform normal cells into cancer cells, a topic we will learn more about in Chapter 24. Many other nonreceptor tyrosine kinases have been discovered, and most of them are similar in structure to the Src protein.

The Activation of Receptor Tyrosine Kinases. Signal transduction is initiated when a ligand binds, causing the receptor tyrosine kinases to aggregate (Figure 14-16b). In many of the best-understood cases, two receptor molecules cluster together within the plasma membrane when they bind ligand. Once the receptors cluster in this way, the tyrosine kinase associated with each receptor phosphorylates the tyrosines of neighboring receptors. Since the receptors phosphorylate other receptors of the same type, this process is referred to as **autophosphorylation**.

Receptor Tyrosine Kinases Initiate a Signal Transduction Cascade Involving Ras and MAP Kinase

Receptor tyrosine kinases use a different method of initiating signal transduction from that seen with G protein-linked receptors. Many of the key events in RTK signaling were identified using mutants in model organisms such as *Drosophila* and *Caenorhabditis elegans*, a topic we explore in **Box 14B**. Here, we present an outline of this important pathway.

Once autophosphorylation of tyrosine residues on the cytosolic portion of the receptor occurs in response to ligand binding (1, Figure 14-17), the receptor recruits a number of cytosolic proteins to interact with itself. Each of these proteins binds to the receptor at a phosphorylated

tyrosine residue. To bind to the receptor, each cytosolic protein must contain a stretch of amino acids that recognizes the phosphotyrosine and a few neighboring amino acids on the receptor. The portion of a protein that recognizes one of these phosphorylated tyrosines is called an **SH2 domain**. The term *SH2*, for Src homology (domain) 2, was originally used because proteins with SH2 domains have sequences of amino acids that are strikingly similar to a portion of the Src protein.

Recruitment of different SH2 domain-containing proteins activates different signal transduction pathways. As a result, receptor tyrosine kinases can activate several different signal transduction pathways at the same time. These include the inositol-phospholipid-calcium second messenger pathway, which we have already discussed (Figure 14-12), and the Ras pathway, which ultimately activates the expression of genes involved in growth or development.

Ras is important in regulating the growth of cells. Unlike the heterotrimeric G proteins associated with G protein-linked receptors, Ras comprises a single subunit. Ras and other *small monomeric G proteins* are important signaling molecules. Like other G proteins, Ras can be bound to either GDP or GTP, but it is active only when bound to GTP. In the absence of receptor stimulation, Ras is normally in the GDP-bound state. For Ras to become active, it must release GDP and acquire a molecule of GTP. For this to take place, Ras needs the help of another type of protein called a **guanine-nucleotide exchange factor (GEF)**.

The GEF that activates Ras is **Sos** (so called because it was originally identified from a genetic mutation in fruit flies called *son of sevenless* that results in the failure of cells in the compound eye to develop properly; Box 14B). For Sos to become active, it must bind indirectly to the receptor tyrosine kinase through another protein, called **GRB2**

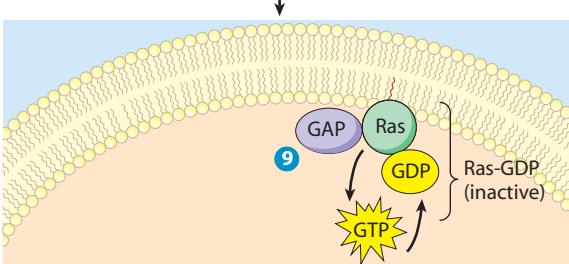

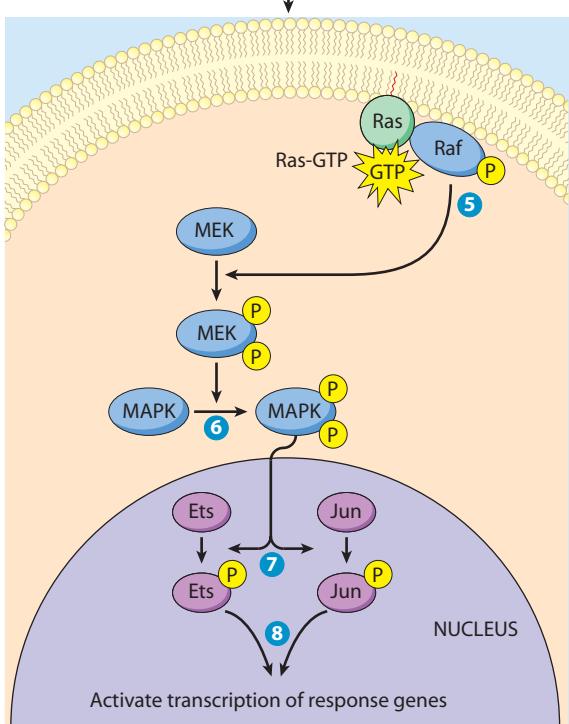

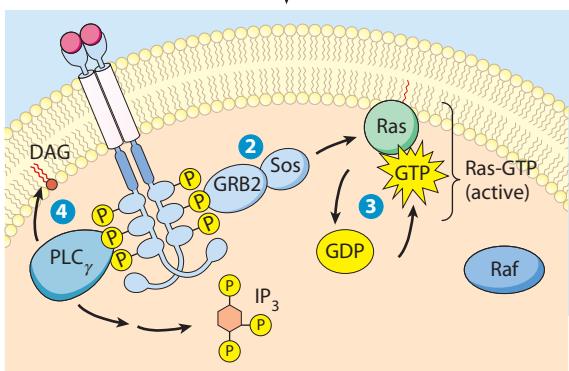

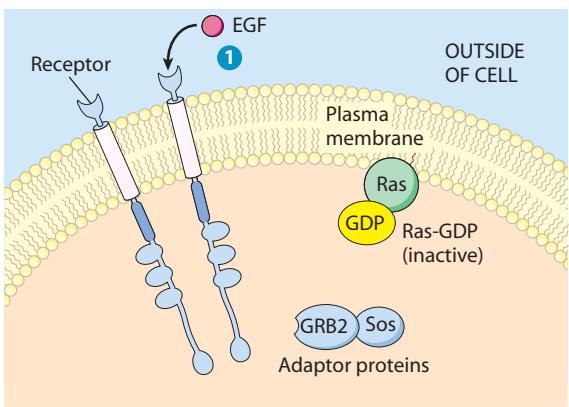

FIGURE 14-17 Signal Transduction Through Receptor Tyrosine Kinases.

Upon ligand binding, receptor tyrosine kinases, such as epidermal growth factor (EGF), aggregate and undergo autophosphorylation. Once a receptor is phosphorylated at tyrosine residues in its cytosolic tail, proteins with SH2 domains such as GRB2 bind to the receptor, recruiting Sos, a GEF for Ras. Sos then causes the activation of Ras by helping it release GDP and acquire GTP. At the same time, the binding of phospholipase C γ to the activated receptor results in its activation and the cleavage of PIP₂ into IP₃ and DAG. Activated Ras initiates a cascade of phosphorylation events, beginning with the protein Raf, which catalyzes the phosphorylation of MEK. Ultimately, MAP kinase (MAPK) becomes phosphorylated. Activated MAPK catalyzes phosphorylation of proteins such as Ets and Jun, which act in the nucleus, along with other proteins, to regulate the transcription of response genes. Ras is inactivated by hydrolysis of its bound GTP, a step facilitated by a GAP.

Figure 14-17), which contains an SH2 domain. Thus, to activate Ras, the receptor becomes tyrosine phosphorylated, and GRB2 and Sos form a complex that binds to the receptor, activating Sos. Sos then stimulates Ras to release GDP and acquire GTP, which converts Ras to its active state (3, Figure 14-17).

Once Ras is active, it triggers a series of phosphorylation reactions (5, Figure 14-17). The first protein in this cascade is a protein kinase called Raf. Activated Raf in turn phosphorylates serine and threonine residues in a protein kinase known as MEK. MEK can then phosphorylate threonines and tyrosine residues in a class of proteins known as **mitogen-activated protein kinases**, or **MAP kinases** (MAPKs; 6, Figure 14-17). MAPKs are activated when cells receive a stimulus to grow and divide (such a signal is sometimes called a *mitogen*, hence the name of the kinase). One function of MAPKs is to phosphorylate nuclear proteins, known as transcription factors, that regulate gene expression (7, Figure 14-17). One such nuclear protein is called Jun, a component of the AP-1 transcription factor, along with proteins that are members of the *Ets* family of transcription factors. These proteins in turn regulate the expression of genes whose protein products are needed for cells to grow and divide (8, Figure 14-17).

Once Ras is in its active state, it must be inactivated by hydrolysis of the GTP bound to it to avoid continued stimulation of the Ras pathway. GTP hydrolysis is facilitated by a **GTPase activating protein** (GAP; 9, Figure 14-17). GAPs can accelerate inactivation of Ras a hundredfold.

Receptor Tyrosine Kinases Activate a Variety of Other Signaling Pathways

Receptor tyrosine kinases, like G protein-linked receptors, can also activate phospholipase C (4, Figure 14-17). We have already seen that the activation of phospholipase C leads to production of IP₃ and DAG and that IP₃ releases calcium from intracellular stores. However, phospholipase C γ (activated by receptor tyrosine kinases) is different from phospholipase C β (activated by the G protein-linked receptors) in that it contains an SH2 domain and must bind to the receptor. Once it binds to the receptor,

Using Genetic Model Systems to Study Cell Signaling

Modern cell biologists use a variety of experimental tools to study key cell biological events, including genetic analysis of mutants that show defects during specific signaling events. The use of genetic model systems, including the budding yeast, *Saccharomyces cerevisiae*, the nematode worm *Caenorhabditis elegans*, and the fruit fly, *Drosophila melanogaster*, revolutionized our ability to connect the functions of specific proteins with important signaling pathways. For example, studies in budding yeast provided key information regarding how the cell cycle is controlled (see Chapter 19). Here, we focus on how genetic model systems have uncovered key aspects of an important cellular pathway: the receptor tyrosine kinase (RTK) pathway.

Receptor Tyrosine Kinase Signaling and the Fly Eye

Genetic analysis of signal transduction downstream of RTKs was conducted at about the same time in two systems: the compound

eye of *Drosophila* and the egg-laying structures, or vulva, of the nematode, *C. elegans*. Here, we will consider the *Drosophila* eye.

The compound eye of *Drosophila* is composed of roughly 800 individual “eyes” called ommatidia (singular, ommatidium; **Figure 14B-1a**). Each ommatidium consists of 22 cells. Eight of these are photoreceptors, named on the basis of their position (R1–R8). Mutations in Ras can dramatically affect the appearance of the eye (**Figure 14B-1c**) because formation of ommatidia depends on an RTK encoded by the *sevenless* gene (abbreviated *sev*). Loss of *Sev* results in loss of the R7 cell, which differentiates as a cone cell instead (**Figure 14B-1d**). Subsequent studies identified a ligand on the neighboring cell, R8, that activates the Sevenless receptor, called Bride of sevenless (abbreviated *Boss*). *Boss* protein on R8 binds to the *Sev* receptor on R7, initiating signaling.

Results from strong *sev* mutants were clear: unlike normal eyes (**Figure 14B-2a**), when *Sev* is absent no R7 cell forms

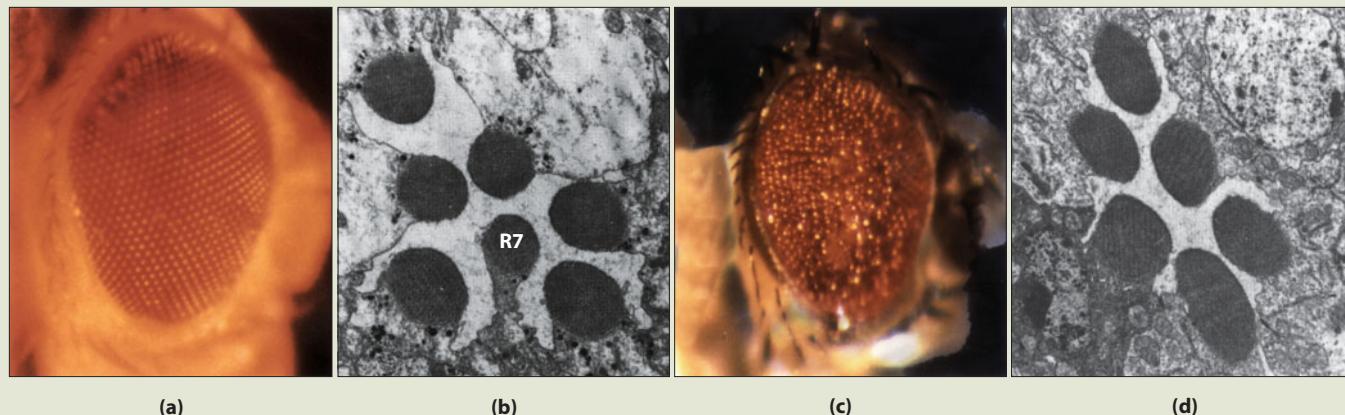

FIGURE 14B-1 The Compound Eye of *Drosophila*. (a) A normal eye (light micrograph). (b) Cross section of a normal ommatidium at high magnification (TEM). The R7 cell lies in the center. (c) An eye expressing a dominant, activated form of Ras appears rough. (d) In a *sevenless* mutant, which does not express the RTK required for R7 to differentiate properly, no R7 cell is present.

phospholipase C γ is phosphorylated by the receptor tyrosine kinase and becomes active.

In addition, receptor tyrosine kinases can activate other enzymes, such as *phosphatidylinositol 3-kinase* (PI 3-kinase), which phosphorylates the plasma membrane phospholipid phosphatidylinositol. This enzyme is important in regulating cell growth and cell movement via its action on various phosphatidylinositides. The roles of this kinase are diverse and complex. Later in this chapter, we will examine one role of PI 3-kinase during insulin signaling.

Scaffolding Complexes Can Facilitate Cell Signaling

We have seen that receptor tyrosine kinases can stimulate a series of phosphorylation reactions initiated by the active Ras

protein. Recent research suggests that signaling components like those in the Ras pathway are sometimes assembled into large multiprotein complexes, which make such cascading reactions more efficient and confine the cellular responses to signals to a small area. One well-studied example involves the mating pathway of the budding yeast, *Saccharomyces cerevisiae*. Under favorable conditions, yeast are haploid. In times of stress, however, cells of mating type *a* secrete a chemical signal called *a factor*, which can bind to specific G protein-linked receptors on nearby *α* cells (**Figure 14-18a**). At the same time, *α* cells secrete *α factor*, which binds to corresponding receptors on *a* cells. Such *mating factor* signaling results in widespread changes in the two cells, including polarized secretion, alterations in the cytoskeleton, and changes in gene expression. Ultimately, the two cells fuse to create a diploid *a/α* cell.

(Figure 14B-2b). To identify additional components of the *sev* pathway, conditions were found in which just enough functional Sev receptor was present to allow R7 to develop (geneticists call conditions like this a “sensitized background”). Mutations were then isolated in which eye defects were caused only when the flies also carried this sensitizing defect in Sev (Figure 14B-2c). Researchers reasoned that such mutations would affect the same pathway that Sev/Boss activates. By using this approach, they identified several important components of RTK signaling. In conjunction with biochemical studies on cultured cells, these pioneering studies identified proteins essential for RTK signaling.

In other studies, the effects of multiple mutations in the *sev* pathway were examined. For example, in double mutants that lack functional Sevenless but also carry a dominant mutation in Ras that results in reduced GTPase activity (such a mutation makes Ras *constitutively active*; i.e., it is overstimulated), R7 differentiates, even though it cannot receive the signal from R8 (Figure 14B-2d). This provides evidence that the *sev* pathway normally works by activating Ras. When Ras is activated on its own, the events at the cell surface are no longer necessary. Through these and similar studies in *C. elegans*, signaling pathways downstream of RTK signaling were clarified.

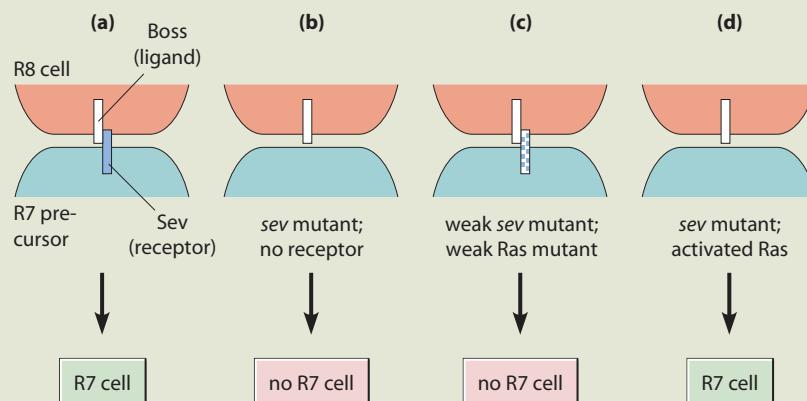

FIGURE 14B-2 Mutations in the Ras Pathway Can Either Bypass or Enhance Defects in RTK Signaling. (a) In normal larvae, Boss ligand on the surface of the R8 cell activates the Sev receptor on the adjacent R7 precursor cell, leading to its normal differentiation. (b) In *sev* mutants, lack of the Sev receptor results in failure of the R7 precursor cell to receive the signal from R8, and the cell does not become an R7 cell. (c) When the fly lacks functional Sev protein, but the R7 cell expresses a dominant, active form of Ras, a normal R7 cell can form. (d) When Sev contains a weak mutation that normally allows an R7 cell to form but the R7 precursor cell also carries a weak mutation in Ras, no R7 cell is produced.

As we have already seen, mating factor signaling is mediated through the activated $G_{\beta\gamma}$ subunit of a G protein. $G_{\beta\gamma}$ recruits a large scaffolding protein, known as *Ste5*, to the plasma membrane. *Ste5* increases the efficiency of signal transduction through the mating pathway by assembling the kinases involved into a large complex. In this case, a specific phosphorylation cascade results in the phosphorylation of MAPK (Figure 14-18b). MAPK in turn phosphorylates proteins that result in changes in gene expression that are important for mating. Other similar scaffolding complexes have been identified in yeast that regulate responses to changes in osmolarity, nutrients, and other environmental signals. Scaffolding complexes are not unique to yeast. Neuronal synapses, for example, contain multiprotein complexes; it is likely that many signaling pathways exploit this same strategy. One important class of

proteins that binds numerous signaling molecules and regulates their functions in multiprotein complexes is a class of proteins known as *14-3-3 proteins*.

Dominant Negative Mutant Receptors Are Important Tools for Studying Receptor Function

Growth factor signaling is important for many cellular events, as we have seen. But how can we identify which receptors are important for particular events? One way is through the use of genetics (Box 14B). However, another way is by introducing mutations into the receptor to study the effects. For example, consider **fibroblast growth factor (FGFs)** and their receptor tyrosine kinases, the **fibroblast growth factor receptors (FGFRs)**. FGFs and their receptors

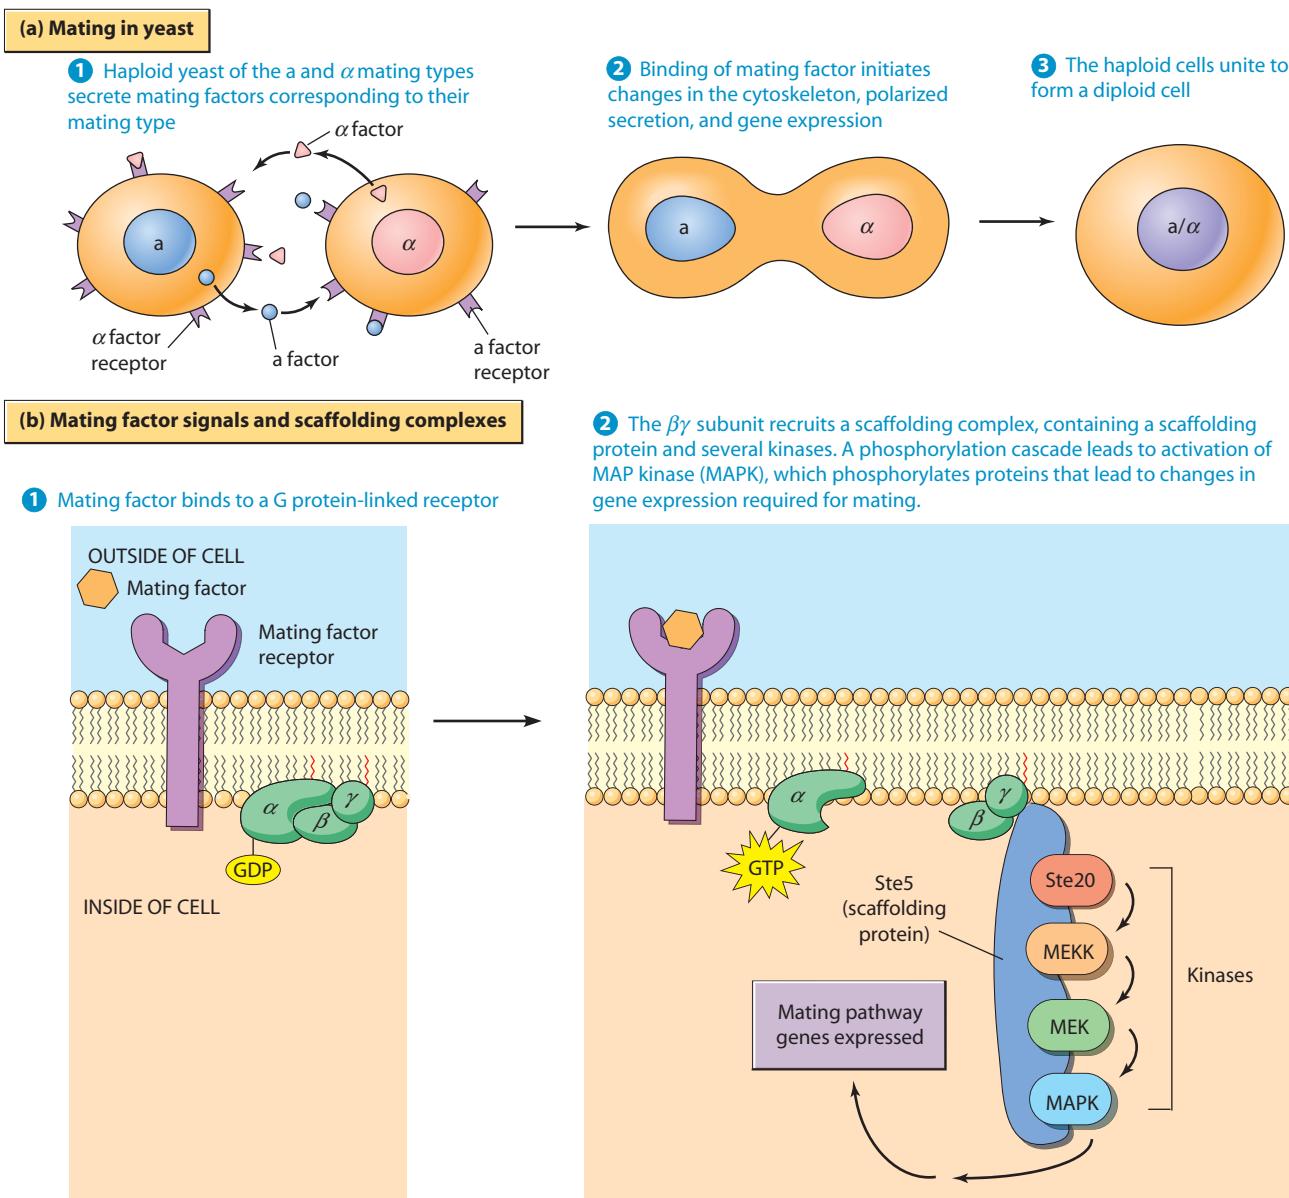

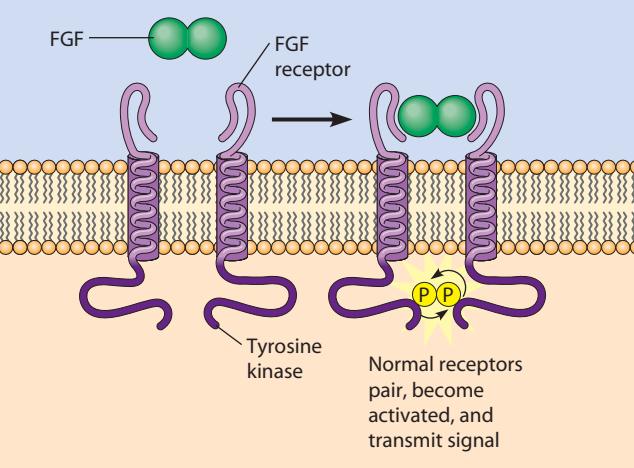

FIGURE 14-18 Scaffolding Complexes Can Facilitate Cell Signaling. (a) Mating in yeast involves the exchange of mating factors by haploid cells of different mating types. Mating factor receptors are G protein-linked receptors. (b) Mating factor signaling involves the recruitment of a scaffolding complex in response to the $G_{\beta\gamma}$ subunit of a G protein associated with mating factor receptors.

mediate many important signaling events in animal embryos and adult tissues. Normal FGFRs, like receptors for epidermal growth factor, undergo autophosphorylation upon ligand binding as shown in **Figure 14-19a**. Some types of mutant FGFRs, however, are capable of binding to normal receptors but do not result in normal autophosphorylation. If a cell produces such mutant receptors, even though the cell makes a substantial quantity of normal, functional receptor, the presence of the mutant receptor prevents the normal receptor from functioning properly. Normal function is inhibited because FGFRs must act together as dimers to bind FGFs. If a normal receptor dimerizes with a mutant receptor, then the phosphorylation events that normally occur within the tyrosine kinase

portion of the receptor fail to occur, blocking signal transduction (Figure 14-19b). A mutation that overrides the function of the normal receptor is sometimes called a **dominant negative mutation**. Such mutations are dominant because the mutant receptor “dominates” over any normal receptor that may be present. They are “negative” because they result in mutant receptors that no longer function. It is also possible to perform the converse experiment: Some mutations make FGFRs active in signaling, even when no ligand is present. These are known as **constitutively active mutations** because they make the receptor act as if it is always “on.”

Dominant negative mutations can dramatically affect growth and development in vertebrates. For example, when

(a) Normal FGF receptor. Normal receptors form dimers after binding FGF, and transmit the appropriate signal via Ras and MAPK.

(b) Dominant negative FGF receptor. When a cell makes mutant FGF receptors, normal receptors can dimerize as in (a), or the defective receptors can bind to FGF and dimerize with normal receptors. In this case, no signal is transmitted. When sufficient quantities of the mutant receptor are present, most of the normal receptors are paired with mutant receptors, resulting in overall disruption in signaling.

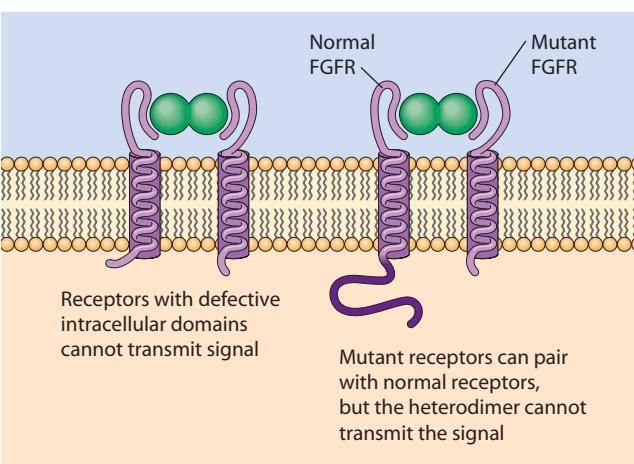

FIGURE 14-19 Dominant Negative Disruption of FGF Receptor Function. Dominant negative mutations in receptors can be used to study the effects of disruption of a growth factor receptor, even in the presence of normal receptors. The example shown here involves fibroblast growth factor (FGF) receptors.

genetically engineered dominant negative FGFRs are expressed in frog embryos, the embryos fail to develop tissues in the trunk and tail, resulting in “tadpoles” with heads but no bodies! In humans, dominant mutations in the transmembrane portion of the *FGFR-3* gene result in the most common form of dwarfism, known as *achondroplasia*. Heterozygous individuals have abnormal bone growth, in which the long bones suffer from abnormal ossification (i.e., the process by which cartilage is converted to bone during childhood). A related condition known as *thanatophoric dysplasia* often results from a single amino acid change in the cytosolic portion of the *FGFR-3* protein.

In this case, more severe bone abnormalities result, and affected individuals die soon after birth. The dramatic effect of a single amino acid change in a single protein demonstrates the key role that growth factor receptors play during human development.

Other Growth Factors Transduce Their Signals via Receptor Serine-Threonine Kinases

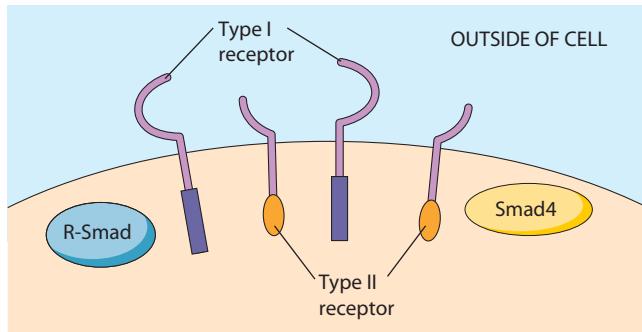

We have seen that when receptor tyrosine kinases bind ligand, they activate a set of signal transduction events within the cell that results in changes within the cell receiving the signal. Another major class of protein kinase-associated receptors uses a very different set of signal transduction pathways to elicit changes within the cell. These receptors phosphorylate serine and threonine residues rather than tyrosines. One major class of **serine-threonine kinase receptors** comprises a family of proteins that bind members of the **transforming growth factor β (TGF β)** family of growth factors. This growth factor family regulates a wide range of cellular functions in both embryos and adult animals, including cell proliferation, programmed cell death, the specialization of cells, and key events in embryonic development.

The first step in TGF β signaling is the binding of growth factor by the transmembrane receptor (1 and 2, **Figure 14-20**). In general, TGF β family members bind to two types of receptors within the receiving cell: the *type I* and *type II receptors*. Some of the TGF β family members form dimers with one another before binding to the appropriate receptors. When ligand is bound, the type II receptor phosphorylates the type I receptor (Figure 14-20). The type I receptor then initiates a signal transduction cascade within the cell, phosphorylating a class of proteins known as **Smads** (a name coined from two of the founding members of this class of proteins). There are three types of Smads. Those that are phosphorylated by a complex of anchoring proteins and activated receptors are known as receptor-regulated, or *R-Smads* (3, Figure 14-20). Another Smad, *Smad4*, forms a multiprotein complex with phosphorylated R-Smads. When Smad4 molecules bind R-Smads, the entire complex can move into the nucleus, where it can associate with other cofactors and DNA-binding proteins to regulate gene expression (4, Figure 14-20). Still other Smads act at various points in TGF β signaling to inhibit the pathway; one type can bind to and inhibit receptors, while another can bind and inhibit Smad4. Smad signals are terminated when the R-Smad is degraded or the R-Smad moves back into the cytosol. Smad4 can shuttle from the nucleus back to the cytosol to be reused when the cell receives another signal.

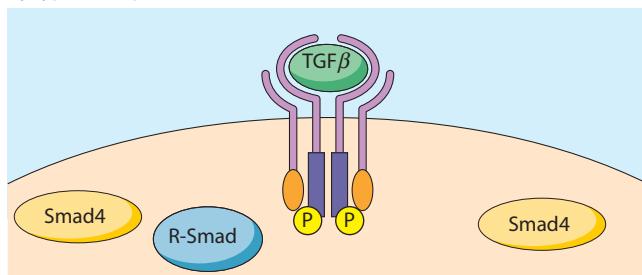

Disruption of Growth Factor Signaling Can Lead to Cancer

We have seen that growth factors regulate events such as cell proliferation, cell movement, and gene expression. We have also seen that embryonic development requires

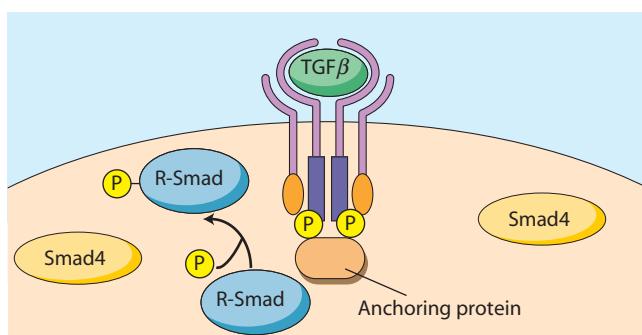

- 1** In the absence of TGF β , the type I and type II receptors for TGF β are not clustered or phosphorylated. R-Smads and Smad4 are in the cytosol.

- 2** Binding of TGF β results in clustering of type I and type II receptors, followed by phosphorylation of type I receptors by type II receptors.

- 3** The activated type I receptors bind a complex of an anchoring protein and an R-Smad, resulting in R-Smad phosphorylation.

- 4** The phosphorylated R-Smad binds Smad4, and the complex enters the nucleus. Along with other proteins, they activate or repress gene expression. Eventually, the R-Smad is degraded or leaves the nucleus, and Smad4 returns to the cytosol, terminating the signal.

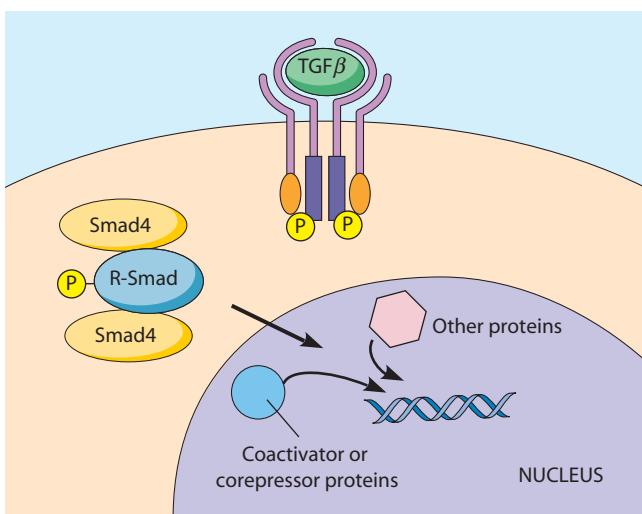

FIGURE 14-20 Signal Transduction by TGF β Receptor

Family Proteins. TGF β receptors transduce their signals to the nucleus via proteins called Smads. After ligand binding activates the receptor, receptor-regulated Smads (R-Smads) become phosphorylated, bind Smad4, and enter the nucleus, leading to changes in gene expression. A variety of inhibitory proteins can block receptor activation, interactions of R-Smads with receptors, or interaction of R-Smads with Smad4.

growth factors to tightly regulate cell biological events. If embryonic development is a prime example of the processes that are correctly regulated by growth factors, many types of cancer are exactly the opposite. We now know that some cancers result from loss of regulation of growth factor signaling. For example, one of the first cancer-causing genes to be identified was a mutant form of Ras. Mutations in Ras are often associated with cancer, as we will explore in more detail in Chapter 24. Mutations in the epidermal growth factor receptor can result in breast cancer, glioblastoma (a cancer of glial cells in the brain), and fibrosarcoma (a type of cancer of long bones). Similarly, mutations in the TGF β type I receptor occur in one-third of ovarian cancers, and mutations in the type II receptor occur in many colorectal cancers. Mutations in Smad4 occur in one-half of all pancreatic cancers.

Growth Factor Receptor Pathways Share Common Themes

Although the details are different in each case, several common themes are involved in most growth factor signaling events. Ligand binding often results in the activation and/or clustering of receptors. Receptor activation then leads to a cascade of events, in which various intermediary proteins often lose or gain phosphate groups. Not all growth factor receptors have their own kinase activity, however. For example, the binding of some growth factors to their receptors causes the receptor to activate a separate intracellular protein kinase called the *Janus activated kinase*.

Often the end result of growth factor signaling is a change in one or more proteins that enter the nucleus, resulting in changes in gene expression within the cell receiving the signal. The specific response of the cell receiving such signals depends on the history of the cell and on the combination of signals the cell is being exposed to at any given time. In the next section, we will see that the same logic operates during the long-range signaling mediated by hormones.

Hormonal Signaling

Growth factors operate at short range to regulate cellular function. However, large organisms must also be able to coordinate the function of various cells and tissues over long distances. To do so, plants and animals use secreted chemical signals called **hormones**. In both plants and animals, hormones are often transported via the vasculature. Hundreds of different hormones regulate a wide range of

physiological functions, including growth and development, rates of body processes, concentrations of substances, and responses to stress and injury. A few are listed in **Table 14-4**.

Although we can consider them as a group based on their regulatory functions, hormones differ in many ways. Both plants and animals produce a wide array of hormones. Some hormones are steroids or other hydrophobic molecules that are targeted to intracellular receptors. Other hormones, such as the adrenergic hormones discussed later in this section, are targeted to a wide variety of G protein-linked receptors. Still others, such as insulin, are ligands for receptor tyrosine kinases. Plants produce steroid hormones called *brassinosteroids* that regulate leaf growth. Similarly, the organic molecule *ethylene* regulates ripening of fruit, and *abscisic acid* causes the closing of stomata during drought conditions. However, because animal hormones are so much better understood, we will focus on them for the remainder of our discussion. In particular, we will focus on endocrine hormones.

Hormones Can Be Classified by the Distance They Travel and by Their Chemical Properties

Endocrine hormones travel by means of the circulatory system from the cells where they are released to other cells where they regulate one or more specific functions. Endocrine hormones are synthesized by the *endocrine tissues* of the body and are secreted directly into the bloodstream. Once secreted into the circulatory system, endocrine hormones have a limited life span, ranging from a few seconds for epinephrine (a product of the adrenal gland) to many hours for insulin. As they circulate in the bloodstream, hormone molecules come into contact with receptors in tissues throughout the body. A tissue that is specifically affected by a particular hormone is

called a *target tissue* for that hormone (**Figure 14-21**). For example, the heart and the liver are target tissues for epinephrine, whereas the liver and skeletal muscles are targets for insulin.

Hormones can also be classified according to their chemical properties. Chemically, the endocrine hormones fall into four categories: amino acid derivatives, peptides, proteins, and lipid-like hormones such as the steroids. An example of an amino acid derivative is epinephrine, derived from tyrosine. *Antidiuretic hormone* (also called *vasopressin*) is an example of a peptide hormone, whereas insulin is a protein. *Testosterone* is an example of a steroid hormone. The steroid hormones are derivatives of cholesterol (see Figure 3-30) that are synthesized either in the gonads (the *sex hormones*) or in the adrenal cortex (the *corticosteroids*).

Control of Glucose Metabolism Is a Good Example of Endocrine Regulation

Since hormones modulate the function of particular target tissues, an important aspect of studying hormones is understanding the specific functions of those target tissues. To illustrate how endocrine hormones act, we will look more closely at the **adrenergic hormones** epinephrine and norepinephrine. (Epinephrine is also called adrenaline; the two words are of Greek and Latin derivation, respectively, and mean “above, or near, the kidney,” referring to the location in the body of the *adrenal glands*, which synthesize this hormone.) The overall strategy of adrenergic hormone actions is to put many of the normal bodily functions on hold and to deliver vital resources to the heart and skeletal muscles instead, as well as to produce a heightened state of alertness. When secreted into the bloodstream, epinephrine and norepinephrine stimulate changes in many different

Table 14-4 Chemical Classification and Function of Hormones

Chemical Classification	Example	Regulated Function
Endocrine Hormones		
Amino acid derivatives	Epinephrine (adrenaline) and norepinephrine (both derived from tyrosine)	Stress responses: regulation of heart rate and blood pressure; release of glucose and fatty acids from storage sites
Peptides	Thyroxine (derived from tyrosine) Antidiuretic hormone (vasopressin) Hypothalamic hormones (releasing factors)	Regulation of metabolic rate Regulation of body water and blood pressure Regulation of tropic hormone release from pituitary gland
Proteins	Anterior pituitary hormones	Regulation of other endocrine systems
Steroids	Sex hormones (androgens and estrogens) Corticosteroids	Development and control of reproductive capacity and secondary sexual characteristics Stress responses; control of blood electrolytes
Paracrine Hormones		
Amino acid derivative	Histamine	Local responses to stress and injury
Arachidonic acid derivatives	Prostaglandins	Local responses to stress and injury

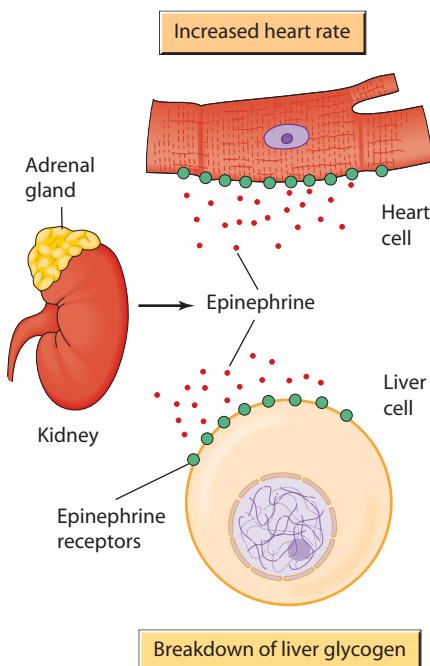

FIGURE 14-21 Target Tissues for Endocrine Hormones.

Cells in a target tissue have hormone-specific receptors embedded in their plasma membranes (or, in the case of the steroid hormones, present in the nucleus or cytosol). Heart and liver cells can respond to epinephrine synthesized by the adrenal glands because these cells have epinephrine-specific receptors on their outer surfaces. A specific hormone may elicit different responses in different target cells. Epinephrine causes an increase in heart rate but stimulates glycogen breakdown in the liver.

tissues or organs, all aimed at preparing the body for dangerous or stressful situations (the so-called fight-or-flight response). Overall, the adrenergic hormones trigger increased cardiac output, shunting blood from the visceral organs to the muscles and the heart, and cause dilation of arterioles to facilitate oxygenation of the blood. In addition, these hormones stimulate the breakdown of glycogen to supply glucose to the muscles.

Adrenergic hormones bind to a family of G protein-linked receptors known as **adrenergic receptors**. They can be broadly classified into α - and β -adrenergic receptors. The α -adrenergic receptors bind both epinephrine and norepinephrine. These receptors are located on the smooth muscles that regulate blood flow to visceral organs. The β adrenergic receptors bind epinephrine much better than norepinephrine. These receptors are found on smooth muscles associated with arterioles that feed the heart, smooth muscles of the bronchioles in the lungs, and skeletal muscles.

The α - and β -adrenergic receptors stimulate different signal transduction pathways because they are linked to different G proteins. For example, the G proteins activated by one type of α -adrenergic receptor, the α_1 -adrenergic receptors, are G_q proteins, whereas the β -adrenergic receptors activate G_s . As we discussed earlier, activation of G_s stimulates the cAMP signal transduction pathway, leading to relaxation of certain smooth muscles. Activation

of G_q stimulates phospholipase C, leading to the production of IP_3 and DAG, which in turn elevates intracellular calcium levels. As a specific example of cAMP-mediated regulation, we will consider the control of glycogen degradation by the hormone epinephrine in liver or muscle cells.

Intracellular Effects of Adrenergic Hormones: Control of Glycogen Degradation.

One action of the adrenergic hormones is to stimulate the breakdown of glycogen to provide muscle cells with an adequate supply of glucose. The breakdown of glycogen is facilitated by the enzyme *glycogen phosphorylase*, which catalyzes a reaction in which the glycosidic linkage between two glucose subunits undergoes attack by inorganic phosphate. This results in release of a molecule of glucose-1-phosphate. The glycogen phosphorylase system was the first cAMP-mediated regulatory sequence to be elucidated. The original work was published in 1956 by Earl Sutherland, who received a Nobel Prize in 1971 for this discovery.

The sequence of events that leads from hormonal stimulation to enhanced glycogen degradation is shown in

Figure 14-22. It begins when an epinephrine molecule binds to a β -adrenergic receptor on the plasma membrane of a liver or muscle cell. The receptor activates a neighboring G_s protein, and the G_s protein in turn stimulates adenylyl cyclase, which generates cAMP from ATP. The resulting transient increase in the concentration of cAMP in the cytosol activates protein kinase A (1, Figure 14-22). PKA then activates another cascade of events that begins with the phosphorylation of the enzyme *phosphorylase kinase* (2, Figure 14-22). This leads to the conversion of *glycogen phosphorylase* from phosphorylase *b*, the less active form, to phosphorylase *a*, the more active form (3, Figure 14-22), and thus to an increased rate of glycogen breakdown (4, Figure 14-22).

cAMP also stimulates the inactivation of the enzyme system responsible for glycogen synthesis. PKA also phosphorylates the enzyme *glycogen synthase*. Rather than activating this enzyme, however, phosphorylation inactivates it. Thus the overall effect of cAMP involves both an increase in glycogen breakdown and a decrease in its synthesis.

α_1 -Adrenergic Receptors and the IP_3 Pathway.

Another important adrenergic pathway is represented by the α_1 -adrenergic receptors, which stimulate the formation of IP_3 and DAG. The α_1 -adrenergic receptors are found mainly on smooth muscles in blood vessels, including those controlling blood flow to the intestines. When α_1 -adrenergic receptors are stimulated, the formation of IP_3 causes an increase in the intracellular calcium concentration. The elevated level of calcium causes smooth muscle contraction, resulting in constriction of the blood vessels and diminished blood flow. Thus, the activation of α_1 -adrenergic receptors affects smooth muscle cells in a manner opposite to that of β -adrenergic activation, which causes smooth muscles to relax.

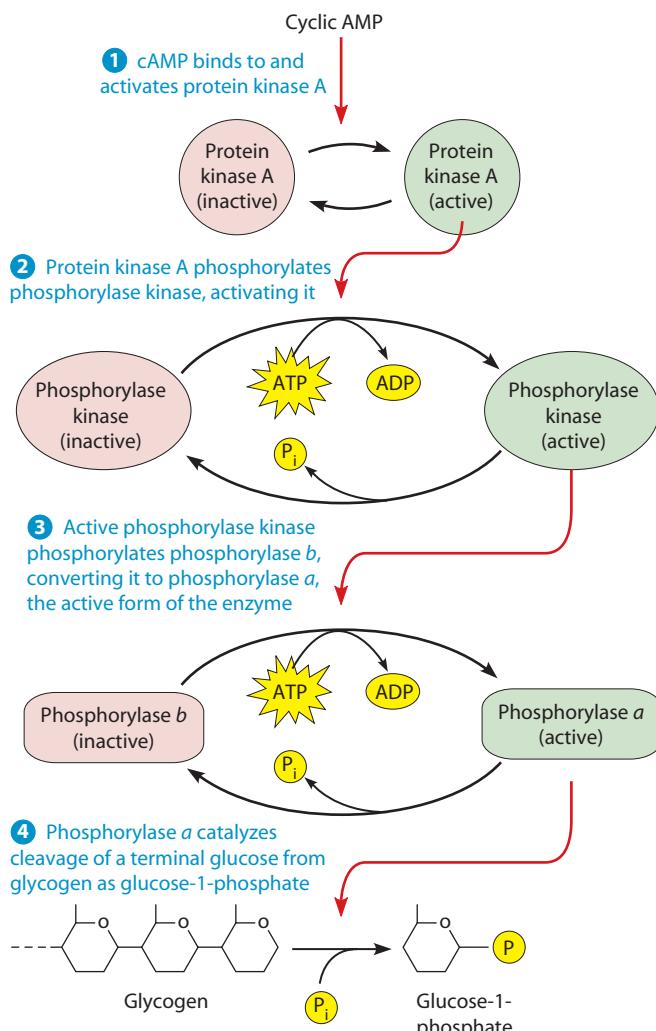

FIGURE 14-22 Stimulation of Glycogen Breakdown by Epinephrine. Muscle and liver cells respond to an increased concentration of epinephrine in the blood by increasing their rate of glycogen breakdown. The stimulatory effect of extracellular epinephrine on intracellular glycogen catabolism is mediated by a G protein–cyclic AMP regulatory cascade.

Insulin Signaling Acts Through PI 3-Kinase to Regulate Resting Glucose Levels. We have seen how epinephrine, acting via G protein-mediated signals, regulates metabolic processes—including the production and use of glucose in liver and muscle cells—in stressful situations. During periods of normal activity, however, two peptide hormones, produced by specialized cells in the pancreas known as *islets of Langerhans*, regulate blood glucose levels. One of these, the peptide hormone **glucagon**, acts via the same G_s protein activated by epinephrine, and so it acts to increase blood glucose by the breakdown of glycogen when the level of glucose in the blood is too low. The other hormone, **insulin**, acts in a manner opposite to epinephrine and glucagon, *reducing* blood glucose levels. It does so by stimulating uptake of glucose into muscle and adipose cells and by stimulating glycogen synthesis. A disease with major worldwide consequences is *type I diabetes*,

which results in loss of insulin-producing beta cells in the Islets of Langerhans. The discovery that type I diabetics can be successfully treated with insulin led to a Nobel Prize for Frederick Banting and John Macleod in 1923. Unfortunately, insulin treatment is less effective in treating type II diabetes, which has reached epidemic proportions and afflicts hundreds of millions of adults worldwide. Type II diabetes appears to result from resistance to insulin, rather than an inability to produce it.

Insulin has both very rapid and longer-lasting effects on a variety of cells. In muscle and adipose cells, for example, insulin causes uptake of glucose within a few minutes and does not require the synthesis of new proteins. Long-term effects of insulin, such as production of enzymes involved in glycogen synthesis, require higher levels of insulin sustained over many hours. To exert its effects, insulin binds to receptor tyrosine kinases. Unlike the epidermal growth factor receptor, however, the insulin receptor has two α subunits and two β subunits. When insulin binds the receptor, β subunits of the receptor phosphorylate a protein called *insulin receptor substrate 1* (IRS-1). Phosphorylated IRS-1 can stimulate two different pathways (Figure 14-23). First, IRS-1 can recruit GRB2, activating the Ras pathway (1, Figure 14-23). Second, IRS-1 can bind an enzyme known as phosphatidylinositol 3-kinase (abbreviated as PI 3-kinase, or PI3K). PI 3-kinase then catalyzes the addition of a phosphate group to the plasma membrane lipid PIP₂ (phosphatidylinositol-4, 5-bisphosphate), which converts PIP₂ into PIP₃ (phosphatidylinositol-3,4,5-trisphosphate; 2, Figure 14-23). PIP₃ in turn binds to a protein kinase called Akt (also called *protein kinase B*), which is activated by phosphorylation of other kinases (3, Figure 14-23). How much PIP₃ is present is also regulated by enzymes that act to oppose PI 3-kinase. One such protein is PTEN, a phosphatase that removes a phosphate group from PIP₃ and thereby prevents the activation of Akt (3, Figure 14-23).

Activation of Akt has two important consequences (4, Figure 14-23). First, it leads to movement of a glucose transporter protein known as GLUT4 from vesicles in the cytosol to the plasma membrane, allowing glucose uptake. Second, Akt can phosphorylate a protein known as *glycogen synthase kinase 3* (GSK3), reducing its activity. This leads to an increase in the amount of the unphosphorylated, more active form of glycogen synthase, which we have seen enhances the production of glycogen. By stimulating absorption of glucose and its polymerization into glycogen, insulin signaling is thus a key component of glucose homeostasis.

Steroid Hormone Receptors Act Primarily in the Nucleus, not the Cell Surface

Not all hormone receptors act at the cell surface. Steroid hormones, an important class of hormones, bind to receptors that act primarily in the nucleus rather than at the cell surface. These **steroid receptor** proteins mediate the

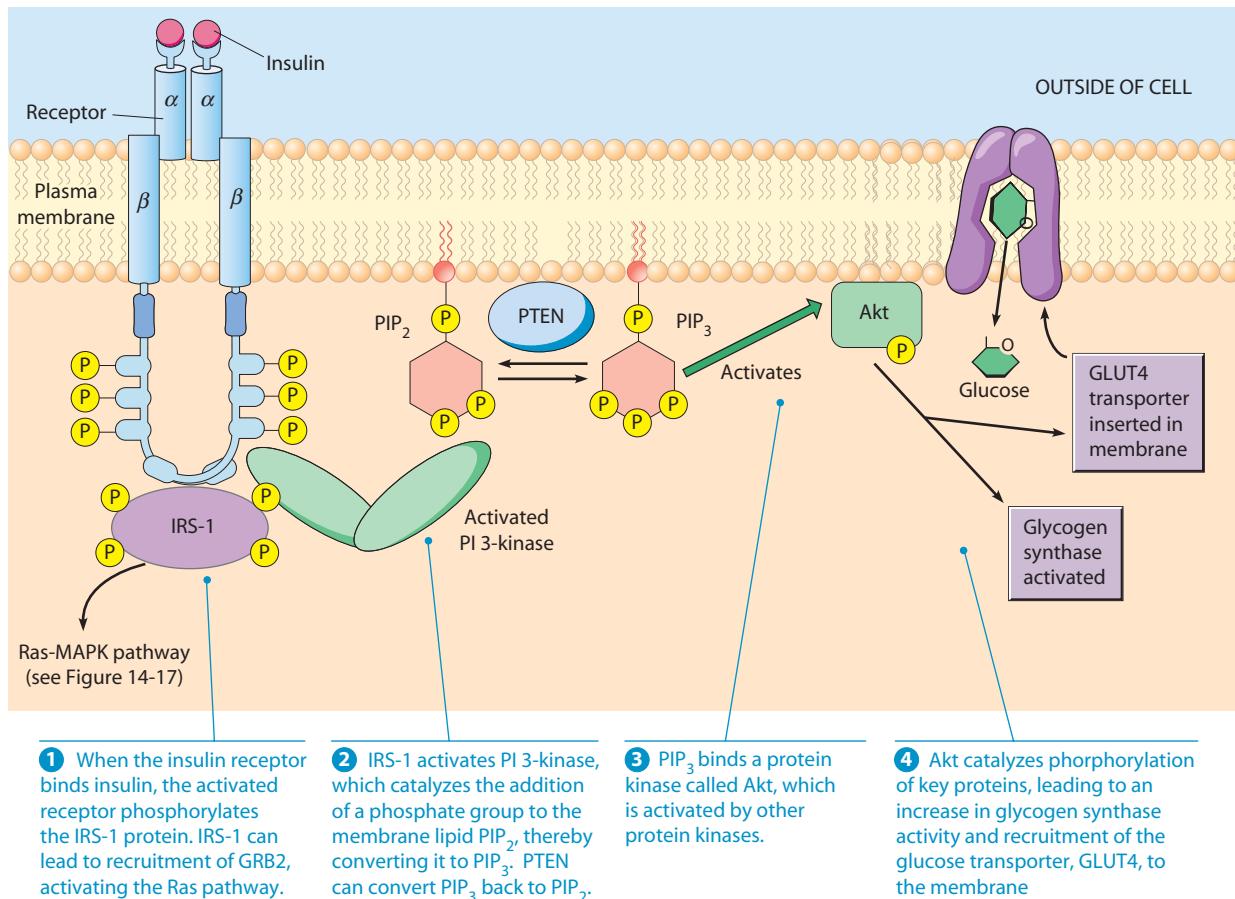

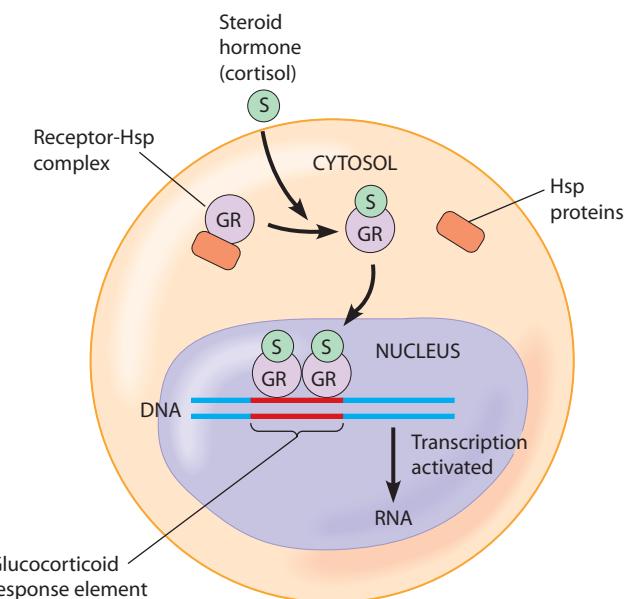

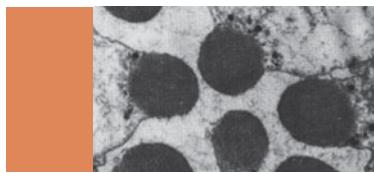

FIGURE 14-23 The Insulin Signaling Pathway. The insulin signaling pathway influences glucose homeostasis by regulating multiple signaling pathways. The insulin receptor is a multisubunit receptor tyrosine kinase. When it binds insulin, recruitment and activation of the IRS-1 protein initiates signal transduction, leading to glucose import, stimulation of glycogen synthesis, and regulation of gene expression.

actions of steroid hormones such as progesterone, estrogen, testosterone, and glucocorticoids. (Related receptors for thyroid hormone, vitamin D, and retinoic acid work in a similar way.) Steroid hormones are lipid signaling molecules synthesized by cells in endocrine tissues. The hormones are released into the bloodstream and travel throughout the body, transmitting signals to cells that possess the appropriate receptors. After entering a target cell, a steroid hormone binds to its corresponding receptor protein, triggering a series of events that ultimately activates, or in a few cases inhibits, the transcription of a specific set of genes (**Figure 14-24**).

FIGURE 14-24 Activation of Gene Transcription by Steroid Hormone Receptors. The example shown here is the steroid hormone cortisol (S). Cortisol diffuses through the plasma membrane and binds to the glucocorticoid receptor (GR), causing the release of heat-shock proteins (Hsp) and activating the GR molecule's DNA-binding site. The GR molecule then enters the nucleus and binds to a glucocorticoid response element in DNA, which in turn causes a second GR molecule to bind to the same response element. The resulting GR dimer activates transcription of the adjacent gene.

SUMMARY OF KEY POINTS

Principles of Cell Signaling

- Cells use a variety of specific receptors to respond to hormones, growth factors, and other substances (ligands) present in the extracellular fluid. Many receptors are transmembrane proteins.
- Ligand binding is followed by transmission of the signal to the interior of the cell, thereby regulating specific intracellular events. Signal transmission is often carried out by second messengers, which can dramatically amplify signaling responses.
- One ligand can trigger multiple signaling pathways, and cells often integrate multiple signals at any given time. Ultimately, signals must be terminated. Different pathways accomplish this action in different ways.
- Drugs or other chemicals that bind a receptor can be used to stimulate the receptors artificially (agonists) or inhibit them (antagonists).

G Protein Signaling

- A heterotrimeric G protein is activated when a ligand binds to its associated receptor, resulting in exchange of GDP for GTP on the G_{α} subunit and dissociation of G_{α} and $G_{\beta\gamma}$. The G_{α} or $G_{\beta\gamma}$ subunits then activate various signaling pathways. Once G_{α} hydrolyzes its bound GTP, $G_{\beta\gamma}$ and $G_{\beta\gamma}$ can reassociate. RGS proteins regulate G_{α} activity by stimulating more rapid hydrolysis of GTP.
- The second messenger cyclic AMP is synthesized when adenylyl cyclase is activated by a G_{α} protein. cAMP can bind and activate protein kinase A (PKA), which can catalyze phosphorylation of many different proteins. Phosphodiesterase can catalyze cleavage and inactivation of cAMP. Activation of other G protein-linked receptors results in production of cyclic GMP instead.
- Inositol trisphosphate (IP_3) and diacylglycerol (DAG) are produced from phosphatidylinositol bisphosphate when other G proteins activate the enzyme phospholipase C_{β} .
- $G_{\beta\gamma}$ subunits can activate signaling pathways as well, including those regulating potassium channels in neurons.

Calcium

- Release of Ca^{2+} from internal stores within the endoplasmic reticulum is triggered by IP_3 .

- Ca^{2+} effects are often mediated by calcium-binding proteins, such as calmodulin.
- Calcium-induced calcium release allows rapid propagation of calcium signals, such as during fertilization of animal eggs.

Receptor Protein Kinases

- Growth factors regulate cell growth and behavior. Many growth factors bind receptor tyrosine kinases; others bind receptor serine-threonine kinases.
- Receptor tyrosine kinases become phosphorylated on specific tyrosines via autophosphorylation after binding ligand. Phosphorylated receptors recruit SH2 domain-containing proteins, which activate major signal transduction pathways (including the Ras and phospholipase C_{γ} pathways).
- Ras is a monomeric G protein, regulated by GTPase activating proteins (GAPs) and by the guanine-nucleotide exchange factor (GEF), Sos. Ras activates a cascade of phosphorylation events, which results in activation of transcription factor proteins that regulate gene expression.
- Receptor serine-threonine kinases act via receptor-regulated Smads and their binding partner, Smad4, which enter the nucleus as a complex following receptor activation.
- In some cases, such as the yeast mating pathway, components of signaling pathways are held in close proximity by scaffolding proteins.

Hormones

- Endocrine hormones regulate the activities of body tissues distant from the tissues that secrete them.
- Adrenergic hormones, secreted by the adrenal medulla, bind G protein-linked β -adrenergic receptors, which stimulate the formation of cAMP, and α -adrenergic receptors, which stimulate phospholipase C_{β} , resulting in elevation of intracellular Ca^{2+} .
- Insulin regulates glucose homeostasis by stimulating multiple signaling pathways, including the Ras and PI 3-kinase pathways.
- Steroid hormones act by binding cytosolic receptor proteins. The hormone-receptor complex then acts in the nucleus to regulate gene expression.

MAKING CONNECTIONS

In this chapter, you learned that a crucial feature of cells in a multicellular organism is the ability to send and receive signals. Some of these signals, such as growth factors, act at very short range, much like the neurotransmitters we

examined in Chapter 13. Others, such as hormones, act at long range. Because most receptors are transmembrane proteins, signals received at the cell surface must be transmitted deep inside the cell. In some cases, the relay system

involves cascades of phosphorylation, a topic you first learned about in Chapter 6. Cell signaling controls a vast array of cellular processes—from glucose utilization, which feeds into the metabolic pathways you learned about in Chapters 9 and 10, to endo- and exocytosis, which you learned about in Chapter 12, to embryonic development and cell death. Two tightly controlled

processes regulated by cell signaling are the cell cycle and apoptosis, which you will learn much more about in Chapter 19. When such signaling goes awry, cancer can result; in Chapter 24 you will learn more about this process. The assembly and disassembly of the cytoskeleton are a set of crucial processes regulated by cell signaling; we turn to these processes in the next two chapters.

PROBLEM SET

More challenging problems are marked with a •.

14-1 Chemical Signals and Second Messengers. Fill in the blanks with the appropriate terms.

- (a) _____ is an intracellular protein that binds calcium and activates enzymes.
- (b) Glucagon is an example of an _____ hormone.
- (c) A substance that fits into a specific binding site on the surface of a protein molecule is called a _____.
- (d) Two products of phospholipase C activity that serve as second messengers are _____ and _____.
- (e) Cyclic AMP is produced by the enzyme _____ and degraded by the enzyme _____.
- (f) Calcium ions are released within cells mainly from the _____.

14-2 Heterotrimeric and Monomeric G Proteins. G protein-linked receptors interact with heterotrimeric G proteins to activate them.

- (a) Upon binding to the receptor, the $G_{\beta\gamma}$ subunit catalyzes GDP/GTP exchange by the G_{α} subunit. How is this similar to the activation of Ras by a receptor tyrosine kinase?
- (b) What similarities are there at the molecular level between how cells regulate the rate of GTP hydrolysis by the catalytically active portion of a heterotrimeric G protein and by Ras?

14-3 Calcium Chelators and Ionophores. Two important tools that have aided studies of the role of Ca^{2+} in triggering different cellular events are *calcium chelators* and *calcium ionophores*. Chelators are compounds such as EGTA and EDTA that bind very tightly to Ca^{2+} ions, thereby reducing nearly to zero the free (or available) Ca^{2+} ion concentration outside of the cell. Ionophores are compounds that shuttle ions across lipid bilayers and membranes, including the plasma membrane and internal membranes such as the ER. For Ca^{2+} ions, two of the commonly used ionophores are A23187 and ionomycin. Using these tools, describe how you could demonstrate that a hormone exerts its effect by (1) causing Ca^{2+} to enter the cell through channels or (2) releasing Ca^{2+} from intracellular stores such as the ER.

• **14-4 The Eyes Have It.** For this question, please consult Box 14B. Recall that each ommatidium in the compound eye contains a photoreceptor cell, R7, which must receive a signal from a neighboring cell, R8, to differentiate. This pathway depends on the Ras signaling pathway. Also, recall that mutants provide insight into this pathway. For each of the following situations,

indicate whether the R7 cell would be expected to differentiate. In each case, clearly state your reasoning, based on your understanding of the molecular pathway involved.

- (a) R7 cells are mutated so that their Sevenless receptors lack the SH2-binding domain.
- (b) R7 cells are mutated so that they lack functional Sos but contain a constitutively active, dominant mutation in Ras.
- (c) R7 cells are mutated so that they have no functional MAP kinase.
- (d) R8 cells are mutated so that they produce too much of the Bride of sevenless ligand, and R7 cells lack Sevenless.

14-5 Membrane Receptors and Medicine. *Hypertension*, or high blood pressure, is often seen in elderly people. A typical prescription to reduce a patient's blood pressure includes compounds called *beta-blockers*, which block β -adrenergic receptors throughout the body. Why do you think beta-blockers are effective in reducing blood pressure?

• **14-6 Following Ras activation.** It is possible to use engineered molecules to follow the activation of individual Ras molecules in stimulated cells using a technique called fluorescence resonance energy transfer (FRET; see the Appendix for further details).

Figure 14-25 shows the time course of Ras activation following stimulation by epidermal growth factor (EGF).

- (a) Based on the graph, how long does it take for maximal Ras activation to be achieved?
- (b) Why does Ras activity decline after a few minutes, even when EGF is still present?

14-7 Chemoattractant Receptors on Neutrophils. *Neutrophils* are blood cells normally responsible for killing

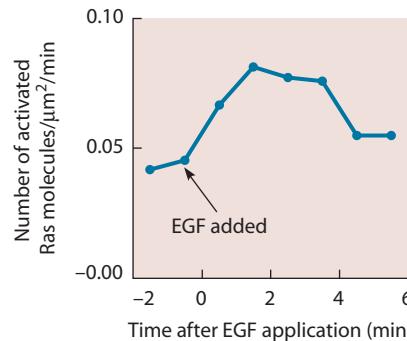

FIGURE 14-25 Activation of Ras following Epidermal Growth Factor (EGF) stimulation. See Problem 14-6.

bacteria at sites of infection. Neutrophils are able to find their way toward sites of infection by the process of *chemotaxis*. In this process, neutrophils sense the presence of bacterial proteins and then follow the trail of these proteins toward the site of infection. Suppose you find that chemotaxis is inhibited by pertussis toxin. What kind of receptor is likely to be involved in responding to bacterial proteins?

14-8 Once Is Enough. A person who smokes for the first time tends to experience much more severe effects from a cigarette than does someone who smokes frequently. Given that the smoke contains nicotine, provide a reasonable explanation for this difference.

• **14-9 Scrambled Eggs.** Unfertilized starfish eggs can be induced to produce foreign proteins either by injecting them with mRNA encoding the protein of choice or they can be directly injected with purified molecules. What do you predict would happen in the following cases, and why?

- (a) “Caged calcium,” a combination of Ca^{2+} ions and a chelator, is injected into an egg. A flash of light is then used to induce the chelator to release its Ca^{2+} in a small region of the egg.
- (b) mRNA for IP_3 receptors that do not allow Ca^{2+} release is injected, and then the egg is fertilized.
- (c) Fluo3, a molecule that fluoresces in response to elevated Ca^{2+} levels, is injected into normal eggs, which are then fertilized.

Cytoskeletal Systems

In the preceding chapters, we examined a variety of cellular processes and pathways, many of which occur in the organelles of eukaryotic cells. We also examined signaling events, initiated at the cell surface, that have profound effects on cellular function. We now come to the cytosol, the region of the cytoplasm between and surrounding organelles. Until a few decades ago, the cytosol of the eukaryotic cell was regarded as the generally uninteresting, gel-like substance in which the nucleus and other organelles were suspended. Advances in microscopy and other investigative techniques have revealed that the interior of a eukaryotic cell is highly structured. Part of this structure is provided by the **cytoskeleton**: a complex network of interconnected filaments and tubules that extends throughout the cytosol, from the nucleus to the inner surface of the plasma membrane. The cytoskeleton plays important roles in cell movement and cell division, and in eukaryotes it actively moves membrane-bounded organelles within the cytosol. It also plays a similar role for messenger RNA and other cellular components. The cytoskeleton is also involved in many forms of cell movement and is intimately related to other processes such as cell signaling and cell-cell adhesion. The cytoskeleton is altered by events at the cell surface and, at the same time, appears to participate in and modulate these events.

The term cytoskeleton accurately expresses the role of this polymer network in providing an architectural framework for cellular function. It confers a high level of internal organization on cells and enables them to assume and maintain complex shapes that would not otherwise be possible. The name does not, however, convey the dynamic, changeable nature of the cytoskeleton and its critical involvement in a great variety of cellular processes.

Major Structural Elements of the Cytoskeleton

Eukaryotes Have Three Basic Types of Cytoskeletal Elements

The three major structural elements of the cytoskeleton in eukaryotes are *microtubules*, *microfilaments*, and *intermediate filaments* (Table 15-1). The existence of three distinct systems of filaments and tubules was first revealed by electron microscopy. Biochemical and cytochemical studies then identified the distinctive proteins of each system. The technique of *indirect immunostaining* (see the Appendix, Figure A-12) was especially important in localizing specific proteins to the cytoskeleton.

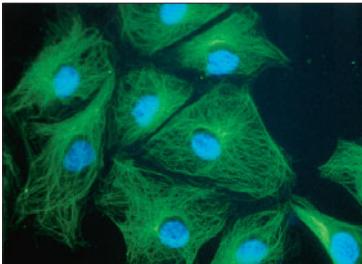

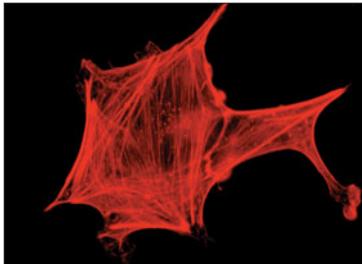

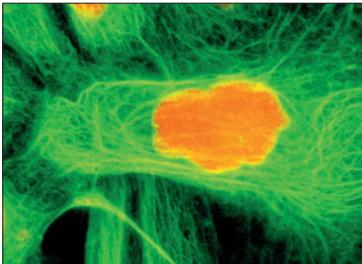

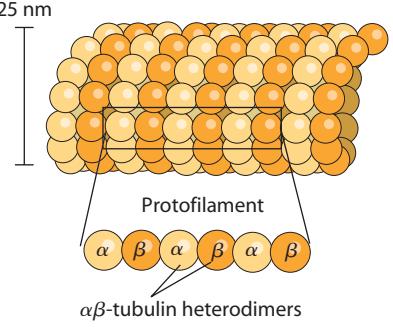

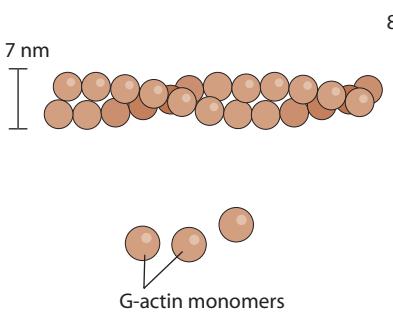

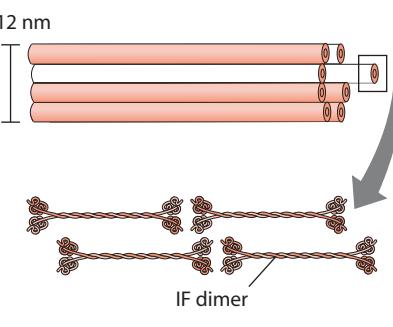

Each structural element of the cytoskeleton has a characteristic size, structure, and intracellular distribution, and each element is formed by the polymerization of a different kind of subunit (Table 15-1). Microtubules are composed of the protein *tubulin* and are about 25 nm in diameter. Microfilaments, with a diameter of about 7 nm, are polymers of the protein *actin*. Intermediate filaments have diameters in the range of 8–12 nm. Intermediate filament subunits differ depending on the cell type. In addition to its major protein component, each type of cytoskeletal filament has a number of other proteins associated with it. These accessory proteins account for the remarkable structural and functional diversity of cytoskeletal elements.

Bacteria Have Cytoskeletal Systems That Are Structurally Similar to Those in Eukaryotes

Until recently, cytoskeletal proteins were thought to be unique to eukaryotes. However, recent discoveries have shown that bacteria, such as rod-shaped bacteria, and

Table 15-1

Properties of Microtubules, Microfilaments, and Intermediate Filaments

	Microtubules	Microfilaments	Intermediate Filaments
			
Polymer			
Structure	Hollow tube with a wall consisting of 13 protofilaments	Two intertwined chains of F-actin	Eight protofilaments joined end to end with staggered overlaps
Diameter	Outer: 25 nm Inner: 15 nm	7 nm	8–12 nm
Monomers	α -tubulin β -tubulin	G-actin	Several proteins; see Table 15-4
Polarity	(+), (-) ends	(+), (-) ends	No known polarity
Functions	Cytoplasmic: Organization and maintenance of animal cell shape and polarity Chromosome movements Intracellular transport/trafficking, and movement of organelles Axonemal: Cell motility	Muscle contraction Cell locomotion Cytoplasmic streaming Cytokinesis Maintenance of animal cell shape Intracellular transport/trafficking	Structural support Maintenance of animal cell shape Formation of nuclear lamina and scaffolding Strengthening of nerve cell axons (neurofilament protein) Keeping muscle fibers in register (desmin)

the Archaea have polymer systems that function in a manner very similar to microfilaments, microtubules, and intermediate filaments (Figure 15-1). Based on the effects of mutating these proteins, it is clear that they play roles similar to their eukaryotic counterparts. For example, the actin-like *MreB* protein is involved in DNA segregation, the tubulin-like *FtsZ* protein is involved in determining where bacterial cells will divide, and the intermediate filament-like *crescentin* protein is an important regulator of cell shape. Significantly, the *FtsZ* protein is produced by certain organelles in some eukaryotes, such as chloroplasts and mitochondria, and localizes to sites where these organelles divide. These findings provide further evidence for the endosymbiont theory discussed in Chapter 4. Although the

bacterial proteins are not very similar to their eukaryotic counterparts at the amino acid level, X-ray crystallography has shown that when they are assembled into polymers, their overall structure is remarkably similar (Figure 15-1e). Moreover, the equivalent proteins bind the same phosphonucleotides as their eukaryotic equivalents, indicating striking similarities at the biochemical level as well.

The Cytoskeleton Is Dynamically Assembled and Disassembled

The cytoskeleton currently is a topic of great research interest to cell biologists. Microtubules and microfilaments are perhaps best known for their roles in cell motility. For

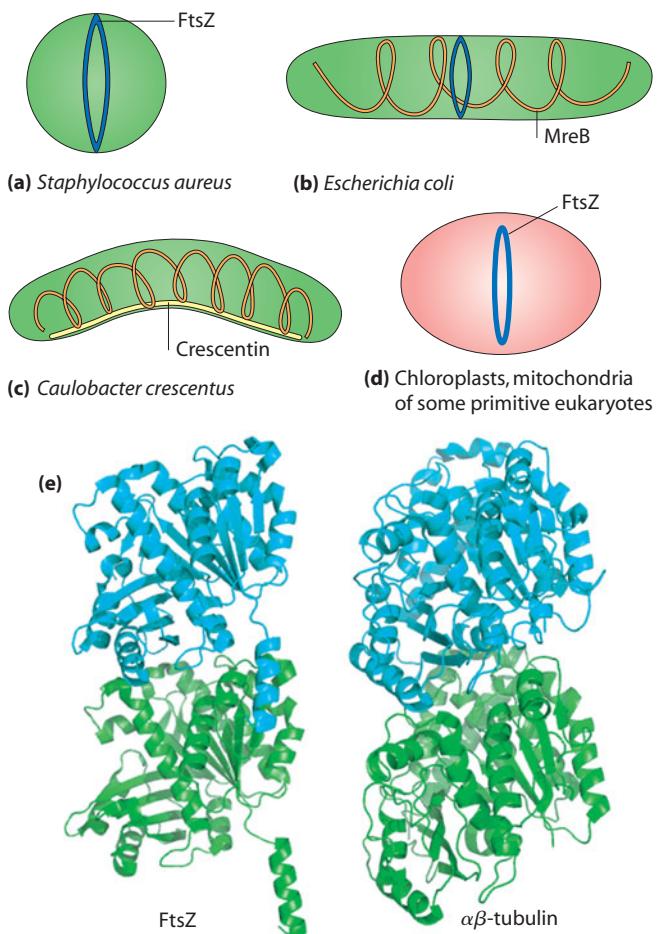

FIGURE 15-1 Cytoskeletal Proteins in Bacteria Are Similar to Those in Eukaryotes. The distribution of several bacterial cytoskeletal proteins are shown in parts a-d. Blue: the microtubule-like FtsZ protein. Orange: the actin-like MreB protein. Yellow: the intermediate-filament-like protein Crescentin. (a) *S. aureus*. (b) *E. coli*. (c) *Caulobacter*. (d) Some plastids and mitochondria in some primitive eukaryotes express FtsZ at sites of division. (e) Comparison of the structure of FtsZ (left) and an $\alpha\beta$ -tubulin heterodimer (X-ray crystallography). Note the similarity in structure.

example, microfilaments are essential components of *muscle fibrils*, and microtubules are the structural elements of *cilia* and *flagella*, appendages that enable certain cells to either propel themselves through a fluid environment or move fluids past the cell. These structures are large enough to be seen by light microscopy and were therefore known and studied long before it became clear that the same structural elements are also integral parts of the cytoskeleton in most cells. With the advent of sophisticated microscopy techniques, it eventually became clear that most cells dynamically regulate where and when specific cytoskeletal structures are assembled and disassembled. Recent progress in understanding cytoskeletal structure relies heavily on a combination of powerful microscopy techniques: various types of *fluorescence microscopy*, *digital video microscopy*, and various types of *electron microscopy* (**Table 15-2**). Each technique is described in more detail in the Appendix. In addition, specific drugs can be used to

perturb cytoskeletal function (**Table 15-3**). In parallel with increasingly sophisticated biochemical studies, these techniques have revealed the incredibly dynamic nature of the cytoskeleton and the remarkably elaborate structures it comprises.

In this chapter, we will focus on the structure of the cytoskeleton and how its components are dynamically assembled and disassembled. In each case, we will consider the chemistry of the subunit(s), the structure of the polymer and how it is polymerized, the role of accessory proteins, and some of the structural and functional roles each component plays within the cell. In doing so, we will be discussing microtubules, microfilaments, and intermediate filaments as though they were separate entities, each with its own independent functions. In reality, the components of the cytoskeleton are linked together both structurally and functionally, as we will see in the last section of this chapter. We begin our discussion with microtubules.

Microtubules

Two Types of Microtubules Are Responsible for Many Functions in the Cell

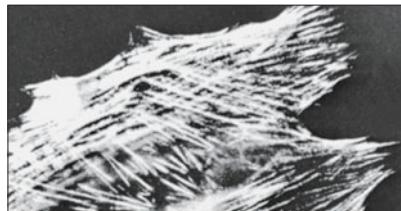

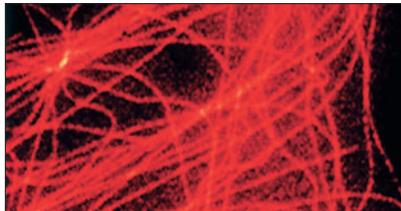

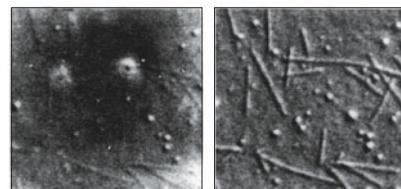

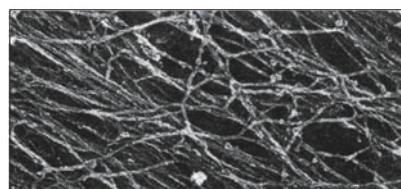

Microtubules (MTs) are the largest of the cytoskeletal elements (see Table 15-1). Microtubules in eukaryotic cells can be classified into two general groups, which differ in both degree of organization and structural stability.

The first group comprises an often loosely organized, dynamic network of **cytoplasmic microtubules**. The occurrence of cytoplasmic MTs in eukaryotic cells was not recognized until the early 1960s, when better fixation techniques permitted direct visualization of the network of MTs now known to pervade the cytosol of most eukaryotic cells. Since then, fluorescence microscopy has revealed the diversity and complexity of MT networks in different cell types.

Cytoplasmic MTs are responsible for a variety of functions (see Table 15-1). For example, in animal cells they are required to maintain axons, nerve cell extensions whose electrical properties we examined in Chapter 13. Some migrating animal cells require cytoplasmic MTs to maintain their polarized shape. In plant cells, cytoplasmic MTs govern the orientation of cellulose microfibrils deposited during the growth of cell walls (see Chapter 17). Significantly, cytoplasmic MTs form the mitotic and meiotic spindles that are essential for the movement of chromosomes during mitosis and meiosis (see Chapter 19). Cytoplasmic microtubules also contribute to the spatial disposition and directional movement of vesicles and other organelles by providing an organized system of fibers to guide their movement.

The second group of microtubules, **axonemal microtubules**, includes the highly organized, stable microtubules found in specific subcellular structures associated with cellular movement, including cilia, flagella, and the

Table 15-2 Techniques for Visualizing the Cytoskeleton

Technique	Description	Example
Fluorescence microscopy on fixed specimens*	Fluorescent compounds directly bind to cytoskeletal proteins, or antibodies are used to indirectly label cytoskeletal proteins in chemically preserved cells, causing them to glow in the fluorescence microscope.	A fibroblast stained with fluorescent antibodies directed against actin shows bundles of actin filaments. 
Live cell fluorescence microscopy*	Fluorescent versions of cytoskeletal proteins are made and introduced into living cells. Fluorescence microscopy and video or digital cameras are used to view the proteins as they function in cells.	Fluorescent tubulin molecules were microinjected into living fibroblast cells. Inside the cell, the tubulin dimers become incorporated into microtubules, which can be seen easily with a fluorescence microscope. 
Computer-enhanced digital video microscopy	High-resolution images from a video or digital camera attached to a microscope are computer processed to increase contrast and remove background features that obscure the image.	Two micrographs showing several microtubules were processed to make them visible in detail. 
Electron microscopy	Electron microscopy can resolve individual filaments prepared by thin section, quick-freeze deep-etch, or direct-mount techniques.	A fibroblast cell is prepared by the quick-freeze deep-etch method. Bundles of actin microfilaments are visible. 

*Confocal, deconvolution, multiphoton, and total internal reflection fluorescence (TIRF) microscopy are often used to improve detection of fluorescent signals. See the Appendix for more details.

basal bodies to which these appendages are attached. The central shaft, or *axoneme*, of a cilium or flagellum consists of a highly ordered bundle of axonemal MTs and associated proteins. Given their order and stability, it is not surprising that the axonemal MTs were the first of the two

groups to be recognized and studied. We have already encountered an example of such a structure; the axoneme of the sperm tail shown in Figure 4-12 consists of MTs. We will consider axoneme structure and microtubule-mediated motility further in Chapter 16.

Table 15-3 Drugs Used to Perturb the Cytoskeleton

Drug	Source	Affect
Drugs Affecting Microtubules		
Colchicine, colcemid	Autumn crocus, <i>Colchicum autumnale</i>	Binds tubulin monomers, inhibiting assembly
Nocadazole	Synthetic benzimidazole	Binds β -tubulin, inhibiting polymerization
Vinblastine, vincristine	Periwinkle plant, <i>Vinca rosea</i>	Aggregates tubulin heterodimers
Taxol	Pacific yew tree, <i>Taxus brevifolia</i>	Stabilizes microtubules
Drugs Affecting Microfilaments		
Cytochalasin D	Fungal metabolite	Prevents addition of new monomers to plus ends
Latrunculin A	Red sea sponge, <i>Latrunculia magnifica</i>	Sequesters actin monomers
Phalloidin	Death cap fungus, <i>Amanita phalloides</i>	Binds and stabilizes assembled microfilaments

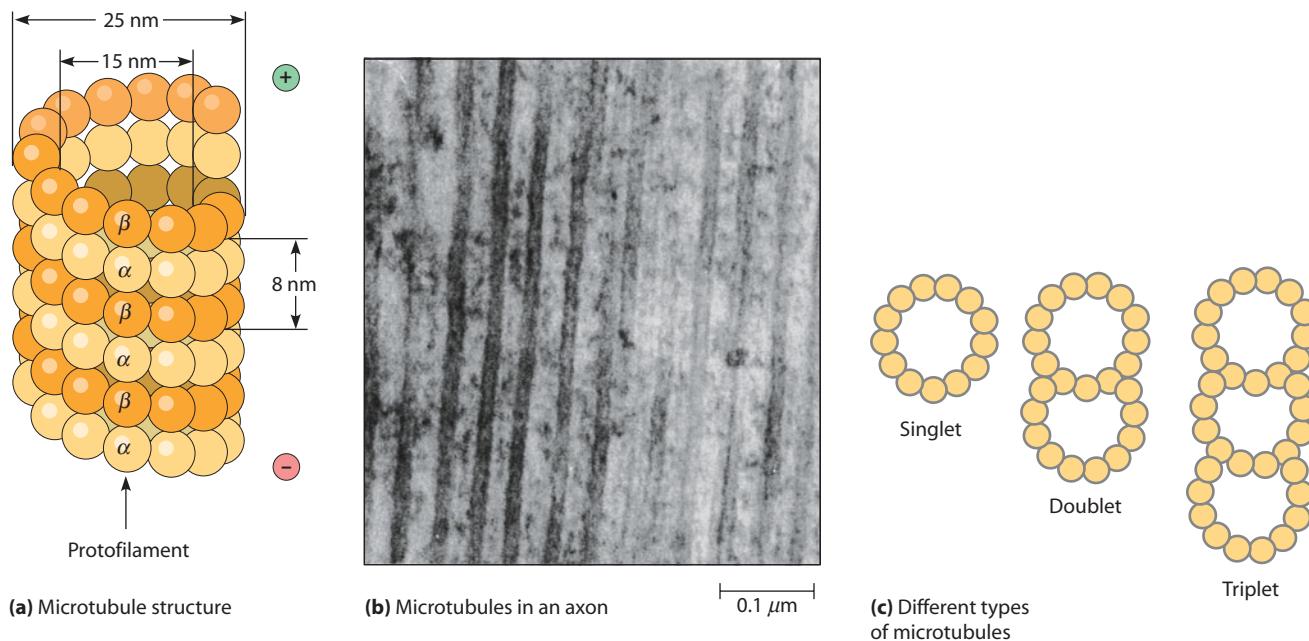

FIGURE 15-2 Microtubule Structure. (a) A schematic diagram showing a microtubule as a hollow cylinder enclosing a lumen. The outside diameter is about 25 nm, and the inside diameter is about 15 nm. The wall of the cylinder consists of 13 protofilaments, one of them indicated by an arrow. A protofilament is a linear polymer of tubulin dimers, each consisting of two polypeptides— α -tubulin and β -tubulin. All heterodimers in the protofilaments have the same orientation, thus accounting for the polarity of the microtubule. (b) Microtubules in a longitudinal section of an axon (TEM). (c) Microtubules can form as singlets (13 protofilaments around a hollow lumen), doublets, and triplets. Doublets and triplets contain one complete, 13-protofilament microtubule (the *A tubule*) and one or two additional, incomplete tubules (called *B* and *C tubules*) consisting of 10 protofilaments.

Tubulin Heterodimers Are the Protein Building Blocks of Microtubules

MTs are straight, hollow cylinders with an outer diameter of about 25 nm and an inner diameter of about 15 nm (**Figure 15-2**). Microtubules vary greatly in length. Some are less than 200 nm long; others, such as axonemal MTs, can be many micrometers in length. The MT wall consists of longitudinal arrays of linear polymers called **protofilaments**. There are usually 13 protofilaments arranged side by side around the hollow center, or lumen; although some MTs in some animals contain more or less than 13 protofilaments, this number is by far the most common.

As shown in Figure 15-2, the basic subunit of a protofilament is a heterodimer of the protein **tubulin** (for a three-dimensional structure, see Figure 15-1e). The heterodimers that form the bulk of protofilaments are composed of one molecule of **α -tubulin** and one molecule of **β -tubulin**. As soon as individual α - and β -tubulin molecules are synthesized, they bind noncovalently to each other to produce an **$\alpha\beta$ -heterodimer** that does not dissociate under normal conditions.

Individual α - and β -tubulin molecules have diameters of about 4–5 nm and molecular weights of 55 kDa. Structural studies show that α - and β -tubulins have nearly identical three-dimensional structures, even though they

share only 40% amino acid sequence identity. Each has a GTP-binding domain at the N-terminus, a domain in the middle to which colchicine can bind (colchicine is a MT poison that blocks MT assembly; see below), and a third domain at the C-terminus that interacts with MT-associated proteins (MAPs; we will discuss MAPs later in this chapter).

Within a microtubule, all of the tubulin dimers are oriented in the same direction, such that all of the α -tubulin subunits face the same end. This uniform orientation of tubulin dimers means that one end of the protofilament differs chemically and structurally from the other, giving the protofilament an inherent polarity. Because the orientation of the tubulin dimers is the same for all of the protofilaments in an MT, the MT itself is also a polar structure.

Most organisms have several closely related but non-identical genes for each of the α - and β -tubulin subunits. These slightly different forms of tubulin are called **tubulin isoforms**. In the mammalian brain, for example, there are five α - and five β -tubulin isoforms. These isoforms differ mainly in the C-terminal domain, which suggests that various tubulin isoforms may interact with different proteins. In addition to different isoforms, tubulin can be chemically modified. For example, acetylated tubulin tends to form more stable MTs than non-acetylated tubulin does.

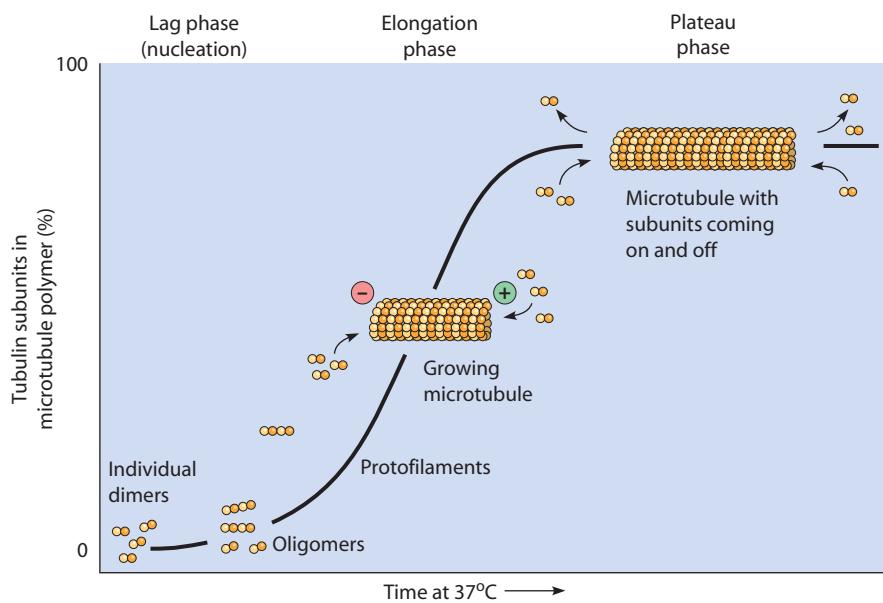

FIGURE 15-3 The Kinetics of Microtubule Assembly In Vitro. The kinetics of MT assembly can be monitored by observing the amount of light scattered by a solution containing GTP-tubulin after it is warmed from 0°C to 37°C. (Microtubule assembly is inhibited by cold and activated upon warming.) Such light-scattering measurements reflect changes in the MT population as a whole, not the assembly of individual microtubules. When measured in this way, MT assembly exhibits three phases: lag, elongation, and plateau. The lag phase is the period of nucleation. During the elongation phase, MTs grow rapidly, causing the concentration of tubulin subunits in the solution to decline. When this concentration is low enough to limit further assembly, the plateau phase is reached, during which subunits are added and removed from MTs at equal rates.

Microtubules Can Form as Singlets, Doublets, or Triplets

Cytoplasmic MTs are simple tubes, or *singlet* MTs, built from 13 protofilaments. Some axonemal MTs are more complex, however: they can contain *doublet* or *triplet* MTs. Doublets and triplets contain one complete, 13-protofilament microtubule (the *A tubule*) and one or two additional, incomplete tubules (called *B* and *C* tubules) consisting of 10 or 11 protofilaments (Figure 15-2c). Doublets are found in cilia and flagella; triplets are found in basal bodies and centrioles. We will examine cilia and flagella in much more detail in Chapter 16.

Microtubules Form by the Addition of Tubulin Dimers at Their Ends

Microtubules form by the reversible polymerization of tubulin dimers. The polymerization process has been studied extensively *in vitro*; a schematic representation of MT assembly *in vitro* is shown in Figure 15-3. When a solution containing a sufficient concentration of tubulin dimers, GTP, and Mg²⁺ is warmed from 0°C to 37°C, the polymerization reaction begins. (MT formation in the solution can be readily measured with a spectrophotometer as an increase in light scattering.) A critical step in the formation of MTs is the aggregation of tubulin dimers into clusters called *oligomers*. These oligomers serve as “nuclei” from which new microtubules can grow, and hence this process is referred to as **nucleation**. Once an MT has been nucleated, it grows by addition of subunits at either end, via a process called **elongation**.

Microtubule formation is initially slow, a period referred to as the *lag phase* of MT assembly. This period reflects the relatively slow process of MT nucleation. The elongation phase of MT assembly—the addition of tubulin dimers—is relatively fast compared with nucleation.

Eventually, the mass of MTs increases to a point where the concentration of free tubulin becomes limiting. This leads to the *plateau phase*, where MT assembly is balanced by disassembly.
